Available literature and quality of the evidence

- Level I: 1 RCT.

Findings

Lee et al. evaluated 157 patients with distal radius fractures with confirmed DRUJ instability by intraoperative manual stress test.[8] All radius fractures were treated using volar locking plates. These patients were divided into three groups: Group A

consisted of patients without ulnar styloid fractures, Group B of patients with ulnar styloid tip fractures, and Group C of patients with ulnar styloid base fractures. Patients in each group were further randomized into subgroups. Subgroup 1 (A-1, B-1, C-1) was treated with sugar-tong splinting (conservative treatment). Subgroup 2 (A-2, B-2, C-2) was treated surgically. Subgroups A-2 and B-2 were treated with Kirschner wire (K-wire) transfixion. Subgroup C-2 was further divided into groups C-2-a, treated with K-wire transfixion, C-2-b treated with tension-band wiring of the ulnar styloid fracture, and C-2-c treated with hook plating of the ulnar styloid fracture. Group A had an additional subgroup (A-3) consisting of patients treated with arthroscopic TFCC (triangular fibrocartilaginous complex) repair. At three-month follow-up, the operative groups showed significantly greater ROM than the nonoperative groups (mean group ROMs not reported; $p = 0.028$ for flexion-extension, $p = 0.036$ for supination-pronation). However, there was no difference in ROM between the different surgical techniques. At 12-month follow-up, there was no significant difference in ROM, DASH score, modified Mayo Wrist Score, and grip strength between the operative and nonoperative groups. At final follow-up (mean 16.9 months), they found that clinical outcomes were not affected by the presence/absence of ulnar styloid fracture, fracture level, displacement, or the union rate. There was also no difference noted between the operative and nonoperative groups. Chronic DRUJ instability was noted in two patients from the operative groups; however, both patients refused further treatment as they were not bothered by their symptoms.

Resolution of clinical scenario

- Surgical treatment of DRUJ injuries in Galeazzi fractures provides better short-term outcomes than nonsurgical treatment.
- Long-term outcomes are similar for DRUJ injuries treated surgically or conservatively.
- Given that, based on the provided information, neither patient had sustained a Galeazzi fracture, if there was a DRUJ injury in either case, it could be treated surgically or conservatively based on patient values and other contextual considerations.

Question 4: In patients with forearm fractures treated with plate fixation, does plate removal after bony union lead to higher refracture/complication rates compared with patients who retain their hardware?

Rationale

After bony union has been achieved with plate fixation, many patients may wish to remove the implant. This may be due to a belief that the implant is causing them pain, or even if they are asymptomatic they may be uncomfortable with the idea of keeping metal in their bodies. There is currently no consensus regarding plate removal after bony union in forearm fractures.

Clinical comment

Patient A returned to clinic 20 months after his initial injury. He continued to have minimal pain in his forearm, and requested to have the plate removed.

Available literature and quality of the evidence

- Level III: 3 retrospective cohort studies.
- Level IV: 1 case series.

Findings

Yao et al. retrospectively reviewed 122 patients (170 fractures) with forearm fractures treated with plate fixation.[9] The plate implant was removed after bony union in 62 fractures and retained in 108 fractures. The incidence rate of refracture was significantly higher in the implant removed group ($p = 0.013$). Refracture occurred in eight bones after implant removal (12.9%), all without high-energy trauma. Refracture occurred three bones in the implant retained group (2.7%), all caused by high-energy trauma. For the implant removal group, the mean time from implant placement to removal was 14.8 months in patients who refractured and 19 months in patients who did not refracture, although no statistically significant relationship was noted between refracture rate and time to implant removal ($p = 0.792$). Additionally, within the implant removed group, refracture rate was found to be significantly higher in AO/OTA type B fractures $p = 0.049$). They concluded that routine implant removal is not recommended, and when they are removed, they recommend removal >18 months after surgery.

Mih et al. retrospectively reviewed 175 forearm fractures that were treated with plate fixation.[10] These included 122 acute fractures, 38 nonunions, and 15 malunions. Sixty-two implants were removed at an average of 19 months after plate insertion. In this group, there were seven refractures (11%). They occurred at an average of six months after plate removal. No refractures occurred nine months after plate removal. Other complications in this group included compartment syndrome and infection. The overall complication rate in this group was 16%. Additionally, 12% of patients in this group reported having continued discomfort and decreased ROM after the index surgery. After plate removal, 33% believed their symptoms improved, while 58% reported no improvement in symptoms. Many patients (113) retained their implant. In this group, six patients had complications needing surgery: one deep infection, three plate failures, one plate loosening with fracture, and one nickel sensitivity. The overall complication rate in this group was 4.4%; 96% of patients in this group remained asymptomatic; 4% reported pain or loss of function. The difference in complication rates between the two groups was statistically significant ($p <0.008$).

Wolvetang et al. retrospectively reviewed 929 forearm fractures treated with plate fixation.[11] Sixty-nine plates were removed after a median of 12.7 months from surgery. Within six months of plate removal, three of these patients (4.6%) had a refracture at the screw holes secondary to low-energy trauma. Of the remaining 860 fractures with the implant retained, 17 (2%) refractured at the screw holes and at the edge of the plate.

Vos et al. followed patients scheduled for implant removal after bony union.[12] This included 52 radius plates, 19 ulnar plates, and eight radius and ulnar plates. Follow-up at six months was 85%. The most common complications were sensory nerve injuries and wound infections. They reported no refractures and suggested that the risk of refracture after adequate fracture healing is of no importance. They concluded that for upper-extremity fractures treated with plate fixation implant removal after ≥8 months has a low risk of refracture, and had good clinical outcomes. However, this was based on very low-quality evidence.

Resolution of clinical scenario

- Plate removal is not recommended in asymptomatic patients.
- Plate removal should only occur 12–18 months after plate placement.
- For Case 1, if the patient has plate-related symptoms, removal should be delayed until 12–18 months postoperatively.
- For Case 1, if the patient is asymptomatic, there is no indication for plate removal.

Summary of answers

- In distal radius fractures, the radiographic parameters of fracture obliquity >30°, fracture distance >7.5 cm from lunate facet, radial shortening >5 mm, and ulnar styloid fracture have a low sensitivity in predicting DRUJ instability.
- Radiographs alone are insufficient to diagnose DRUJ injuries.
- In addition to a detailed physical examination of the wrist joint, fracture obliquity >30°, fracture distance >7.5 cm from lunate facet, radial shortening >5 mm, and ulnar styloid fracture may be helpful in ruling out DRUJ injuries in patients with distal radius fractures.
- Fractures of the middle and proximal thirds of the radial shaft (>7.5 cm from lunate facet) are less likely to be associated with clinically significant DRUJ injuries
- There remains no clear consensus regarding the best method for treating isolated ulnar shaft fractures.
- Surgical fixation of DRUJ injuries in Galeazzi fractures provides better short-term outcomes than conservative treatment.
- Long-term outcomes are similar for DRUJ injuries treated surgically or conservatively.
- In asymptomatic patients with plate fixation of forearm fractures, removal of hardware is not recommended.
- In symptomatic patients with plate fixation of forearm fractures that would like the plate removed, plate removal should not occur earlier than 12–18 months after index surgery.

Distal Radius Fractures

Boris A. Zelle MD and Riikkaa E. Nomides MD
UT Health San Antonio, Department of Orthopaedics, San Antonio, TX, USA

Clinical scenario

- A 48-year-old female patient, who works as a waitress, presents to the Emergency Department after a fall onto her outstretched right hand.
- The radiographic evaluation shows a displaced and comminuted distal radius fracture with approximately 30° of dorsal angulation, significant shortening, and intra-articular involvement.
- The treating orthopedic surgeon recommends surgical treatment of the distal radius fracture.

Top three questions

1. In patients with displaced intra-articular distal radius fractures, does open reduction and internal fixation (ORIF) with a plate result in improved outcomes as compared to temporary spanning external fixation with or without supplementary pin fixation?
2. In patients with displaced intra-articular distal radius fractures, does dorsal plating result in higher complication rates as compared to volar plating?
3. In patients with displaced intra-articular distal radius fractures, does arthroscopic reduction improve the outcomes over fluoroscopic reduction?

Question 1: In patients with displaced intra-articular distal radius fractures, does open reduction and internal fixation (ORIF) with a plate result in improved outcomes as compared to temporary spanning external fixation with or without supplementary pin fixation?

Rationale

Unstable intra-articular distal radius fractures frequently undergo surgical fixation. Surgical fixation options include the concepts of internal fixation versus external fixation. Temporary spanning external fixation with or without supplementary percutaneous pin fixation is a widely used standard treatment method. Similarly, open reduction and internal plate (dorsal or volar) represents a commonly used standard treatment method.

Clinical comment

External fixation relies on indirect reduction of the fracture, but it can be applied in a minimally invasive fashion. Open reduction and internal fixation (ORIF) offers the benefit of a direct reduction with appropriate visualization of the fracture site. However, it also represents a more invasive treatment method as compared to external fixation.

Available literature and quality of the evidence

In 2013, Esposito et al. published a meta-analysis of all randomized clinical trials that were published prior to

January 2011 (level I evidence).[1] A total of nine randomized clinical trials were included in their analysis. Since then an additional four level I studies comparing temporary spanning external fixation with or without supplementary pin fixation versus ORIF with a plate have been published in the literature.[2–5]

Findings

In their meta-analysis, Esposito et al. reported on the pooled results from nine publications with a total of 707 distal radius fractures treated with ORIF with a plate (n = 356) versus external fixation (n = 351).[1] These authors reported favorable functional results regarding upper extremity function as measured by the Disability of the Arm, Shoulder, and Hand (DASH) score in patients undergoing ORIF with a plate (mean difference [MD]: −5.92; 95% confidence interval (CI): −9.89 to −1.96; p <0.01). Moreover, they reported favorable radiographic results as measured by ulnar variance in patients undergoing ORIF with a plate (MD: −0.70, 95% CI: −1.20 to −0.19; p = 0.006). In addition, the risk of infection was lower in the ORIF with a plate group (risk ratio [RR] = 0.37; 95% CI: 0.19–0.73; p <0.01).

Subsequent randomized clinical trials confirmed these findings. Jeudy et al. reported on 75 patients undergoing ORIF with a plate (n = 36) versus spanning external fixation (n = 39).[2] Patients undergoing ORIF were found to have improved wrist function, as measured by the Green and O'Brien rating scale, at six months after surgery. Moreover, the ulnar variance trended toward superior results in the ORIF group, but this trend was not statistically significant. Williksen et al. reported on 91 patients who were followed for a minimum of five years.[5] They reported significantly less radial shortening in the

ORIF group. Moreover, a subgroup analysis showed favorable functional outcomes, as measured by the Mayo Wrist Score, in patients with C2 type fractures. Roh et al. reported on 74 patients, who were randomized to ORIF with a plate versus external fixation, with a 12-month follow-up.[4] These authors reported improved functional outcomes in the ORIF group at three months after surgery, as measured by the Michigan Hand Questionnaire score. At 12 months after surgery the difference between the two groups was no longer significant. However, the ORIF group showed superior radiographic outcomes as measured by the ulnar variance. Recently, Mellstrand Navarro et al. reported on 140 patients, who were randomized to the two treatment groups.[3] The authors did not identify any statistically significant differences regarding the functional outcomes at the final follow-up. However, the ORIF group showed favorable radiographic outcomes with regards to ulnar variance and restoration of volar tilt.

Resolution of clinical scenario

- Consistent level I evidence suggests that ORIF with a plate results in favorable clinical and radiographic outcomes as compared to temporary spanning external fixation with or without supplemental pin fixation.

Question 2: In patients with displaced intra-articular distal radius fractures, does dorsal plating result in higher complication rates as compared to volar plating?

Rationale

Contemporary implants allow for placement of plates over the dorsal surface of the radius as well as for placement of plates over the volar surface. Precontoured plates are available to the surgeon for both the volar and the dorsal surface. The choice of approach and implant needs to be based on the best available evidence.

Clinical comment

The concept of dorsal plating seems appealing as it provides a posterior buttress for fractures with dorsal displacement. However, there remains the concern of potential extensor tendon irritation and rupture.

Available literature and quality of the evidence

A total of three randomized clinical trials (all level II) have been published in the literature.[6–8]

Findings

A total of 192 patients were enrolled within these three trials. A total of 95 patients underwent dorsal plate fixation, whereas 97 patients underwent volar plating. Within these three trials, a total of four postoperative tendon ruptures were observed, including three patients in the dorsal plate fixation group and one patient in the volar plate fixation group. Pooled data analysis from these three trials did not show a significantly increased risk of tendon rupture in patients undergoing dorsal plate fixation (odds ratio [OR] = 3.1304; 95% CI: 0.3198–30.6422; p = 0.3268). Of note, all patients enrolled in the study by Jakubietz et al. underwent routine hardware removal at six months after surgery as per their treatment protocol, which potentially minimized the risk of local tendon irritation.[6]

All three trials reported significantly better range of motion (ROM) in patients undergoing volar plate fixation as

compared to patients with dorsal plate fixation. Two trials also reported on significantly better grip strength in patients undergoing volar plate fixation.[6,7]

Resolution of clinical scenario

- Both dorsal and volar plating can be considered safe surgical techniques.
- There is no evidence that dorsal plating with contemporary implants increases the risk of local tendon irritation and tendon rupture.
- There is also evidence to suggest there is improved wrist function during the early postoperative period in patients undergoing volar plate fixation, but further study of this issue seems warranted.

Question 3: In patients with displaced intra-articular distal radius fractures, does arthroscopic reduction improve the outcomes over fluoroscopic reduction?

Rationale

One of the major goals of surgical treatment of patients with distal radius fractures is to restore the anatomy of the distal radius and the articular congruency. Intra-articular distal radius fractures may potentially benefit from arthroscopically assisted surgery as it may allow for visualization of the joint surface as well as visualization of associated wrist joint pathology, such as tears of the scapholunate ligament.

Clinical comment

Wrist arthroscopy techniques continue to be refined and have become more widely available. A surgical technique that allows for more precise articular visualization and reduction seems desirable. However, arthroscopically assisted surgery may require additional equipment, increased surgery time, and costs.

Available literature and quality of the evidence

Two studies compared arthroscopic versus fluoroscopic reduction in patients undergoing temporary spanning external fixation with percutaneous pin fixation.[9,10] This included one level I study[10] and one level II study.[9]

One level I study compared arthroscopic versus fluoroscopic reduction in patients undergoing open reduction and internal volar plate fixation.[11]

Findings

In a prospective randomized clinical trial including 40 patients and with 24 months follow-up, Varitimidis et al. reported favorable results in patients undergoing external fixation plus percutaneous pin fixation with arthroscopic assistance as compared to patients undergoing external fixation plus percutaneous pin fixation using fluoroscopically assisted fracture reduction.[10] At final follow-up, the arthroscopic group demonstrated significantly better Mayo Wrist Scores than the fluoroscopic group (91.2 vs 86.7; $p < 0.01$). The DASH scores did not show any significant difference between the two groups. Moreover, the authors recorded a significantly smaller intra-articular step-off in the arthroscopic group (0.3 mm vs 0.8 mm, $p < 0.01$) as a measure of the quality of fracture reduction. Moreover, better wrist ROM was

observed in the arthroscopic group. In a level II study including 30 patients, Ruch et al. did not find any significant differences regarding DASH scores and quality of fracture reduction between these two patient groups.[9] However, they also recorded significantly improved wrist ROM in patients undergoing arthroscopically assisted fracture reduction. Data pooling between these two studies was not possible due to inconsistent reporting of study results.

In a prospective randomized clinical trial including 74 patients, Yamazaki et al. compared open reduction and internal volar plate fixation using arthroscopically guided versus fluoroscopically guided fracture reduction.[11] These authors did not identify any differences between the two groups with regards to DASH scores, quality of fracture reduction, and wrist ROM.

Resolution of clinical scenario

- Level I and level II evidence suggests that arthroscopically assisted fracture reduction may improve the clinical and radiographic outcomes if an external fixation plus percutaneous pin fixation construct is chosen.
- Level I evidence also suggests that patients undergoing open reduction and internal volar plate fixation do not benefit from arthroscopically assisted fracture reduction.

Summary of answers

- Level I evidence suggests that ORIF with a plate results in favorable clinical and radiographic outcomes as

compared to temporary spanning external fixation with or without supplemental pin fixation.

- There is no evidence to suggest that dorsal plating with contemporary implants increases the risk of local tendon irritation and tendon rupture. Both dorsal and volar plating can be considered safe surgical techniques.
- Level I evidence suggests that patients undergoing open reduction and internal volar plate fixation do not benefit from arthroscopically assisted fracture reduction.
- However, level I and level II evidence suggest that arthroscopically assisted fracture reduction may improve the clinical and radiographic outcomes if an external fixation plus percutaneous pin fixation construct is chosen as the treatment method.

Carpal Dislocations

Carl Nunziato MD[1], Geert A. Buijze MD PhD[2], and David Ring MD PhD[3]
[1]Dell Seton Medical Center at the University of Texas at Austin, Austin, TX, USA
[2]Département de chirugie orthopédique et traumatologie, Montpellier, France
[3]Department of Surgery and Perioperative Care, Dell Medical School – The University of Texas at Austin, Austin, TX, USA

Clinical scenario

- A 30-year-old man presents to the Emergency Department after a high-energy motorcycle collision.
- His only injury is to his right-dominant wrist, which is painful, swollen, and deformed.
- Radiographs reveal a dorsal perilunate dislocation of the wrist.
- The neurovascular examination is unremarkable.

Top three questions

1. In patients with perilunate dislocations, does advanced imaging (such as CT scan, US, MRI, or arthroscopy) lead to changes in diagnosis or operative planning compared to radiographs alone?
2. In patients with reducible perilunate dislocations, does delay in operative fixation lead to worse functional

outcomes compared with early fixation?

3. In patients with perilunate dislocations, does temporary fixation of the carpus with screws achieve better functional and radiographic outcomes than Kirschner wire (K-wire) fixation?

Question 1: In patients with perilunate dislocations, does advanced imaging (such as CT scan, US, MRI, or arthroscopy) lead to changes in diagnosis or operative planning compared to radiographs alone?

Rationale

Perilunate dislocations are usually treated with open reduction and it is not clear that computed tomography (CT) scanning or magnetic resonance imaging (MRI) helps with preparation or understanding of the injury beyond that gained with open visualization of the injury.

Clinical comment

Lateral and posteroanterior radiographs suggest a lesser arc perilunate injury without major fracture, but the anatomy is distorted and there are some bone fragments of unclear source.

Available literature and quality of the evidence

- Level IV: 2 case series.[1]
- Level V: 2 expert opinions[2] and 1 case report.[3]

Findings

Despite the fact that posteroanterior and lateral radiographs are almost always sufficient to diagnose carpal dislocations, up to 25% of these injuries are missed at presentation, as shown by Herzberg et al. (level IV).[1] One case report describes a delayed diagnosis of perilunate dislocation via ultrasonographic workup of median neuropathy (level V).[3] Advanced imaging is not routine, but according to Kaewlai et al. (level V) CT with multiplanar and volumetric reformation can be a useful technique to demonstrate the complexity and extent of fractures and dislocations.[2] There are no methodological studies comparing plain radiographs to ultrasound (US), CT imaging, MRI, or diagnostic arthroscopy for carpal dislocations.

Resolution of clinical scenario

- Advanced imaging would not be helpful in the management of this patient's perilunate wrist dislocation. Two- (2D) and three-dimensional (3D) CT might be helpful to nonspecialists and can occasionally assist in evaluating of complexity (overall quality: very low).

Question 2: In patients with reducible perilunate dislocations, does delay in operative fixation lead to worse functional outcomes compared with early fixation?

Rationale

After achieving closed manipulative reduction of a perilunate fracture dislocation, definitive surgery can be planned as an outpatient when median nerve compromise is ruled out. This introduces the potential for a delay in treatment due to access to care or logistical issues. It's not clear that such delays after closed reduction influence the final result.

Clinical comment

If closed reduction can be achieved, surgery can be delayed for up to a week or so after injury in the absence of acute carpal tunnel syndrome, forearm compartment syndrome, or an open wound.

Available literature and quality of the evidence

- Level III: 1 case control study.[4]
- Level IV: 2 case series.[1,5]
- Level V: 4 expert opinions[6–9] and 1 case report.[10]

Findings

In a large retrospective series of 89 patients with closed perilunate dislocations or fracture dislocations reported by Herzberg et al (level IV), 19 patients with delayed diagnosis of perilunate dislocations treated between 7 and 45 days after injury showed a trend toward worse results at >1 year of follow-up using a modified Green and O'Brien scoring system (71 – “fair”) compared to 51 patients treated within seven days (80 – “good”; $p = 0.07$).[1] Delay in treatment of more than 45 days showed significantly worse results (57 – “poor”; $p < 0.05$).

In a study by Komurcu et al. (level III) comparing the outcome of early versus delayed treatment in 12 patients

with greater arc injuries, the six patients treated between 7 and 45 days after injury trended toward reduced flexion/extension arc (95.5°±18.1°), grip strength measured by Jamar dynamometer (26.3 ± 13.5 kg) and modified Green and O'Brien scores (72.5 – “fair”) compared to the six patients treated within seven days. The “early” treatment group was found to have a motion arc of 129.5° ± 20.4°, grip strength of 34.0 ± 12.8 kg and modified Green and O'Brian score of 89.2 (“good”). None of the aforementioned measures reached statistical significance between groups.[4]

Most surgeons suggest surgery when convenient within the next week after injury when the dislocation can be manipulatively reduced in the Emergency Department and within a few days for those that cannot be reduced.[6–10]

Resolution of clinical scenario

- The optimal timing of definitive surgery following closed reduction, in this patient is within a week after injury (overall quality: moderate).

Question 3: In patients with perilunate dislocations, does temporary fixation of the carpus with screws achieve better functional and radiographic outcomes than Kirschner wire (K-wire) fixation?

Rationale

Temporary K-wire fixation of the carpus is standard after open reduction and internal fixation of perilunate

dislocations. Wires are more readily available and are easier to place. Temporary screws may reduce the likelihood of skin problems or infection and may allow earlier mobilization potentially improving functional results.

Clinical comment

Radiographic alignment is easier to restore after open reduction and internal fixation of a perilunate than wrist motion. It is felt that it can take about three months for the wrist ligaments to heal sufficiently to go without the support of internal fixation. The result is that a wrist treated with open reduction and pin fixation will be immobilized for up to three months until the K-wires are removed. Herbert (level V) suggested using temporary screws between the scaphoid and lunate and between the lunate and the triquetrum as an alternative to K-wire fixation.[11] The screws are sturdier and do not cross the midcarpal joint.

Available literature and quality of the evidence

- Level III: 1 case control studies.[12]
- Level IV: 1 case series.[13]
- Level V: 1 expert opinion.[11]

Findings

In the retrospective review by Souer and colleagues (level III) there were no significant differences between small cohorts of nine patients treated with temporary intercarpal screws and nine treated with temporary intercarpal K-wires, at average follow-up of 44 months[12] in arc of wrist flexion and extension (mean 87° for screws, range 50–135° compared mean 73° for wires, range 50–100°; p = 0.34);

grip strength as percentage of the other hand (mean 76% for screws; range 55–90% compared to mean 67% for wires, range 40–96%; p = 0.33); and Mayo Wrist Score mean of 71 for screws (range 60–100) compared to a mean of 66 for wires (range 45–65; p = 0.47). The prevalence of midcarpal arthritis was lower (29% vs 71%) in the screw fixation group. There were two pin infections in the K-wire cohort and the only pin in the screw fixation cohort (used to address ulnocarpal translocation) also became infected, with two patients developing septic arthritis of the wrist.[13]

Resolution of clinical scenario

- Treatment of this patient's perilunate dislocation with temporary intercarpal screws is an alternative to Kirschner wires (overall quality: low).

Summary of answers

- Advanced imaging is not helpful in the diagnosis of perilunate dislocations among experts, but 2D and 3D CT might be helpful to nonspecialists and can occasionally assist in evaluating of complexity (overall quality: very low).
- The optimal timing of definitive surgery for a reducible dislocation is within a week or so after injury in the absence of acute carpal tunnel syndrome or median neuropathy (overall quality: low).
- Treatment with temporary intercarpal screws is an alternative to temporary K-wires (overall quality: low).

Carpal Fractures

Bert Perey MD FRCSC[1], Emanuelle Villemaire-Côté MD FRCSC[2] and Francesc A. Marcano-Fernández MD PhD[3]
[1]University of British Columbia, BC, Canada
[2]Department of Orthopaedics, CHU de Québec-Université Laval, Quebec, Canada
[3]Division of Orthopaedic Surgery, McMaster University, Hamilton, ON, Canada

Clinical scenario

- A 30-year-old laborer fell from his truck and landed on his right upper extremity with the wrist in dorsiflexion.
- He presents to the Emergency Department with pain and swelling of the right wrist, at the anatomical snuffbox.
- Range of motion of the wrist is limited by pain. Radiographs are taken and are shown in Figure 89.1.

Top three questions

1. In patients with a suspected scaphoid fracture but negative findings on initial x-rays, is magnetic resonance imaging (MRI) more sensitive and cost-effective than temporary immobilization and repeated x-rays after two weeks?
2. In patients with a nondisplaced scaphoid fracture undergoing conservative treatment, does a short arm thumb spica cast achieve higher union rates compared to a below-elbow casting without thumb?

3. In patients with a nondisplaced fracture of the scaphoid, does conservative treatment achieve similar union rates to surgical treatment of the scaphoid?

Question 1: In patients with a suspected scaphoid fracture but negative findings on initial x-rays, is magnetic resonance imaging (MRI) more sensitive and cost-effective than temporary immobilization and repeated x-rays after two weeks?

Rationale

A missed scaphoid fracture can have adverse outcomes. It is generally accepted that a delay in diagnosis and treatment of scaphoid fractures can lead to nonunion or malunion resulting in symptomatic osteonecrosis, carpal collapse, or secondary osteoarthritis. This underlines the importance of an accurate and prompt diagnosis.

Clinical comment

Patients presenting with a clinically suspected scaphoid fracture, but negative initial radiographs, are treated with temporary cast immobilization for 10–14 days before a second set of radiographs is performed.

The patient's radiographs are initially negative. You are planning to immobilize the patient in a cast and reassess him in two weeks with repeat radiographs (Figure 89.2), but you are wondering if an immediate bone scan, computed tomography (CT) scan, or MRI would be more appropriate.

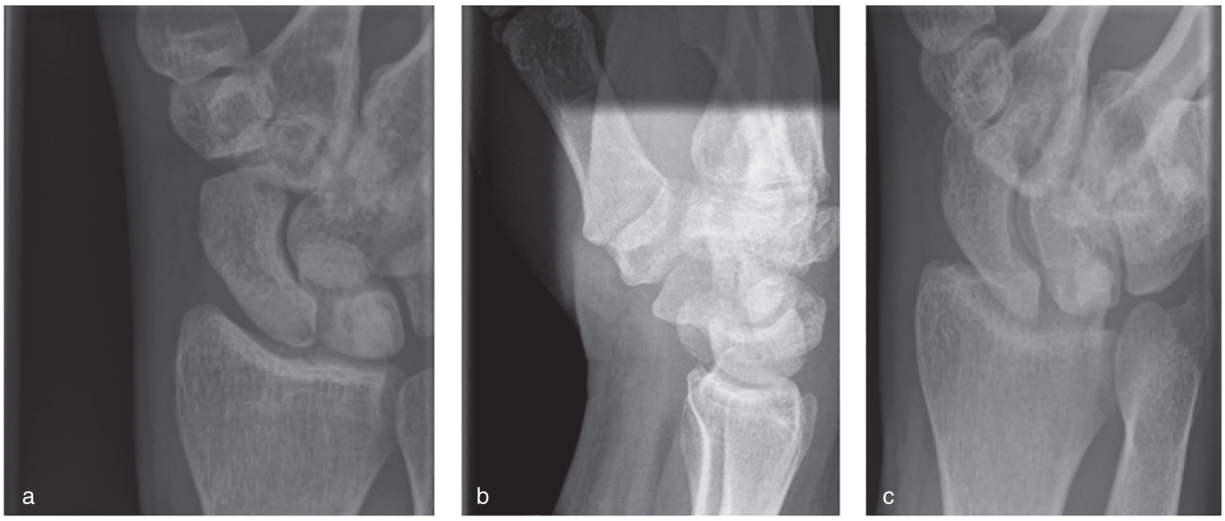

Figure 89.1 PA in ulnar deviation (A), lateral (B), and scaphoid (C) view of the right scaphoid.

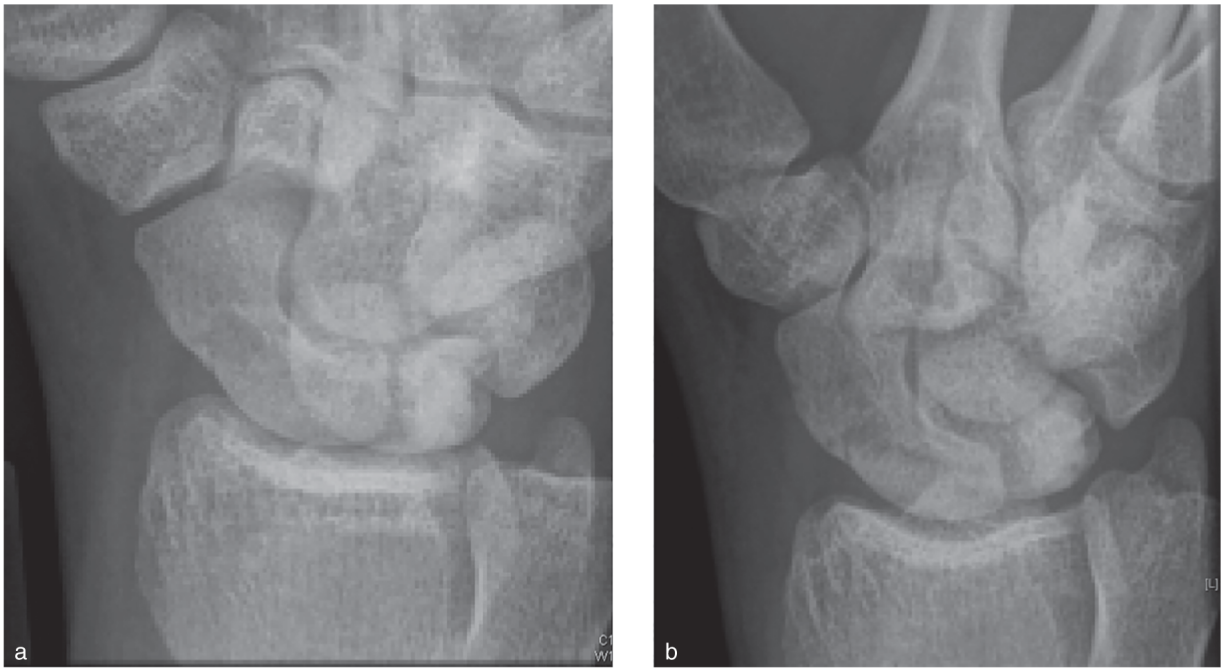

Figure 89.2 Pronated oblique view of the same patient in Figure 89.1: (A) following the injury, there was a doubt about a waist fracture; (B) 10 days later, radiograph reveals more clearly the waist fracture.

Available literature and quality of the evidence

This search produced the following level I studies: a Cochrane meta-analysis,[1] one randomized controlled trial (RCT) comparing the suitability of two imaging techniques (conventional radiography vs a CT scan),[2] two RCTs comparing the cost-effectiveness of MRI versus conventional management,[3,4] and two meta-analyses of mostly prospective cohorts.[5,6]

Whenever possible, these level I studies will be used to answer the question.

Studies with a lower level of evidence will be used to address the role of other imaging modalities that lack high-quality evidence.

Findings

Sensitivity and negative predictive value (NPV) of initial and repeated radiographs

The NPV of initial radiographs varies greatly between studies. One large prospective multicenter study of moderate quality showed a sensitivity of 93.7% (95% CI: 0.88–0.96) and a specificity of 100% (95% CI: 0.99–1.00) for patients with clinical suspicion and after five standardized projections.[7] A collection of smaller studies shows a range of NPV between 50 and 93% with a mean of 82%.[2,3,8–10] To compensate for this variation, patients with clinically suspected acute scaphoid fractures but negative initial x-rays are typically treated with two weeks of cast immobilization followed by repeated examination and radiographic studies.

A meta-analysis by Yin et al. demonstrated that radiographs repeated in less than six weeks have a sensitivity of 91% (95% CI: 0.810–0.978) and a specificity of 99% (95% CI: 0.99–1.00).[11]

Other diagnostic modalities and their utility in avoiding significant, unnecessary immobilization time

Bone scan

The latest Cochrane review reveals that bone scan is sensitive but not specific for diagnosing scaphoid fractures. Sensitivity and specificity of bone scan were 99% (95% CI: 0.69–1.00) and 86% (95% CI: 0.73–0.94).[1] Moreover, it requires a delay of at least 72 hours following the injury to capture the osteoblastic activity of the fracture site[5] and is also the most invasive test with the need for intravenous radioactive isotopes and a higher dose of radiation compared to CT scan.[12]

Magnetic resonance imaging

According to the latest Cochrane meta-analysis, MRI has shown to have a sensitivity of 88% (95% CI: 0.64–0.97) and a specificity of 100% (95% CI: 0.38–1.00) (Figure 89.3).[1] Previous meta-analyses coincide with this high specificity value but grant higher values for sensitivity; 96% (95% CI: 0.91–0.99) and 97% (95% CI: 0.95–0.99).[5,11] This decrease in sensitivity value observed in the latest Cochrane meta-analysis is due to the selection of only high- and moderate-quality studies for this calculation which omitted poor-quality studies.

Figure 89.3 Coronal Fat Sat T2 MRI confirming a suspected proximal pole fracture of the scaphoid.

MRI also allows for the ability to detect associated soft tissue injuries.

Computed tomography

CT scan can also identify occult fractures (Figure 89.4) but is more useful in defining the fracture pattern and the angular deformity.[13] According to the Cochrane review it

has a sensitivity and specificity of 72% (95% CI: 0.36–0.92) and 99% (95% CI: 0.71–1.00), respectively. Similarly to the MRI findings, sensitivity is lower than the one from an earlier meta-analysis which granted it a sensitivity between 93% (95% CI: 0.83–0.98) and 85% (95% CI: 0.73–0.94).[5,11] This reduction in sensitivity is due to the same reasons as the MRI decrease.

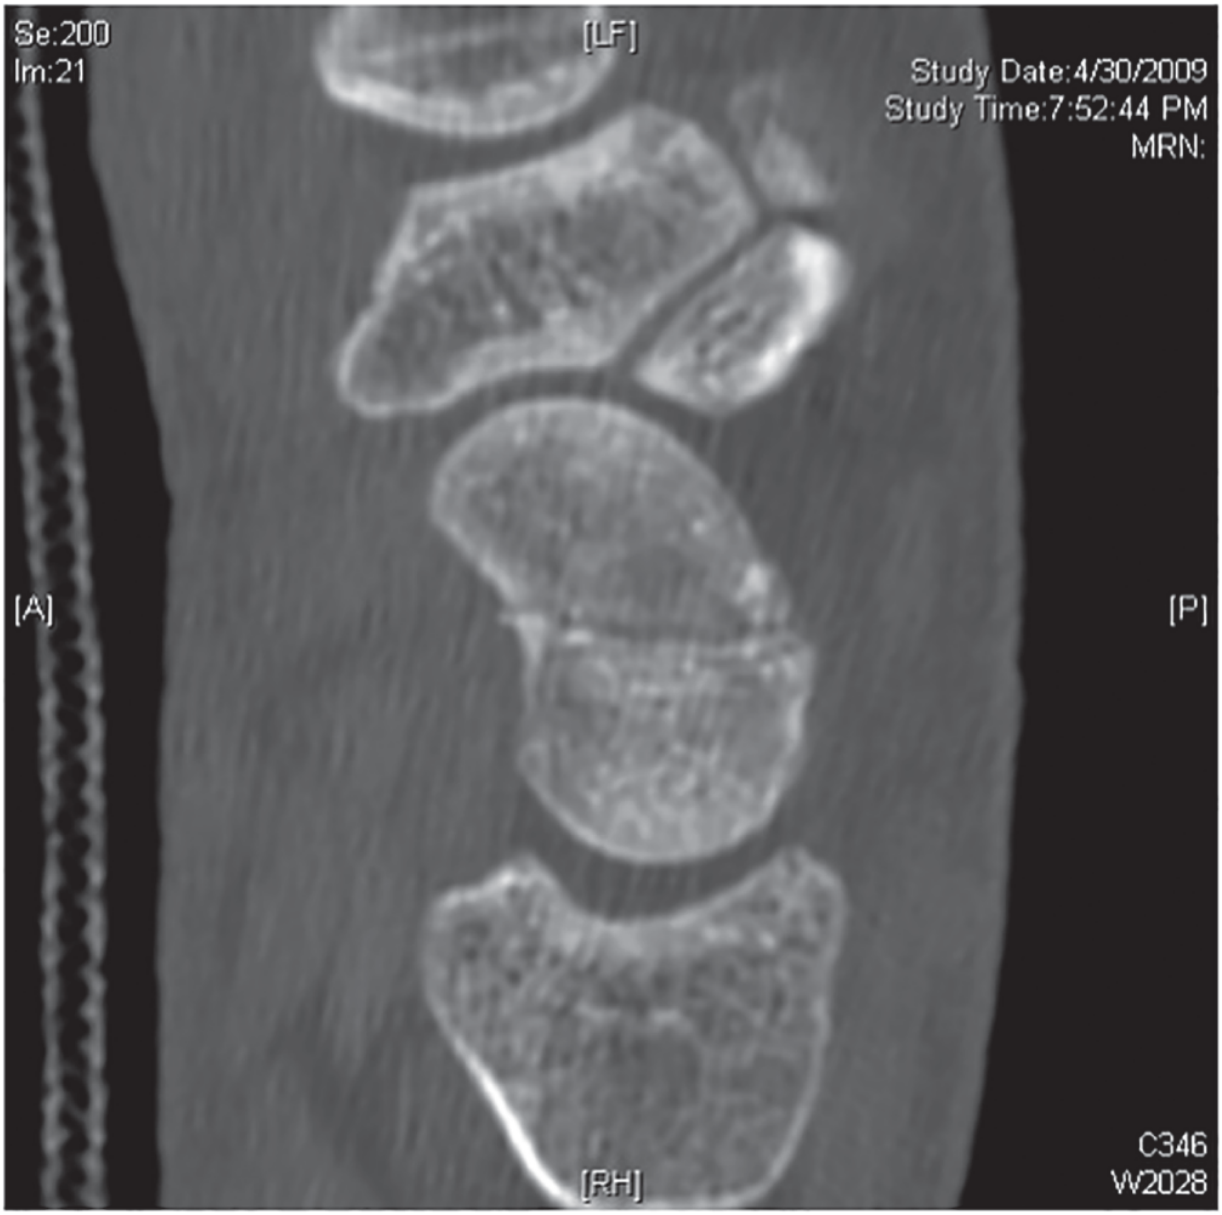

Figure 89.4 CT scan of the same patient in Figure 89.1. CT can identify occult fracture but is more useful in assessing fracture displacement and angulation.

Cost-effectiveness of early MRI as an alternative to repeated x-rays

Two high-quality level I diagnostic RCTs are used to answer this question.[3,4] Brooks investigated the cost-effectiveness of MRI by randomizing 28 patients with a suspected

scaphoid fracture to either MRI or immobilization with radiographs at 10–14 days.[3] Of the patients without fracture, the MRI group had significantly fewer days immobilized: a median of three days (interquartile range 3.0–3.0) versus 10 days (7–12) in the control group (p = 0.006). The total expenditure in the two groups was similar (MRI group = AUS$594, control group = $428; p = 0.19), owing to the direct cost of MRI. Costs from productivity loss and income loss secondary to immobilization were not included in the calculation; however, if considered these may have swayed the conclusion in favor of MRI. Similar results, but with a slight monetary advantage to MRI, were recorded by Patel et al. in the UK, who also showed that the early use of MRI exhibited increased patient satisfaction and fewer fracture clinic appointments and radiographs.[4]

Comparison between follow-up radiographs, bone scan, CT scan and MRI

Eleven level I diagnostic studies looked at diagnostic accuracy of one or two of these tests. In 2015, a Cochrane review pooled the results of the studies to show that CT scans and MRI are not as sensitive as bone scans for diagnostic accuracy.[1] However, since the prevalence of true fractures among suspected fractures is around 20%, the lower specificity of bone scan becomes problematic and would mean overtreatment in 1 out of 10 patients. With its better specificity and sensitivity, MRI is the test of choice in the diagnosis of occult scaphoid fractures. CT scan and follow-up radiographs are less sensitive tests.[6,12]

Resolution of clinical scenario

- An initial normal radiograph cannot accurately guarantee absence of a scaphoid fracture: it is

therefore recommended to proceed with further imaging, either acutely or two weeks later (overall quality: high).

- MRI is the study of choice to diagnose occult scaphoid fracture in the acute setting and has the advantage of avoiding unnecessary immobilization. There is good evidence to support its cost-effectiveness. The availability of this modality may limit its application (overall quality: high).

Question 2: In patients with a nondisplaced scaphoid fracture undergoing conservative treatment, does a short arm thumb spica cast achieve higher union rates compared to a below-elbow casting without thumb?

Rationale

Many casting options are suggested in the literature. The ideal casting method should be one that protects the fracture fragments from moving while providing maximum function to the patient.

A short arm thumb spica cast remains the most widely accepted treatment of nondisplaced scaphoid fracture.

Clinical comment

The patient radiographs reveal a nondisplaced fracture of the waist of scaphoid (Figure 89.5). After discussing the nonsurgical and surgical options with the patient, you decide to treat him conservatively.

Available literature and quality of the evidence

This search produced the following level I studies:

- 3 meta-analyses[14–16]
- 5 high-quality RCTs.[17–21]

Findings

Long-arm versus short-arm cast

There was only one meta-analysis that specifically focused on conservative treatments without comparing it to surgery.[14] The results of two RCTs were pooled comparing below-elbow and above-elbow casting for rates of nonunion and time to union. There were no significant differences in the rates of nonunion between below-elbow casting (four events of nonunion in 76 patients) and above-elbow casting (six events of nonunion in 75 patients); risk ratio (RR) 1.02; 95% CI: 0.05–19.23; p = 0.99).[14] The other two meta-analyses found no difference between the two immobilization techniques.[15,16]

A cadaveric study used CT scan to evaluate the amount of fracture displacement during pronation-supination between nonimmobilized scaphoids and scaphoids immobilized in below-elbow thumb spica cast. Long-arm casting was not tested.[22] Less than 1 mm of displacement was judged to be acceptable. The total magnitude of motion from pronation to supination averaged 0.2 mm in the specimens immobilized with a below-elbow thumb spica cast, suggesting that a short arm cast would be appropriate in preventing motion at the fracture site.

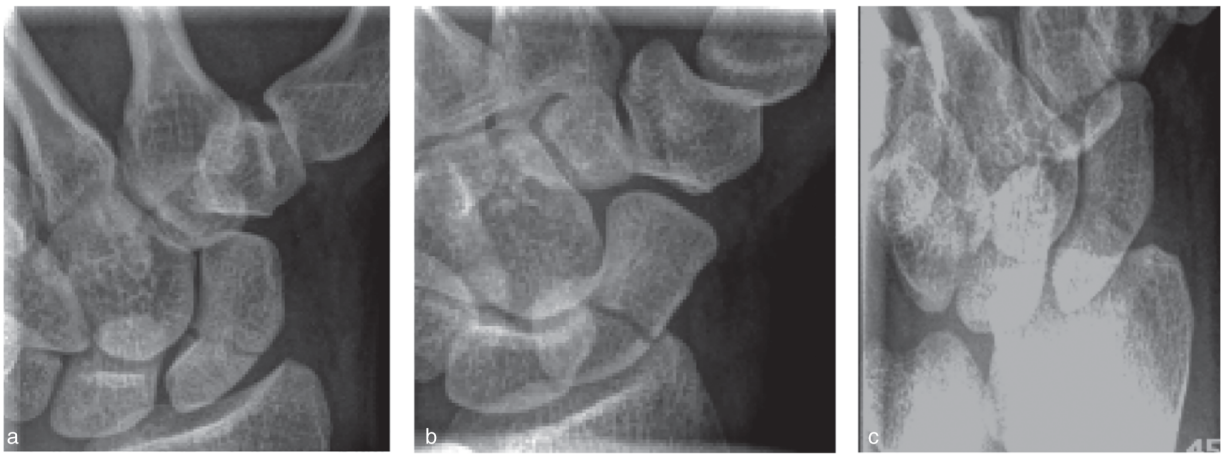

Figure 89.5 (A) AP, (B) pronated oblique, and (C) scaphoid view of a nondisplaced scaphoid fracture.

Lawton et al. compared the forearm rotation allowed by a long-arm thumb spica cast versus an epicondylar-bearing (Munster) thumb spica cast on healthy individuals with no fracture.[19] The authors suggested that the Munster cast could still limit enough forearm rotation to avoid healing complications while allowing more elbow flexion/extension than a long-arm cast; however, the clinical advantages of this type of casting have not been demonstrated.

Inclusion of the thumb

Clay et al. showed, in a RCT, that there was no significant difference in the rate of nonunion between casts that included the thumb (14 events of nonunion in 143 patients) or did not include the thumb (15 events of nonunion in 148 patients); RR 0.97; 95% CI: 0.48–1.93; p = 0.92.[17] This was later confirmed in another level I RCT using CT scan to assess union.[20]

Resolution of clinical scenario

- The evidence does not support the use of a long-arm cast in the treatment of a nondisplaced scaphoid fracture (overall quality: high).

- Inclusion of the thumb in the cast is not critical for scaphoid fracture healing and leads to greater functional impairment during the period of casting (overall quality: high).

Question 3: In patients with a nondisplaced fracture of the scaphoid, does conservative treatment achieve similar union rates to surgical treatment of the scaphoid?

Rationale

Scaphoid fractures can escape early detection because the initial symptoms can be minimal, and the clinical and radiographic signs can be subtle. Many authors suggest that any fracture that presents greater than four weeks from injury is at high risk of nonunion, so when there is a delay in diagnosis some advocate that most scaphoid fractures should be treated operatively.

Clinical comment

The patient presents five weeks following injury to his wrist. Radiographs show a nondisplaced scaphoid waist fracture.

Available literature and quality of the evidence

The highest level of evidence produced by this search was five level IV studies.[23–27]

Findings

Russe reported 27 cases of delayed presentation of scaphoid fractures (range three weeks to three years).[25] All fractures eventually achieved union with cast treatment; however, the duration of immobilization was considerable.

Eddeland et al. reported that the rate of nonunion was 73.3% (11/15) when immobilization was initiated between four weeks to one year, and 96.3% (26/27) when it was initiated at greater than one year.[23] They concluded that a delay in treatment of greater than four weeks from injury is highly predictive for the development of scaphoid nonunion.

Another retrospective review of 285 scaphoid fractures demonstrated that, while the incidence of nonunion was negligible if treatment was initiated within 28 days of injury, the frequency of nonunion significantly increased with a delay in treatment of greater than four weeks ($p < 0.01$).). Of the fractures that eventually healed, a treatment delay of greater than four weeks was associated with a significantly increased time to union from nine weeks in early detection to 17 weeks in delayed fractures ($p < 0.001$).[27]

Finally, Grewal et al. reviewed 28 cases of subacute scaphoid fractures presenting between six weeks and six months of injury.[26] They found an 82% union rate with casting with a mean length of time to union of 11 weeks for waist fractures and 14.2 weeks for proximal pole fractures. Risk factors with significant association to nonunion were diabetes, humpback deformity, and comminution. Exclusion of patients with these risk factors resulted in a union rate of 96%, suggesting that subacute scaphoid fractures can be successfully treated with casting alone.

Resolution of clinical scenario

- Delay in treatment exceeding four weeks from time of injury is associated with higher risk of nonunion or delayed union; however, it is unclear if surgical intervention should be favored over prolonged cast treatment in the absence of comminution, humpback deformity, and diabetes (overall quality: low).

Summary of answers

- An initial normal radiograph cannot accurately guarantee absence of a scaphoid fracture: it is recommended to proceed with further imaging, either acutely or two weeks after injury.
- MRI is the study of choice to diagnose occult scaphoid fractures in the acute setting and has the advantage of avoiding unnecessary immobilization. There is good evidence to support its cost-effectiveness. However, the availability of this modality may limit its application.
- Evidence does not support the use of a long-arm cast in the treatment of a nondisplaced scaphoid fracture.
- Inclusion of the thumb in the cast is not critical for scaphoid fracture healing and leads to greater functional impairment during the period of casting.
- Delay in treatment exceeding four weeks from time of injury is associated with higher risk of nonunion or delayed union; however, it is unclear if surgical intervention should be favored over prolonged cast treatment in the absence of comminution, humpback deformity, and diabetes.

90
Metacarpal Fractures

Christina Ward MD
Department of Orthopaedic Surgery, University of Minnesota, Minneapolis, MN, USA

Clinical scenario

- An adult 22-year-old male injures his dominant right hand in a bicycle accident.
- He has a closed small finger metacarpal neck fracture with radiographs showing 45° of apex dorsal angulation.
- There is no rotational deformity on clinical examination.

Top three questions

1. In adult patients with angulated fifth metacarpal neck fractures, does surgical treatment offer better final range of motion (ROM) or grip strength than nonsurgical treatment?
2. In adult patients with angulated fifth metacarpal neck fractures, does closed reduction and casting improve ROM, grip strength, or patient-reported outcomes compared to less rigid immobilization?
3. In adult patients with a metacarpal neck fracture, does correction of angulation result in improved ROM or grip strength compared to consolidation without angulation correction?

Question 1: In adult patients with angulated fifth metacarpal neck fractures, does surgical treatment offer better final range of motion (ROM) or grip strength than nonsurgical treatment?

Rationale

Many patients with metacarpal neck fractures do well with nonsurgical treatment. Surgical intervention may improve radiographic alignment, but it is associated with additional direct costs and may expose the patient to additional complications such as stiffness, infection, and hardware problems.

Clinical comment

When patients see an angulated fracture on radiographs, they often question whether the fracture should be “fixed” surgically.

A wide variety of fixation methods can be used to treat metacarpal neck fractures including percutaneous pinning (antegrade, retrograde, and transverse), intramedullary fixation, and open reduction internal fixation with plating.

Available literature and quality of the evidence

Several studies compare different types of surgical fixation to one another, but only two studies directly compare surgical treatment with nonsurgical treatment. These include one level I randomized controlled trial (RCT) and one level III prospective cohort study.

Findings

Sletten et al. randomized 85 patients with small finger metacarpal neck fractures angulated >30° into surgical and nonsurgical treatment groups. The surgical group was treated with antegrade intramedullary pinning (aka bouquet pinning).[1] No attempt of closed reduction was made for the patients with metacarpal fractures randomized to the nonsurgical treatment group. Both groups were treated in a plaster splint for one week, followed by a functional brace for three weeks. There was no statistically significant difference between the two groups at one-week, six-week, three-month, or one-year follow-up with regard to QuickDASH scores, grip strength, total active ROM, or patient satisfaction Visual Analog Score (VAS). At three months, 46.5% (20 of 43) patients in the nonsurgical group reported that they were discontent with their hand function compared to 31% (13 of 42) of those who underwent surgical treatment, but these differences resolved at the one-year follow-up. However, at one year, 17.5% (7 of 40) conservatively treated patients reported that they were not content with their hand appearance, compared to 1 of 36 operatively treated patients (2.8%). Patients in the operative group experienced more complications (19 compared to 10) including complex regional pain syndrome, superficial infection, pin migration, and bent pins.

Strub et al. prospectively followed 40 patients for 12 months undergoing either antegrade intramedullary (aka bouquet) pinning or functional bracing without reduction for small finger metacarpal neck fractures angulated 30–70°.[2] There was no difference between the two groups in MP joint ROM at two weeks, six weeks, three months, six months, or one year. Grip strength was only measured at one year after injury and was equal between the two groups. All of the operative patients underwent pin removal at three months. Complications in the operative group

included delayed wound healing after pin removal (one patient), secondary displacement (one patient), and dissatisfaction with scarring (three patients). In the nonsurgical group, 55% (11 of 20) patients reported dissatisfaction with the aesthetic appearance of the knuckle, and four patients complained of feeling the metacarpal head in their palm with heavy grip. Overall patient satisfaction was equivalent in the two groups. Compared to the study by Sletten et al, the Strub et al. study had a smaller sample size and no patient-reported outcome measures. In addition, the authors did not report how they ascertained the patient's opinion of the appearance of their hand, which was one of the few differences between the two groups.

Resolution of clinical scenario

Nonsurgical and surgical treatment for metacarpal neck fractures result in similar patient reported outcomes, grip strength, and ROM.

Surgical intervention may improve patient satisfaction with the appearance of their hand, but also carries an increased risk of complications when compared to nonsurgical treatment.

Question 2: In adult patients with angulated fifth metacarpal neck fractures, does closed reduction and casting improve ROM, grip strength, or patient-reported outcomes compared to less rigid immobilization?

Rationale

Surgeons utilize a wide variety of immobilization methods for metacarpal fractures, ranging from short-arm ulnar gutter casts that include the whole ray to removable braces to elastic bandage wraps.

Clinical comment

Each immobilization method carries different direct costs, as well as varying degrees of interference with patient activities, but controversy exists regarding which method is superior.

Available literature and quality of the evidence

Four level I RCTs compare different types of immobilization for metacarpal neck fractures. The inclusion criteria vary somewhat from study to study with regard to fracture type and location and maximal fracture angulation.

Findings

Van Aaken et al. randomized adult patients with a fifth metacarpal neck fracture angulated ≤70° to either no reduction and soft wrap with buddy taping for three weeks or closed reduction and metacarpophalangeal (MCP) extension casting for four weeks.[3] At four months, they found no significant difference between the two groups with respect to ROM, grip strength, satisfaction with aesthetic appearance, Visual Analog Scale (VAS) score, or Disabilities of the Arm, Shoulder, and Hand (DASH) score. Those patients who had undergone closed reduction experienced gradual loss of reduction, such that the final fracture angulation was equivalent between the two groups. Patients in the soft wrap group reported fewer days out of work than those treated with casting (22 days vs 33 days).

The results of the Van Aaken et al. study are supported by several other studies, although the inclusion criteria for these studies vary slightly from the Van Aaken study. Braakman et al. randomized 50 patients to either functional taping or an ulnar gutter cast for fifth metacarpal fracture (including shaft and neck fractures).[4] Patients treated with functional taping had better grip strength, better pulling strength, and less extensor lag at one week and four weeks after injury. At four weeks, 11 of 25 patients in the casting group had an extension deficit, compared to 0 of 25 patients in the taping group. All patients in the taping group had restoration of 50% pulling strength by four weeks, compared to 52% from the casting group. Likewise, Hansen and Hansen compared randomized patients with ring or small finger metacarpal neck fractures angulated <60° to either an elastic bandage, a functional brace, or a plaster cast.[5] At one month, patients in the plaster cast had less MCP motion than the other two groups, but at three months demonstrated equal motion to the functional brace group. At one month and three months, patients in the elastic bandage group had slightly less MCP motion than those treated with a functional brace, and these patients also reported more pain.

Statius Muller et al. randomized 40 patients with metacarpal neck fractures to either a plaster cast for three weeks or a pressure bandage for one week followed by mobilization as tolerated.[6] They found no significant differences in MCP ROM or pain between the two groups. Twelve weeks after injury, 80% of patients in each group reported “good” satisfaction with their treatment and outcome.

Resolution of clinical scenario

Rigid casts do not appear to be superior to functional bracing or soft wrap with regard to maintenance of fracture alignment, DASH outcome scores, or MCP motion for small finger metacarpal neck fractures. Correction of angulation with closed reduction was not maintained with cast immobilization. With that information, the type of immobilization can be chosen based on patient needs, cost, and ease of use.

Question 3: In adult patients with a metacarpal neck fracture, does correction of angulation result in improved ROM or grip strength compared to consolidation without angulation correction?

Rationale

Some surgeons advocate surgical intervention for angulated small finger metacarpal neck fractures based on the idea that a metacarpal neck fracture that heals in an angulated position interferes with hand function.

Clinical comment

Residual angulation of a metacarpal neck fracture can result in a visible change in hand appearance, but the impact on hand function is not completely understood. Given the lack of high-quality studies, surgeons struggle to know when to intervene to correct angulation in a metacarpal neck fracture.

Available literature and quality of the evidence

No clinical study directly addresses this question as a primary outcome. Information from two biomechanical studies has not clearly been corroborated with clinical findings. Two level I RCTs are also available which indirectly answer this question.

Findings

Historically, two biomechanical studies have significantly influenced treatment of metacarpal neck fractures. One cadaver study by Ali et al. examined the excursion of the flexor digiti minimi and third volar interosseous muscles with changes in metacarpal neck angulation.[7] They concluded that angulation >30° would decrease grip strength by creating slack in flexor digiti minimi. Based on their model, they reported a 30° angulation would result in 92% flexor digiti minimi strength and 78% small finger total ROM compared to an intact small finger metacarpal. A second cadaver study by Birndorf et al. also looking at work of flexion also identified 30° of angulation as the point at which work of flexion increased significantly.[8]

Despite these biomechanical models, clinical studies have not reported significant deterioration of function with >30° of angulation. For example, Van Aaken et al. reported low QuickDASH scores, good grip strength, and ROM for their patients who had a mean fracture angulation >45°.[3]

Although no clinical study directly addresses the correlation between fracture angulation and function, two studies provide some analysis as part of their secondary aims. Sletten et al. found no correlation between QuickDASH score, total active motion deficit, or relative grip strength and the degree of angulation in healed fractures at one year. In addition, they reported no correlation between the final VAS score for satisfaction and the degree of fracture angulation.[1] The mean angulation in

their nonoperatively treated fractures was 41° (range 30–58°).

In their report on patients treated nonoperatively, Statius Muller et al. found no difference in the mean fracture angulation between patients who had full ROM and patients who had decreased ROM.[6] Likewise, there was no difference in the mean fracture angulation between patients who were satisfied with their hand function and those who were not satisfied. However, there were very small numbers in both the decreased ROM and dissatisfied with function groups, limiting any strong conclusions from these data.

Resolution of clinical scenario

The degree of metacarpal neck angulation that results in clinical impairment is not known. Despite biomechanical models suggesting impaired function with greater than 30° of angulation, clinical studies report relatively normal grip strength and ROM in fractures angulated approximately 45°, such as the fracture in this clinical scenario.

Summary of answers

- Nonsurgical and surgical treatment for metacarpal neck fractures result in similar patient reported outcomes, grip strength and range of motion.
- Rigid casts do not appear to be superior to functional bracing or soft wrap with regard to maintenance of fracture alignment, DASH outcome scores, or MP motion for small finger metacarpal neck fractures.
- The degree of metacarpal neck angulation that results in clinical impairment is not known.

Pelvic Fractures

G. Yves Laflamme MD FRCS(c)[1], Jonah Hébert-Davies MD FRCS(c),c[2] and Dominique M. Rouleau MD MSc FRCS(c)[1]
[1]Sacré-Coeur Hospital, University of Montreal, Montreal, QC, Canada
[2]Harborview Medical Center, University of Washington, Seattle, WA, USA

Clinical scenario

- A 37-year-old woman is severely injured in a motor vehicle accident and is brought to the Emergency Department with complaints of pelvic pain.
- She is unresponsive to initial volume resuscitation.
- On examination, her left and right thighs are swollen and bruised. Blood pressure is 90/60 with tachycardia of 130/min.
- The neurological exam, the chest x-ray, and the abdominal ultrasound are negative.

Top three questions

1. During the initial management of patients with suspected pelvic bleeding, does the application of an invasive external fixator provide superior pelvic hemorrhage control when compared to a noninvasive external pelvic binder (PB)?

2. For patients with ongoing pelvic bleeding after resuscitation, does giving priority to pre-peritoneal pelvic packing (PPP), before angioembolization (AE), reduce mortality?
3. In pelvic fracture patients at high risk of bleeding and pulmonary embolism (PE), is mechanical thromboprophylaxis or even prophylactic inferior vena cava (IVC) filter insertion safer than a chemical strategy?

Question 1: During the initial management of patients with suspected pelvic bleeding, does the application of an invasive external fixator provide superior pelvic hemorrhage control when compared to a noninvasive external pelvic binder (PB)?

Rationale

Temporary stabilization is crucial for the survival of patients with a life-threatening pelvic ring injury. Until recently, urgent application of external fixation was widely used. Experimental studies have shown that the retroperitoneal compartment is an open space[1] and that the *tamponade effect* of the pelvis is minimal. According to the ATLS (acute trauma life support)guidelines, a PB should be applied before mechanical fixation.

Clinical comment

During the immediate resuscitative period, the trauma team can quickly wrap a simple bedsheet around her pelvis and thighs before the orthopedic surgeon arrives. Blood pressure and heart rate improve dramatically 10 minutes post application.

Available literature and quality of the evidence

- Level I–II: 0 randomized controlled trials (RCT).
- Level III: 3 case-controls.
- Level III and IV: 2 systematic reviews.

Findings

Two systematic reviews have been published on the effectiveness of circumferential pelvic compression devices for unstable pelvic fractures.[2,3] The most recent, published in 2016, found sufficient evidence to suggest that external compression mechanically reduces disrupted pelvic rings. Although the short-term physiological effectiveness of PB has been shown, the long-term outcome regarding mortality remains unclear.[2] Similar conclusions were reported in the other systematic review that included 17 articles with only one level III study. Authors concluded that, although PB appears to be effective, there was a lack of prospective data.[3]

A trauma registry analysis by Croce et al. compared external fixators to PB in a cohort of 186 patients and found a lower mortality rate in the PB group but the results were not statistically significant ($p = 0.011$).[4] However, blood transfusions at 24 (4.9 vs 17.1 units) and 48 hours (6 vs 18.6 units) were statistically lower for the PB group than for the external fixation group ($p < 0.0001$). In a retrospective study of 585 patients treated with and without PB upon arrival at a trauma center, Fu et al.

reported a significant reduction in transfusion rates (398 ± 417 ml vs 1954 ± 249 ml, p = 0.006) and a shorter intensive care length of stay (6.6 vs 11.8 days, p = 0.02).[5] Another retrospective analysis on 118 patients treated with PB upon patient arrival and continued for 24 to 72 hours, compared them with historical controls in the preceding year (n = 119).[6] PB had no effect on mortality (23% vs 23%, p = 0.92), need for pelvic AE (11% vs 15%, p = 0.35), or 24-hour transfusions (5.2 ± 10.0 vs 4.6 ± 9.0 U, p = 0.64).

Resolution of clinical scenario

In the hemodynamic unstable pelvic fracture, evidence suggests (overall quality: low):

- Emergent stabilization of the pelvis is beneficial.
- External fixation is not superior to noninvasive stabilization devices. Therefore, we recommend the immediate application of a PB during resuscitation from life-threatening hypovolemic shock in patients with unstable pelvic injuries.

Question 2: For patients with ongoing pelvic bleeding after resuscitation, does giving priority to pre-peritoneal pelvic packing (PPP), before angioembolization (AE), reduce mortality?

Rationale

Reducing blood loss is crucial for the survival of patients with a pelvic injury and hemodynamic instability. In conjunction with bone stabilization, there are two possible

methods of hemorrhage control: PPP and AE. Guidelines currently provide contradictory recommendations over which treatment should be preferred.

Clinical comment

After temporary hemodynamic stabilization, the patient undergoes a secondary drop in blood pressure to 85/50. Repeated secondary survey does not reveal any other source of bleeding. The general surgeon wants to perform PPP while the orthopedic team would prefer beginning with AE. Following a publication from the American Association for Surgery of Trauma, embolization (10%) is used much more frequently than PPP (5%) to control bleeding in unstable pelvic injuries in the USA,[7] whereas PPP is more frequently reported in European literature. The most common complication for PPP is infection in 15% of cases. The unique complications reported for embolization are ischemia of the gluteus muscles and those related to IV contrast.[8]

Available literature and quality of the evidence

- Level I–II: 1 RCT
- Level III: 2 case-controls.
- Level IV: 2 retrospective studies of prospective database.

Findings

- Level II: a quasi-randomized study on 56 patients with a pelvic fracture and instability showed that PPP was quicker than angiography (60 ± 14 minutes vs 84 ± 12 minutes, $p < 0.001$) and that the delay was shorter (77 ± 19 minutes vs 102 ± 27 minutes, $p = 0.01$). However, there was an important limitation to this study because

the randomization was done according to the time of day with significantly higher ISS for overnight cases which all received PPP. The authors were not able to demonstrate differences in mortality ($p = 0.449$), length of stay in intensive care ($p = 0.214$), or transfusion between both groups ($p = 0.124$).[9]

- Level III: case control study. Osborn et al. published a retrospective study in 2009 comparing 20 patients treated with PPP to 20 patients treated with embolization.[10] From 1998 to 2004, first line treatment for patients was angiography, changing to PPP from November 2004 to June 2006. The groups were not comparable with patients in the angiography group having lower ISS scores (46 ± 9 vs 55 ± 13, $p = 0.014$). Delay between admission and treatment was shorter for the PPP group (45 vs 130 minutes, $p < 0.01$) with fewer transfusions in the PPP group in the first 24 hours after treatment (7 vs 12 units, $p < 0.01$).
- Level III: case control study. Another comparative historical case control study was published by Tai et al.[11] Thirty patients were studied in the angiography group and 11 in the PPP group after a protocol modification at their level I trauma. Time to angiography was longer than time to the odds ratio (OR) for PPP (140 ± 95 vs 79 ± 24 minutes, $p = 0.248$). Mortality was also greater in the angiography group (69% vs 36%, $p = 0.107$). However, both results were not significant as this study was underpowered.
- Level IV: a Japanese study comparing *laparotomy first* to *embolization first* for patients with pelvic fractures and positive FAST used data from a national database between 2004 and 2010. Among the 317 eligible patients, 51% were hypotensive upon arrival. After adjusted regression analysis, they demonstrated that

there was no difference in mortality between both methods.[12] The adjusted OR was of 1.20 (95% confidence interval [CI]: 0.61–2.39).

Resolution of clinical scenario

In the hemodynamic unstable pelvic fracture, poor to modest evidence suggests that:

- Access to PPP is faster than AE.
- Time needed for the procedure is less for PPP than AE.
- There were no conclusive data to help prioritize one method over the other. However, PPP seems promising.
- Every level I trauma center should establish a clear algorithm for management of pelvic fractures with hemodynamic instability, based on local accessibility to embolization and the operating room.

Question 3: In pelvic fracture patients at high risk of bleeding and pulmonary embolism (PE), is mechanical thromboprophylaxis or even prophylactic inferior vena cava (IVC) filter insertion safer than a chemical strategy?

Rationale

Patients with pelvic fractures are at high risk for both bleeding and DVT (deep vein thrombosis). Choosing appropriate thromboprophylaxis is essential to minimize bleeding complications while still protecting against potential DVT and PE.

Clinical comment

With current insertion techniques performed by experienced clinicians, the short-term complication rates associated with IVC filter use are lower than historical results. Without thromboprophylaxis, patients with a pelvic fracture have a DVT risk that is as high as 60%,[13] and PE is the third-leading cause of death in those who survive beyond the first day.[14] Current prophylaxis guidelines for thromboprophylaxis are directed toward major trauma patients, but their effectiveness, especially in the patient with an injured pelvis, is still debated.

Available literature and quality of the evidence

- Level II: 4 systematic reviews/meta-analyses; 1 randomized control.
- Level III: 1 propensity matched; 2 retrospective cohort studies.
- Level IV: 3 case series.

Findings

One small retrospective study[15] (level IV) and one systematic review[16] of the prophylactic use of IVC filter in trauma patients showed no significant difference in PE rate compared to patients without filter placement (level II). Two more recent systematic reviews found that while IVC filters may be an appropriate alternative in patients unable to receive chemical thromboprophylaxis, the paucity of high level data did not justify the use of prophylactic IVC filters.[17,18] These findings may have influenced the use of these implants as a recent National Trauma Databank study reveal a sharp decline in use (22–78% decrease) with no observable change in PE rate (level III).[19]

A systematic review by Slobogean et al. in 2009 (level II) found that no strong evidence-based recommendations for venous thromboembolism prevention in patients with pelvic and acetabular fractures can be made.[20] This was mostly due to a lack of prospective studies, small sample sizes, and nonstratified larger studies where pelvic/acetabular data could not be isolated. One prospective study evaluated the effect of timing of administration of LMWH for patients with pelvic fractures (level III).[21] They found a significantly increased rate of PE and DVT when low-molecular-weight heparin (LMWH) was administered at >24 hours from injury. The efficacy of LMWH compared to unfractionated heparin (UH) was confirmed in trauma patients in a large retrospective cohort study by Byrne et al. (level III).[22] They found an OR of 0.56 (0.50–0.63) for PE using LMWH compared to UH. One significant issue with LMWH is postdischarge compliance, as one prospective study found patients with LMWH were significantly less likely to adhere to prophylaxis compared to twice daily aspirin use (OR = 2.34)[23] (level II). This issue is currently being investigated as part of a larger study evaluating the effect of twice daily aspirin compared to LMWH for thromboprophylaxis in trauma patients (PREVENTion of Clot in Orthopaedic Trauma, PREVENT CLOT). Currently, available data are not robust enough to support routine use in these patients.[24,25]

Resolution of clinical scenario

For pelvic trauma patients, evidence suggests.

- Early administration of LMWH demonstrated a clear reduction in DVT and PE (overall quality: moderate).
- LMWH prophylaxis significantly protects against DVT in the major trauma patient (overall quality: moderate).

- Systematic use of prophylactic vena cava filters does not significantly reduce the risk of PE or mortality (overall quality: low).
- Routine use of an IVC filter as thromboprophylaxis is not recommended (overall quality: low).
- Use of IVC filters in patients with contraindications to chemical prophylaxis may result in a decreased rate of PE with an acceptable complication rate (overall quality: low).

Summary of answers

- The priority is saving the patient's life and then managing the pelvic fracture in order to reduce the high morbidity associated with pelvic fractures.
- Every Emergency Department, together with the surgical and radiological team, must create and apply a simple algorithm based on available resources for unstable patients with a pelvic fracture, to prevent confusion and the loss of precious time in cases of life-threatening pelvic injury.

92
Acetabular Fractures

Juan Antonio Porcel Vázquez MD and Ernesto Guerra-Farfán
Vall d'Hebron Hospital, Barcelona, Spain

Clinical scenario

- An 80-year-old woman with a pathological history of epilepsy is brought to the Emergency Department due to pain in her left hip and functional disability after falling from standing height.
- Anteroposterior (AP) pelvis x-ray shows an incongruity at the level of the articular surface of the left hip, without alterations in the morphology of the proximal femur. The diagnosis of suspicion is acetabular fracture.
- Judet projections inclined at 45° (alar and obturator views) are performed, in addition to computed tomography (CT). The presence of a fracture of the left acetabulum, simple posterior wall pattern, is confirmed. In addition, there is a fracture of the femoral head that had gone unnoticed on the initial radiographs.

Top three questions

1. In elderly patients (over 65 years old) with acetabular fractures, does surgical treatment achieve better functional outcomes compared to conservative treatment?

2. In elderly patients (over 65 years old) with acetabular fractures, does surgical fixation delay the need for total hip arthroplasty (THA) compared to conservative treatment?
3. In elderly patients (above 65 years) with acetabular fractures, does acute THA achieve better patient-reported outcomes and fewer surgical complications compared to a delayed THA?

Question 1: In elderly patients (over 65 years old) with acetabular fractures, does surgical treatment achieve better functional outcomes compared to conservative treatment?

Rationale

The number of acetabular fractures in the elderly is on the rise, due to an aging population, greater functional demands, and patients remaining active later into life. Although nondisplaced and stable fractures in older patients can be treated conservatively, the gold standard for the treatment of acetabular fractures is surgical osteosynthesis.[1] The goal is to preserve the survival and function of the native hip as much as possible.

Clinical comment

The incidence of acetabular fractures has increased 2.4 times over the past decade. They are associated with a mortality rate of between 8 and 25%.[2] The main purpose of surgical treatment is to restore the function of the hip, accelerate recovery, and avoid future complications.

Deciding which is the best treatment of these fractures requires considering several factors. Apart from fracture pattern and the surgeon's ability to achieve the best possible reduction, there are also important patient-related factors to consider. In addition, an aging population with multiple co-morbidities might mean that some patients are not ideal candidates for surgical treatment.

Available literature and quality of the evidence

- Level II: 1 study
- Level III: 9 studies
- Level IV: 1 study.

Findings

When operative management is required for anterior column fractures, minimally invasive techniques result in lower mortality, morbidity, and complications, compared to open surgery.[3] With operative treatment compared to nonoperative treatment, the recovery of function is much faster, allowing early weightbearing in elderly patients.[4] Sixty-five percent of patients recover their previous functional level, although in many cases with persistent pain.[5] Conversely, results obtained by Daurka et al. showed that results are worse for percutaneous osteosynthesis when compared with open reduction and internal fixation (ORIF).[6]

Fractures compromising the acetabular roof are usually managed surgically. In older patients it will depend on the medical condition.[7] In patients with low functional demands or those who are at high surgical risk because of co-morbidities, nonsurgical treatment can be chosen, followed by THA if secondary osteoarthritis develops. Patients should be mobilized as soon as possible if pain

management allows, to avoid prolonged periods of rest or traction in bed. Optimal outcomes are achieved when patients start with flat foot weightbearing for 6–8 weeks, and then progress gradually from there to full weightbearing.[8]

Posterior wall fractures are the most frequent acetabular fractures, representing around 30–47%.[1] They are generally associated with poorer prognosis, particularly when associated with a posterior dislocation, which is often associated with femoral head damage as well.

Other fractures that occur more inferiorly in the acetabulum that do not affect the weightbearing surface can be treated conservatively. Similarly, bi-columnar fractures can be successfully treated nonoperatively if secondary congruence of the femoral head respect to the acetabular roof is maintained without traction.

Ryan et al. reported similar functional results in patients with high surgical risk who were treated nonoperatively and those who underwent ORIF. No differences were found in overall Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC) or Short Form 8 (SF-8) scores at one-year follow-up.[8]

Resolution of clinical scenario

- In older or younger patients with co-morbidities and surgical risk, nonsurgical treatment of acetabular fractures is associated with worse outcomes in terms of pain and morbidity.
- Mortality is similar in patients with high risk who undergo nonsurgical treatment compared to those in which surgical treatment was performed.

- In older patients with high surgical risk, it is reasonable to opt for nonoperative management and reserve arthroplasty as a rescue alternative. Patients should be counselled about this possibility at time of injury.

Question 2: In elderly patients (over 65 years old) with acetabular fractures, does surgical fixation delay the need for total hip arthroplasty (THA) compared to conservative treatment?

Rationale

Acetabular fractures are commonly associated with marked joint injury making articular surface reconstruction very challenging. Even when a satisfactory reduction is achieved, results are variable, and in many cases poor. In addition, failure rates are high, so some patients need to undergo rescue procedures (i.e. THA). It is controversial whether surgical fixation allows patients to delay the time to THA compared to conservative treatment.

Clinical comment

The goal of ORIF is to restore joint anatomy by reducing both columns, the quadrilateral plate, and the acetabular rim, thereby maximizing native hip function and survival. If anatomic reduction is not achieved, there is a higher likelihood of THA being required in the future.[9–12] Studies have shown that proper reduction delays the need for THA. Nonetheless, even nonanatomic reductions outside the weightbearing zone are generally well-tolerated.[2,13]

Available literature and quality of the evidence

- Level II: 2 studies
- Level III: 12 studies
- Level IV: 6 studies
- Level V: 1 study.

Findings

Classically, it has been reported that 10–37% of patients will eventually require THA following ORIF for an acetabular fracture,[14,15] and as mentioned above, fractures that affect the posterior wall have a poorer prognosis.[9,16]

According to Giannoudis et al., 20–25% of acetabular fractures will have poor results in the medium term, with the quality of reduction being a key predictor. Minimal step-off (step-offs <2 mm) are associated with a failure rate of 14%, while a step-off >2 mm can reach failure rates of up to 40%.[17] Even when satisfactory reduction is achieved, one of the important factors to consider is the cartilage damage sustained at the initial trauma, and this must be assessed in the medium-long term.

Ding et al. found that if the fracture affected the posterior wall, 36% of patients required delayed THA compared to only 17% patients in whom the fracture did not affect the posterior wall.[18] Kreder et al. reported the need for arthroplasty in 56% of elderly patients with posterior wall fractures they treated within the first two years surgery.[19]

Fractures of the anterior component of the acetabulum associated with femoral head protrusion are frequent in older patients. Archdeacon et al. showed a case-series of patients over 70 years in which they reported a conversion rate to THA of 19% in the first 18 months.[14,20]

Resolution of clinical scenario

- If a fracture has poor prognostic factors, the rate of secondary osteoarthritis is high. In addition, even following ORIF, these fractures have a relatively high rate of failure.
- The gold standard in surgical treatment through osteosynthesis is to obtain an anatomical reduction, with fractures that are not well reduced being at greater risk of failure.
- Failure is usually early, within the first two years, and there are associated high rates of morbidity and mortality in elderly patients.

Question 3: In elderly patients (above 65 years) with acetabular fractures, does acute THA achieve better patient-reported outcomes and fewer surgical complications compared to a delayed THA?

Rationale

The gold standard for acetabular fractures is surgical treatment. Given the poor prognosis presented by these fractures and the group of fragile patients in which they occur, it is not clear which is the best surgical treatment option. Due the high rates of failure with internal fixation, hip replacement could play an important role in this group of patients.

Clinical comment

Surgical treatment of acetabular fractures in the elderly has evolved over time. There is a trend toward performing early THA as a definitive procedure, although it is not clear whether to carry it out in one or two stages. The goal of the two-step approach is to reconstruct the joint using osteosynthesis to facilitate future arthroplasty. Meanwhile, one-step arthroplasty aims to avoid future reinterventions in this fragile patient population.

Available literature and quality of the evidence

- Level II: 1 study
- Level III: 13 studies
- Level IV: 2 studies.

Findings

Normally, THA occurs in the first two years after osteosynthesis of an acetabular fracture.[21,22] Ding et al. reported a 28% rate of THA in the first 2.5 years following index ORIF.[2,18] There are no differences in the need to perform a rescue THA depending on the type of fixation; Daurka et al. showed that the rates of THA were 22 and 25% following ORIF and percutaneous osteosynthesis, respectively.[6]

If it is difficult to reconstruct the posterior wall and the fracture presents risk factors for poor outcomes with surgical fixation such as marginal impaction ($p = 0.01$) or wall comminution ($p = 0.005$), primary THA should be considered as an option, especially in patients older than 50–60 years ($p = 0.01$).[15,19]

Placement of the acetabular component can be difficult depending on the size and location of posterior wall fragments (e.g. large fragments located near the roof are

technically more difficult to fix). If the prosthesis is indicated as the initial procedure, it is not clear whether it is better to do it with osteosynthesis and conventional prosthesis, or with complex prostheses (revision cups, cup cage, graft, etc.). In the former case, the objective of osteosynthesis is not necessarily anatomic reduction but rather to provide stability to the arthroplasty components.

If a combined procedure is carried out, the failure rates range from 13 to 45%.[23,24] Reconstruction rings can also be used, but it can be difficult to place them in bi-columnar fractures. The main problems with acetabular components are proximal migration and medialization, along with malpositioning leading to dislocation. Failure rates of the acetabular component for acetabular fracture are four to five times higher than in primary elective THA.[25]

Early arthroplasty in acetabular fractures has better results than late conversion to arthroplasty of a failed osteosynthesis.[26] The results of arthroplasty as a rescue of a failed osteosynthesis, based on the Harris Hip Score, are worse than the results of a nontraumatic primary arthroplasty.[27,28]

Data on survival are somewhat mixed. Morison et al. reported that in rescue THA failure was seen about five years earlier than primary arthroplasties.[29] However, other authors showed high survival rates in their articles. Lizaur-Utrilla didn't see differences in terms of aseptic loosening of a cementless acetabular component in patients undergoing THA after an acetabular fracture or compared to primary elective THA.[27] Ranawat et al. reported that five-year survival with revision, loosening, dislocation, or infection as an endpoint was 79%.[30]

Resolution of clinical scenario

- If the acetabular fracture associates to extensive impaction and comminution, and/or there is damage to the articular cartilage of the femoral head, an early THA should be considered in elderly patients.
- Early arthroplasty seems to have better results than late THA after osteosynthesis failure in elderly patients.
- The results of rescue arthroplasties are inferior to those of nontraumatic arthroplasty in terms of function, though it's unclear if there is a significant difference in implant survival.

Summary of answers

- Non-surgical treatment of acetabular fractures is associated with worse outcomes
- The gold standard with open reduction internal fixation is to achieve anatomic reduction, particularly of the joint surface
- Early THA should be considered in elderly patients with extensively impacted and/or comminuted fractures

[3]University of Missouri, Columbia, MO, USA

Clinical scenario

- A 40-year-old male is brought to the Emergency Department after a motor vehicle crash. He was an unrestrained passenger in the front seat.
- He is complaining of significant pain in the left hip and buttock region. His left extremity is slightly flexed, adducted, and internally rotated, and appears to be his only injury.
- X-ray demonstrates a posterior left hip dislocation with a small posterior wall acetabular fracture.
- After uneventful reduction in the Emergency Department, his hip remains concentrically reduced. Stress examination reveals that the hip is stable through range of motion. Nonoperative management is selected.
- Due to persistent pain two weeks later, he undergoes magnetic resonance imaging (MRI), and is diagnosed with a labral tear.

Top three questions

1. In patients with a traumatic dislocation of the hip, does a delay in hip reduction increase the risk of femoral head osteonecrosis (avascular necrosis [AVN]) as compared with an earlier reduction?
2. In patients with an isolated traumatic hip dislocation, do advanced imaging examinations (computed tomography [CT] and/or MRI) change treatment approach, as compared with X-rays alone?
3. In patients with hip dislocations who are diagnosed with an acetabular labral tear after closed reduction, does surgical treatment (with debridement and/or repair) achieve better functional outcomes than nonsurgical management?

Question 1: In patients with a traumatic dislocation of the hip, does a delay in hip reduction increase the risk of femoral head osteonecrosis (avascular necrosis [AVN]) as compared with an earlier reduction?

Rationale

- Traumatic hip dislocations are uncommon but severe injuries mainly observed after motor vehicle crashes and occasionally associated with sporting injuries. They represent 5.2% of all traumatic joint dislocations.[1]
- Posterior dislocations are more common (accounting for nearly 90% of all hip dislocations)[2] and tend to occur after what is known as a *dashboard injury* (the

seated driver/passenger's knee strikes the dashboard during sudden deceleration, causing the hip to dislocate posteriorly).

Clinical comment

Femoral head AVN – an undesirable complication after a traumatic hip dislocation – can lead to significant morbidity.[3] It may be caused by disruption and/or kinking of retinacular vessels supplying the femoral head.[4] Most surgeons believe that rapid reduction of hip dislocations is important to minimize AVN risk, but this is unproven. Knowledge regarding whether type of dislocation and timing to hip reduction is achieved may have an impact upon development of osteonecrosis and post-traumatic arthritis can assist orthopedic surgeons when informing hip dislocation patients about their prognosis and offering them the appropriate treatment.

Available literature and quality of the evidence

This search produced the following results: one level III meta-analysis[1] and one level IV systematic review and meta-analysis.[5] Numerous case series and case reports are already included in the previous two articles.

Findings

Femoral head osteonecrosis and hip dislocations

Kellam et al. performed a systematic review and meta-analysis that assessed femoral head osteonecrosis and post-traumatic osteoarthritis (PTOA) rates after traumatic hip dislocation.[5] They included 13 retrospective observational cohort studies (level of evidence: IV) with 795 posterior hip dislocations and 86 anterior hip dislocations, and found that, for both anterior and posterior dislocations, the event

rate of AVN and PTOA was higher as the severity of the injury increased. On the other hand, Ahmed et al. conducted a meta-analysis where they found that time to hip reduction was unimportant, and data pooled from the selected studies showed a trend toward higher femoral head AVN in high-grade traumatic hip dislocations (Thompson and Epstein grade IV–V) when compared to low-grade traumatic hip dislocations (Thompson and Epstein grade I–III), but this did not reach statistical significance (odds ratio [OR] = 1.71; 95% confidence interval [CI]: 0.22–13.22; I^2 = 68.9%; p = 0.012).[1]

Time to reduction and AVN

From the 13 studies included by Kellam et al.,[5] only two reported data about time to hip reduction. Sahin et al. showed that patients developed AVN after hip dislocation less frequently when reduction was performed within the first 12 hours (1/35, 2.9%), as compared to later than 12 hours (4/27, 14.8%) after the injury.[6] However, when comparing traumatic hip dislocations reduced in <6 hours and those reduced between 6 and 12 hours from the injury, they did not find any difference in AVN rates. Brav et al. reported AVN in 3/204 (1.47%) versus 33/58 (56.9%) cases when comparing patients who underwent articular reduction within or after 12 hours, respectively.[7] Although the number of studies reporting on timing was small, Kellam et al. calculated an increased risk (OR = 5.63; 95%CI: 2.97–10.67; p <0.005) for development of AVN for all types of hip dislocations when reduction is performed after 12 hours.[5]

Ahmed et al. considered a different timeframe in their study. They compared femoral head AVN rates when hip reduction was done early (considered to be <6 hours from the time of injury) versus late (>6 hours).[1] They included

five studies (all retrospective cohort studies) encompassing 236 traumatic hip dislocations. Patients who underwent late hip reduction had a significantly higher risk of femoral head AVN (OR = 5.00; 95% CI: 1.30–19.29; I^2 = 48.6%), as compared to those who had an early reduction. Dreinhöfer et al., in a cohort of 50 patients who underwent hip reduction after a traumatic hip dislocation, found an overall femoral head AVN rate of 12%, but found no difference in the rates between patients who underwent reduction within one hour compared to between one and six hours after injury.[8]

Resolution of clinical scenario

In this clinical scenario, considering the best available evidence, the orthopedic surgeon should be prepared to perform a reduction of a dislocated hip within six hours from injury. However, as evidence associating femoral head AVN with time to reduction of a hip dislocation is moderate, the recommendation remains to perform reduction as soon as possible in order to avoid further articular damage and, possibly, femoral head AVN (overall quality: moderate).

Question 2: In patients with an isolated traumatic hip dislocation, do advanced imaging examinations (computed tomography [CT] and/or MRI) change treatment approach, as compared with X-rays alone?

Rationale

- Hip dislocations are normally diagnosed with orthogonal plane x-rays. Traditionally, after closed

reduction is achieved, CT scans have been the imaging technique of choice to assess for associated fractures and/or intra-articular fragments.

- Controversy exists about the best imaging modality for evaluation of patients after closed reduction of hip dislocations, due to concern for associated soft tissue injuries and/or intra-articular fragments that may be missed by CT scan.[9]

Clinical comment

Arthroscopy has emerged as an important therapeutic tool after traumatic hip dislocation to treat some patients with persistent pain or mechanical symptoms associated with intra-articular loose bodies or other injuries, such as labral tears. Arthroscopy has been used as the gold standard when comparing the accuracy of different imaging techniques for the identification of intra-articular pathology.

Available literature and quality of the evidence

This search identified a level IV systematic review including 14 case series and 17 case reports. evaluating the diagnostic precision of CT and against arthroscopy as the gold standard.[10] Whenever possible, this review was used to answer the question, but when assessing the role of advanced-imaging techniques compared to conventional x-rays, five small retrospective studies (level IV) were used to help answer this question.

Findings

Arthroscopy after traumatic hip dislocations

No specific study answering the specific clinical question was found. However, some studies compared advanced

imaging findings after hip dislocation, with arthroscopy as a gold standard, because of persistent pain or mechanical symptoms.

Mandell et al. included 31 studies in a systematic review including 151 patients who underwent hip arthroscopy after a traumatic hip dislocation.[10] Patient mean age was 25.2 years (range 8–54) and 74% were males, with most dislocations being secondary to a motor vehicle crash (57%). The median time to arthroscopy from injury was 37.5 days. Specific findings about the presence or absence of intra-articular fragments were described in 119 patients. CT scan identified loose bodies in 89 cases (74.8%), compared to 102 cases (85.7%) identified by arthroscopy, thus CT had a sensitivity of 87.3%. From the 30 patients without intra-articular fragments identified on CT scan, 13 (43.3%) had chondral, osteochondral, or osseous intra-articular fragments seen during arthroscopy. This is also consistent with the findings of Khanna et al., in which CT scans identified only 2 of the 17 intra-articular bodies (12%) found in a cohort of 29 patients who underwent hip arthroscopy.[11]

On the other hand, 23 patients received a preoperative MRI with labral appearance being described in 21 cases. Nineteen labral tears were diagnosed by MRI, and all of them were confirmed by arthroscopy. One false-negative and one true-negative were identified. Thus, MRI had a sensitivity of 95% and a specificity of 100%. Additionally, the presence of intra-articular bodies was evaluated by MRI and in the six cases with MRI-identified loose bodies, arthroscopy confirmed the findings.[10]

Conventional x-rays versus CT

Hougaard et al. reviewed 15 cases in which both a CT and plain radiographs were performed after reduction of a

posterior hip dislocation.[12] Loose fragments were identified in five cases with CT scan (fragment of between 1 cm^2 and 6 cm^2), all of which were removed by open surgery. Plain radiographs only identified loose fragments in one case. Additionally, in six cases, CT scans demonstrated a fracture that would otherwise have been overlooked based on radiographs. Sauser et al. reported that, in a series of 13 patients with hip and pelvis injuries (six hip dislocations), CT scans provided useful information not seen on radiographs, modifying the treatment in four patients (30.8%).[13] Harley et al. and Shirkhoda et al. found both superior sensitivity and specificity when assessing intra-articular bodies with CT scans compared to x-rays, leading to identification of intra-articular loose bodies that were surgically removed and would have been otherwise overlooked.[14,15]

Resolution of clinical scenario

When plain radiographs reveal the presence of pathology requiring surgical intervention, advanced imaging techniques may not be necessary. However, in patients with apparently normal hip radiographs following uneventful closed reduction of an isolated hip dislocation, current evidence appears to support adding advanced imaging techniques (CT scan or MRI) in order to increase the likelihood of identifying associated injuries and perhaps changing treatment strategies. However, owing to small sample sizes and poor study design, it is not clear which method should be selected when choosing between CT or MRI. There is minimal evidence that MRI may be superior for the detection of injuries that could cause mechanical symptoms or persistent pain (such as labral injuries or intra-articular fragments) (overall quality: low).

Question 3: In patients with hip dislocations who are diagnosed with an acetabular labral tear after closed reduction, does surgical treatment (with debridement and/or repair) achieve better functional outcomes than nonsurgical management?

Rationale

- Hip dislocations are associated with a broad spectrum of intra-articular pathology, including labral tears, ligamentum teres disruption, intra-articular loose bodies, and chondral injuries. The presence of these types of injuries may explain persistent pain and/or mechanical symptoms after hip reduction is achieved.
- None of the current hip dislocation classification systems (Thompson and Epstein,[16] Stewart and Mildford,[17] Levin[18]) includes these injuries as a component of the classification.

Clinical comment

Associated injuries after a traumatic hip dislocation may slow recovery and potentially lead to future PTOA. Intra-articular bodies and labral tears can both cause chondral damage and increase the risk of hip osteoarthritis.[19,20] Traditionally, open reduction has been the standard of care for the treatment of hip dislocations that require surgery. However, recent sports medicine literature has focused on these hip conditions and their treatments,[21] with hip arthroscopy gaining in popularity in the context of

traumatic hip dislocations as an effective and less invasive approach for evaluation of periarticular soft tissues.

Available literature and quality of the evidence

This search identified one level IV systematic review including 14 case series and 17 case reports[10] evaluating CT and MRI diagnostic precision compared with arthroscopy; a review about the use of hip arthroscopy to treat sequelae of traumatic hip dislocations;[22] another review including the mechanism of injury, epidemiology, associated injuries, evaluation, treatment, and functional outcomes of simple hip dislocations;[23] and a retrospective study including patients who underwent arthroscopic treatment after acetabular fracture or hip dislocation.[21]

Findings

Labral tears after traumatic hip dislocations are a common finding. The use of arthroscopy to evaluate the hip joint after traumatic hip dislocations is increasing.[22] Philippon et al. identified that, in a series of 14 professional athletes who sustained traumatic hip dislocations, all had a labral tear during hip arthroscopy for continued hip pain, at a mean of 125 days postinjury.[24] Khanna et al. used hip arthroscopy to investigate the prevalence of intra-articular pathologic findings after a traumatic injury of the hip, reporting a presence of 93% of labral tears (27 of 29 hips).[11]

Hwang et al. carried out a retrospective study of 13 hip arthroscopy cases.[21] All patients had major hip trauma (acetabular fracture and/or hip dislocation), and were treated by a single senior surgeon due to persistent or aggravating pain and/or intra-articular pathologies such as loose fragments, labral tears, or ligamentum teres injury identified on advanced imaging. Labral tears were debrided

or repaired, loose fragments removed, and torn ligamentum teres debrided. Visual Analog Scale (VAS) and modified Harris Hip Score (mHHS) improved significantly at the final follow-up, from 6.3 and 53.4 to 3.0 and 88.3, respectively ($p = 0.002$ and $p < 0.001$, respectively). However, there were no significant differences in final hip flexion ($p = 0.07$), abduction ($p = 0.414$), adduction ($p = 0.317$), external rotation ($p = 0.084$), and internal rotation ($p = 0.136$).

Of all patients who underwent hip arthroscopy, eight had preoperative Tönnis grade 0 changes and five had grade 1 changes; none showed progression of hip osteoarthritis at the final follow-up (mean follow-up 59.8 months).

Overall, good outcomes have been achieved with arthroscopic labral debridement and repair.[10,21,25] The rest of the available literature appears to address arthroscopic treatment of labral tears not associated with hip dislocations. For instance, Kelly et al. reviewed early outcomes of labral tear debridements in the management of hip injuries in more than 500 athletes reporting good to excellent results in almost 90% of patients.[26] Byrd et al. reported a statistically significant increase in mHHS after arthroscopic labral debridement.[27] A median improvement of 25 points (preoperative, 56 points; postoperative, 81 points) at 10-year follow-up was observed.

Conservative management of labral tears is associated with an accelerated onset of osteoarthritis.[28,29] However, Clegg et al. recommend involving patients in a conservative management program, including physical therapy that involves specific strengthening exercises for the muscles around the hip joint.[23] Additionally, a review of nonsurgical rehabilitation for the treatment of labral tears in athletes has demonstrated a decrease in pain, increase in strength,

increase in function, and return to sport at preinjury levels.[30]

Resolution of clinical scenario

The arthroscopic treatment of intra-articular pathology with debridement and/or repair after traumatic hip dislocations appears to be safe and effective. Arthroscopic treatment significantly improves VAS and mHHS, and may help to stop or slow the progression of hip osteoarthritis. However, the bulk of studies to date include both simple and complex hip dislocations, or do not include traumatic hip dislocations. Long-term studies, including patients with hip dislocations and labral tears treated with hip arthroscopy, are necessary for a more complete evaluation of this technique. Although nonoperative management of acetabular labral tears may alleviate symptoms, the risk of accelerated arthritis may still persist (overall quality: low).

Summary of answers

- When treating a patient with a hip dislocation, based upon moderate-quality evidence, the recommendation is to perform a closed reduction as soon as possible within six hours of the injury to avoid further articular damage and femoral head AVN.
- After hip reduction is achieved, routine use of CT scan may change treatment of patients by increasing the ability to detect intra-articular loose bodies, based upon low-quality evidence.
- For patients with persistent pain or mechanical symptoms after traumatic hip dislocations, MRI may be superior to CT scans and plain radiographs for detecting intra-articular pathology, based upon low-quality evidence.

- Arthroscopic debridement of labral tears appears to be a safe and effective procedure for hip preservation after traumatic hip dislocations but long-term studies are needed. Conservative management of labral tears after hip dislocation may decrease symptoms, but does not appear to reduce the future risk of hip osteoarthritis.

Femoral Head Fractures

Kevin D. Phelps MDJoshua L. Gary MD and Milton Lee "Chip" Routt Jr MD
Department of Orthopaedic Surgery, McGovern Medical School at UTHealth, Houston, TX, USA

Clinical scenario

- A 48-year-old male is involved in a motor vehicle collision.
- Upon presentation he is awake and alert and complains primarily of left hip pain.
- His left lower extremity is flexed, adducted, shortened, and internally rotated.

Top three questions

1. In patients with femoral head fractures, which types benefit from operative intervention more than others?
2. In patients with operatively treated femoral head fractures, does a surgical dislocation utilizing an anterior surgical approach result in improved outcomes compared to the digastric trochanteric flip osteotomy?
3. In patients with femoral head fractures, are there situations in which hip arthroplasty may have improved outcomes compared to open reduction and internal fixation?

Question 1: In patients with femoral head fractures, which types benefit from operative intervention more than others?

Rationale

Although operative reduction and fixation are recommended for most displaced femoral head fractures, the treating physician must know which injury types are best managed nonoperatively. The primary goal of treatment is to achieve/maintain a healed, viable, comfortable, functional, stable, and congruent hip joint.

Clinical comment

Femoral head fractures are uncommon injuries occurring in only 10–15% of native hip dislocations, and are usually due to a high-energy traumatic event such as a head-on motor vehicle collision.[1] The most commonly used classification system is that described by Pipkin, who initially divided femoral head fractures into four types.[2] Type I fractures are those caudal to the fovea capitis, type II fractures are those cephalad to the fovea capitis, type III fractures were those associated with a femoral neck fracture, and type IV fractures were those associated with a fracture of the acetabular rim. The treatment options for displaced femoral head fractures with associated hip joint instability are almost always operative unless the intervention would pose a significant risk to the patient's life. Urgent management should include a prompt and concentric manipulative reduction. Outcomes following femoral head fracture have historically been evaluated using the Thompson and Epstein scale.[3] This system divides the

radiographic outcomes into excellent, good, fair, and poor based on the following criteria:

- Femoral head position.
- Amount of cartilaginous space narrowing.
- Variations in femoral head bone density.
- Subchondral irregularities of the head.
- Acetabular sclerosis.
- Capsular calcification.
- Spur formation.

Available literature and quality of the evidence

High-quality evidence pertaining to the treatment of femoral head fractures is limited due to the low incidence of the injury. Two randomized controlled trials[4,5] (level I) and a systematic review of 29 retrospective studies reporting on 453 femoral head fractures[1] (level II) constitute the best available evidence.

Findings

Chen et al. randomized 24 patients aged 18–60 with suprafoveal Pipkin II fractures to operative versus nonoperative treatment.[4] The operative patients were treated using a Smith-Petersen exposure within 12 hours of injury (without attempted preoperative closed reduction) followed by skin traction for six weeks to restrict hip motion. The nonoperative patients had manipulative closed reductions within 12 hours of injury and were placed in skeletal traction for six weeks. The patients were then followed for a minimum of two years after injury. According to the Thompson and Epstein scoring system,[3] there were two excellent, three good, five fair, and two poor outcomes

in the nonoperative group compared to five excellent, five good, and two fair outcomes in the operative group. One patient in the nonoperative group and five in the operative group developed heterotopic ossification. Two patients developed femoral head aseptic necrosis, both of which were in the nonoperative group. The results from this study concluded that patients with Pipkin type II fractures have improved outcomes when treated operatively.

Lin et al. randomized 36 patients with infrafoveal Pipkin type I fractures into an emergent surgical reduction and fixation group (group one, less than six hours to surgical intervention) and a secondary operative fixation group (group two, closed reduction followed by surgery more than two days after injury).[5] All patients underwent a Smith-Petersen surgical exposure. Patients in group one had 10 excellent, 4 good, 2 moderate, and 2 poor outcomes on the Thompson and Epstein scale compared to 3 excellent, 7 good, 3 moderate, and 5 poor outcomes in group two. Although these data suggest that expeditious treatment of Pipkin I fractures may improve overall clinical outcome, 9 of the 18 patients in group two had a nonconcentric hip after the initial closed reduction due to large fragments interposed in the articular surface. This group of patients had decreased Thompson and Epstein scores and a higher rate of femoral head aseptic necrosis (4/9 in those with a nonanatomic initial reduction compared to 1/9 in those with an anatomic reduction). The study concluded that surgery should be performed on an urgent basis in hips that remain nonconcentric following an emergent closed reduction.

Giannoudis et al. performed a systematic review of 29 retrospective clinical studies involving 453 femoral head fractures.[1] Outcomes data were available for 256 total cases. Criteria noted for conservative treatment included anatomical, concentric closed reduction of the hip

dislocation and femoral head fracture, absence of intra-articular osteochondral fragments, and a stable hip joint. Those patients treated conservatively (54 cases) resulted in 7 (13%) excellent, 16 (29.6%) good, 15 (27.8%) fair, and 16 (26.9%) poor outcomes while those treated operatively (202 cases) resulted in 31 (15.3%) excellent, 92 (45.5%) good, 32 (15.8%) fair, and 47 (23.3%) poor outcomes. Pipkin type I fractures represented the largest percentage of the nonoperative group at 25.3%. Of those Pipkin type I fractures that were managed operatively, 86.7% that had fragment excision had excellent or good results.

Resolution of clinical scenario

- Insufficient evidence exists to make a definitive recommendation regarding nonoperative treatment.
- Infrafoveal (Pipkin type I) fractures that are essentially nondisplaced with concentric hip joints radiographically, which are stable to examination under anesthesia are good candidates for nonoperative management.
- If treated operatively, fragment reduction and fixation is recommended when possible. Fracture fragment excision is performed for stable and concentric Pipkin type I fractures.
- The mainstay of treatment for Pipkin types II, III, and IV injuries is operative to restore a stable and congruent reduction of the hip joint.

Question 2: In patients with operatively treated femoral head fractures, does a surgical dislocation utilizing an anterior surgical approach result in improved outcomes compared to the digastric trochanteric flip osteotomy?

Rationale

The treating surgeon must be familiar with the advantages and disadvantages for each surgical approach when formulating a surgical plan for femoral head fractures.

Clinical comment

The most common surgical approaches for fixation of femoral head fractures include an anterior Smith-Petersen/modified Heuter approach or a posterior digastric trochanteric flip osteotomy, both of which involve surgical dislocation of the hip.[6] More recently, hip arthroscopy has been utilized for certain selected patients.

Available literature and quality of the evidence

One systematic review of 29 retrospective studies (level III),[1] one retrospective case-matched comparison study (level III),[7] and three retrospective studies (level IV) constitute the best available evidence for evaluating an anterior compared to a posterior approach.[15–17] Four studies involving small case series or case reports describe techniques utilizing hip arthroscopy for treatment of femoral head fractures (level IV).[8–11]

Findings

Giannoudis et al. performed a systematic review of 29 retrospective studies involving 453 femoral head fractures.[1] Outcomes data according to the surgical exposure utilized were present in 11 articles for a total of 153 cases. An anterior approach was associated with heterotopic ossification (all Brooker classes) in 17/38 (44.7%) and avascular necrosis (AVN) in 2/38 (5.3%) cases. A Kocher-Langenbeck approach had been reported in several studies and was associated with heterotopic ossification (all Brooker classes) in 21/65 (32.3%) and avascular necrosis in 11/65 (16.9%) cases. With the digastric trochanteric-flip osteotomy 17/36 (47.2%) developed heterotopic ossification (all Brooker classes) and 3/36 (8.3%) developed AVN. They found that there was a 1.87 times higher incidence of heterotopic ossification after a trochanteric-flip osteotomy when compared to a posterior approach (did not reach significance). The authors did not quantify what percentage of those patients with heterotopic ossification with each approach was actually symptomatic. The likelihood of AVN was 3.67 and 2.24 times higher when using a posterior approach compared to a trochanteric-flip osteotomy or anterior approach (did not reach significance). Post-traumatic arthritis was more common when using an anterior (20.3 times, $p = 0.04$) or posterior approach (30.6 times, $p = 0.018$) compared to a trochanteric osteotomy.

Four studies reported complications unique to the digastric trochanteric flip osteotomy.[6,12–14] Out of a total of 306 reported patients that underwent a trochanteric osteotomy (with or without a surgical dislocation), six (2.0%) patients had persistent pain at the site of fixation requiring screw removal, while four (1.3%) had fixation failure and/or nonunion at the site of the osteotomy.

In a case matched comparison of Smith-Petersen (12 patients) versus Kocher-Langenbeck approaches (12 patients) for Pipkin I and II femoral head fractures, Swiontkowski et al. found that the Kocher-Langenbeck approach was often associated with limited visualization of fracture fragments.[7] Three patients in this group developed heterotopic ossification and two developed AVN compared to seven with heterotopic ossification and none with AVN in the Smith-Petersen group. Eight of 12 patients in both groups had good or excellent results.

In the largest retrospective study to date by Scolaro et al. evaluating the outcomes of 78 operatively treated patients, 76 (97%) were treated with a Smith-Petersen approach.[15] Their overall results demonstrated a femoral head union rate of 89.9%. Six patients (9%) developed AVN, while heterotopic ossification developed in 28 (40.6%). Of the 28 patients that developed heterotopic ossification, 17 (60%) were Brooker class I, four (14%) were Brooker class II, four (14%) were Brooker class III, and three (10%) were Brooker class IV. Only two patients required a return to the operating room for heterotopic ossification excision.

Two other clinical manuscripts evaluated the outcomes of the digastric trochanteric flip osteotomy in 25 total patients.[16,17] Solberg et al. looked specifically at 12 patients with Pipkin type IV injuries.[17] Outcomes with the Thompson and Epstein scoring scale involved 10 with good or excellent outcomes, 1 with a fair outcome, and 1 with a poor outcome. Eleven of the femoral head fractures healed, one developed AVN, and four patients developed heterotopic ossification (three with Brooker class II and one with Brooker class III). There was no group for comparison in this study.

Masse et al. reported on 13 patients with femoral head fractures (five Pipkin I, two Pipkin II, six Pipkin IV).[16] This

cohort included eight patients with anatomic hips and five with imperfect hips according to the Matta radiographic criteria.[18] The mean Harris Hip Score at minimum follow-up of two years was 82.[19,20] One patient developed AVN and two others developed asymptomatic heterotopic ossification.

Four studies report on seven patients treated with arthroscopic reduction and fixation of a femoral head fracture.[8–11] No objective outcomes data are available, although the patients were reported to do well postoperatively.

Resolution of clinical scenario

- The chosen approach should be based on fracture morphology, size, and the presence of an ipsilateral acetabular fracture.
- The Smith-Petersen surgical exposure is most commonly used because it allows an anterior surgical hip dislocation with complete visualization of the femoral head fracture, but may be associated with higher rates of heterotopic ossification formation.
- The Kocher-Langenbeck surgical exposure is not recommended for the majority of femoral head fractures because direct visualization of the anterior femoral head fracture is not possible, and it has been associated with higher rates of aseptic necrosis. This exposure can be used to operatively reduce and stabilize an associated unstable posterior wall acetabular fracture.
- The digastric trochanteric flip osteotomy is advocated for those patients with unstable posterior wall acetabular fractures and femoral head fractures.

- A recommendation for or against hip arthroscopy cannot be made based on the current evidence.

Question 3: In patients with femoral head fractures, are there situations in which hip arthroplasty may have improved outcomes compared to open reduction and internal fixation?

Rationale

Femoral head fractures have variable outcomes based on Pipkin classification, as certain fracture types are associated with high complication rates. Therefore, there may be a subset of this patient population that would be better managed with acute hip arthroplasty.

Clinical comment

Outcomes following femoral head fractures are variable depending on the type of fracture and can be devastating for the native hip if AVN occurs. This complication seems to most often occur in Pipkin type III fractures, which also involve a fracture of the femoral neck. Although most young, healthy patients should typically receive attempted operative fixation following femoral head fractures when surgical indications are met, this specific subset may have better outcomes if treated primarily with hip arthroplasty.

Available literature and quality of the evidence

One systematic review of 29 retrospective studies (level III)[1] and two large retrospective case series (level IV).[15,21]

Findings

In the systematic review by Giannoudis et al.,[1] outcomes data according to the Thompson-Epstein criteria were available in a total of 18 articles involving 291 femoral head fractures. Overall, outcomes were found to be excellent in 14.3% of cases, good in 39.8%, fair in 19.3%, and poor in 26.5%. Data from 26 articles involving 405 femoral head fractures showed an overall AVN rate of 11.8%, post-traumatic arthritis in 20%, and heterotopic ossification in 16.8%. This systematic review did not find any significant difference in outcomes among Pipkin subtypes but did note a nearly significant difference when Pipkin types I and II were compared to Pipkin types III and IV ($p = 0.057$). Functional outcomes were available in 11 articles reporting on 155 fractures. Thompson and Epstein scores according to Pipkin subtypes were:

- Pipkin I (n = 34): 5 (14.7%) excellent, 17 (50%) good, 8 (23.5%) fair, 4 (11.8%) poor.
- Pipkin II (n = 56): 14 (25%) excellent, 27 (48.2%) good, 6 (10.7%) fair, 9 (16.1%) poor.
- Pipkin III (n = 8): 0 excellent, 4 (50%) good, 2 (25%) fair, 2 (25%) poor.
- Pipkin IV (n = 57): 9 (15.8%) excellent, 21 (36.8%) good, 8 (14%) fair, 19 (33.3%) poor.

Tonetti et al. performed a retrospective study of 110 patients with femoral head fractures, 78 of which were treated operatively.[21] They reported specifically on rates of conversion to total hip arthroplasty as the primary outcome measure. They found that only Pipkin III fractures were predictive of conversion to total hip arthroplasty. There were a total of four in their study, one of which underwent primary arthroplasty, while the other three underwent secondary arthroplasty following failure of initial

treatment. In their series of 78 operatively treated Pipkin fractures, Scolaro et al. noted a 100% failure rate in Pipkin III fractures (five patients) of the femoral head and also suggested that arthroplasty should be strongly considered as an initial treatment option.[15]

Resolution of clinical scenario

- Strong consideration should be given to primary total hip arthroplasty in Pipkin type III fractures in all adult patients due to high failure rates of open reduction and internal fixation (ORIF).
- For older patients with injuries that need operative treatment, primary total hip arthroplasty may be considered.

Summary of answers

- Insufficient evidence exists to make a definitive recommendation regarding nonoperative treatment.
- Infrafoveal (Pipkin type I) fractures that are essentially nondisplaced with concentric hip joints radiographically, and are stable to examination under anesthesia are good candidates for nonoperative management.
- If treated operatively, fragment excision can be considered in Pipkin type I fractures that are congruent and stable following fragment excision. If instability is identified following fragment excision, the surgeon should fix the femoral head fragment.
- Displaced and unstable Pipkin types II, III, and IV injuries warrant operative treatment.

- Selection of the proper surgical exposure should be based on the fracture morphology and the presence of an associated ipsilateral unstable acetabular fracture.
- The Smith-Petersen surgical exposure is most commonly used but may be associated with a higher incidence of heterotopic ossification.
- The Kocher-Langenbeck is not recommended for femoral head fractures because direct visualization of the anterior femoral head fracture is not possible and it has been associated with higher rates of aseptic necrosis.
- A recommendation for or against hip arthroscopy cannot be made based on the current evidence.
- Strong consideration should be given to primary total hip arthroplasty in Pipkin type III fractures, especially in elderly patients.

Femoral Neck Fractures in Younger Patients

Malynda Wynn MD, Trevor Gulbrandsen MD, Michael Willey MD, and Matthew Hogue MD
Department of Orthopedics and Rehabilitation, University of Iowa Hospital and Clinics, Iowa City, IA, USA

Clinical scenario

- A 26-year-old healthy, nonsmoking male presents to the Emergency Department after a five-foot fall off a trailer.
- Initial radiographs demonstrate a displaced femoral neck fracture (Figure 95.1). On exam the patient's affected hip is flexed, externally rotated, and neurovascularly intact.
- He was treated with open reduction and internal fixation (ORIF) with a sliding hip screw (SHS) four hours after initial injury (Figure 95.2). The patient demonstrates appropriate healing and maintenance of fixation at six-month follow-up (Figure 95.3).

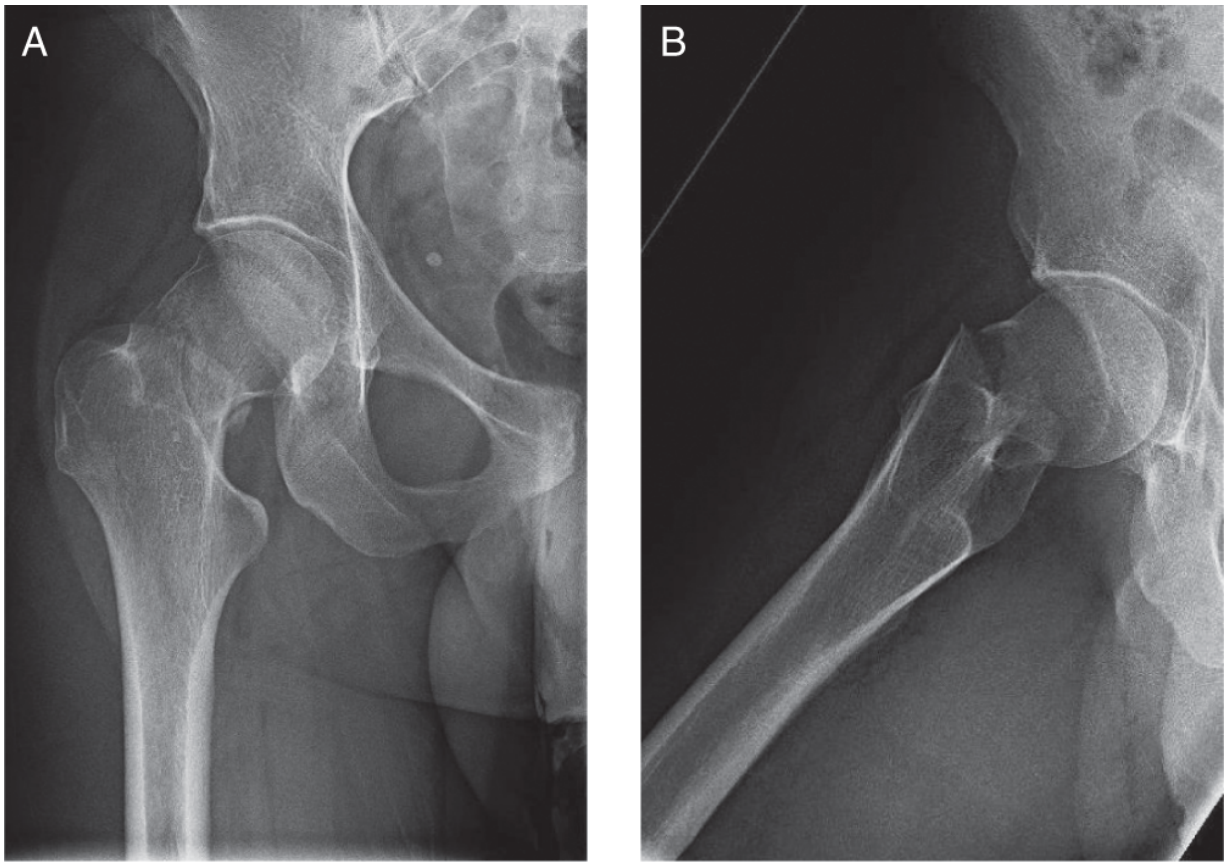

Figure 95.1 Radiographs on presentation showing right femoral neck fracture: (A) AP right hip; (B) lateral right hip.

Top three questions

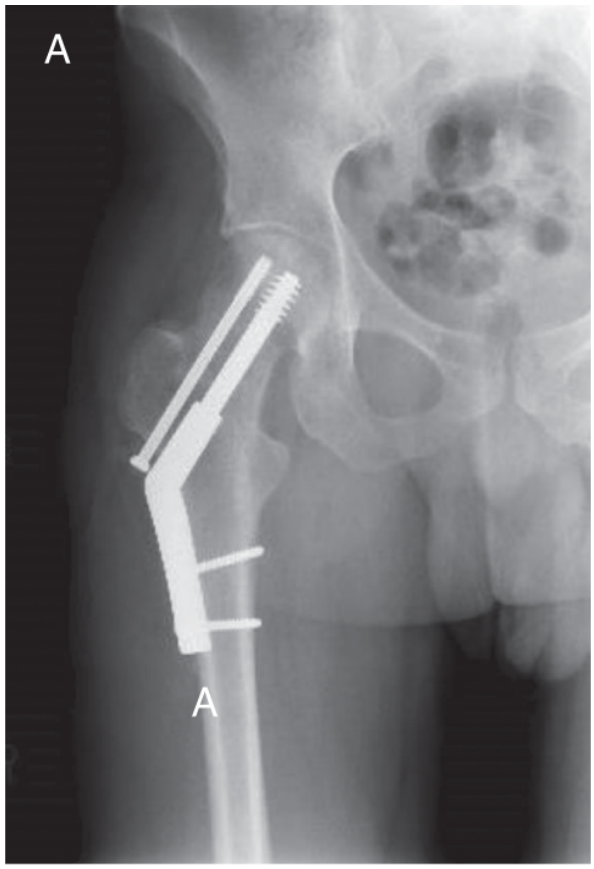
1. In young adult patients with displaced femoral neck fractures, does time to surgery of <6 hours result in lower rates of avascular necrosis (AVN) compared to surgery performed 6–24 hours from injury?
2. In young adult patients with displaced femoral neck fractures, does treatment with open reduction provide superior outcomes compared to treatment with closed reduction?
3. In young adult patients with displaced femoral neck fractures, does implant choice of cannulated screws

(CS) result in higher complication rates when compared to an SHS?

Question 1: In young adult patients with displaced femoral neck fractures, does time to surgery of <6 hours result in lower rates of avascular necrosis (AVN) compared to surgery performed 6–24 hours from injury?

Rationale

Urgent or emergent reduction and fixation of displaced femoral neck fractures has been postulated to decrease postoperative rates of AVN of the femoral head. Optimal timing of intervention is an ongoing debate.



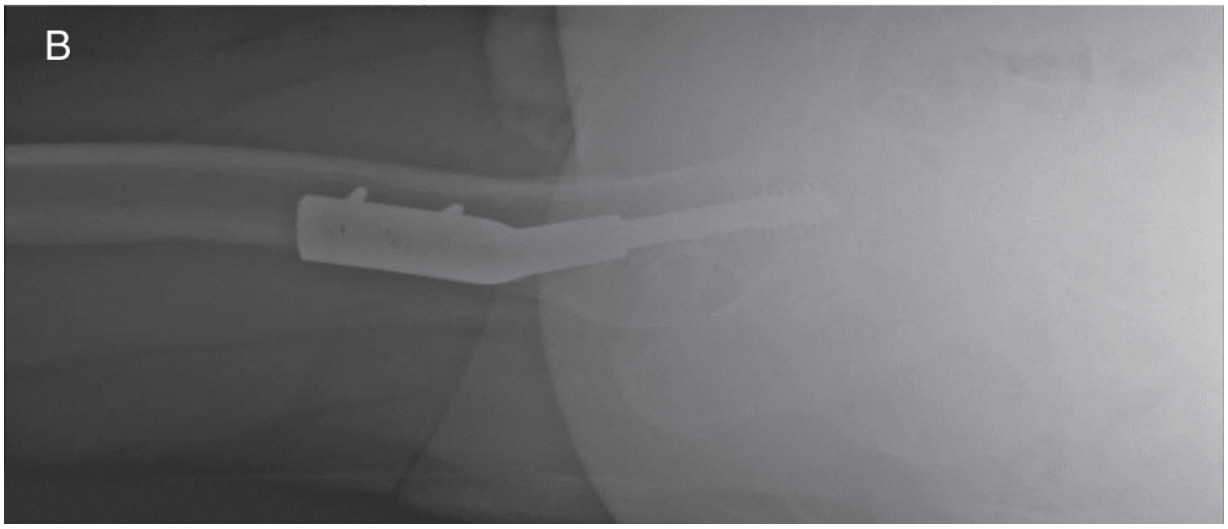


Figure 95.2 Postoperative open reduction and internal fixation with a sliding hip screw and anti-rotational screw: (A) AP right hip; (B) lateral right hip.

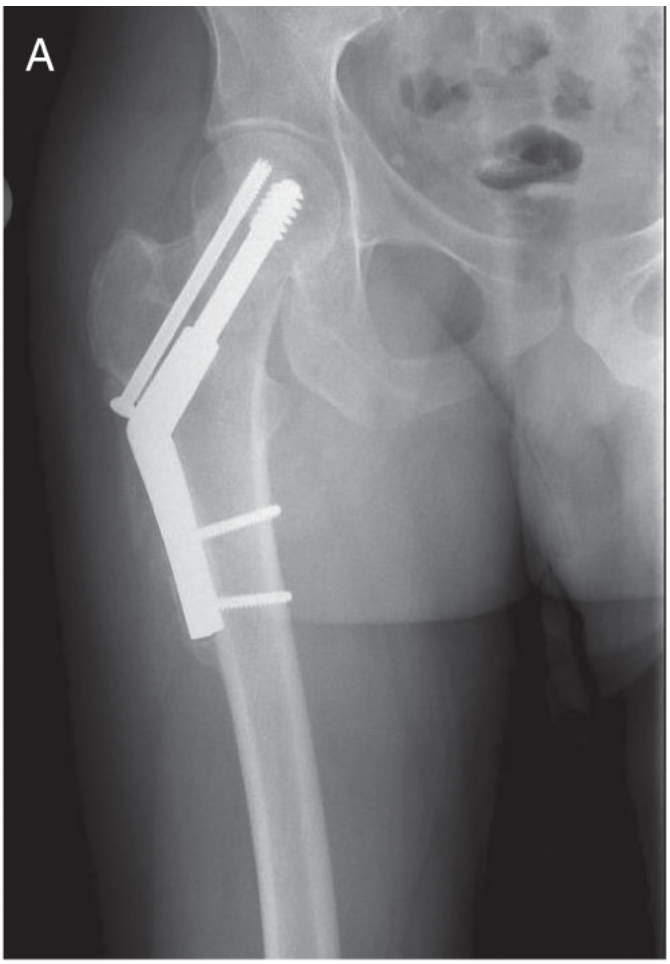
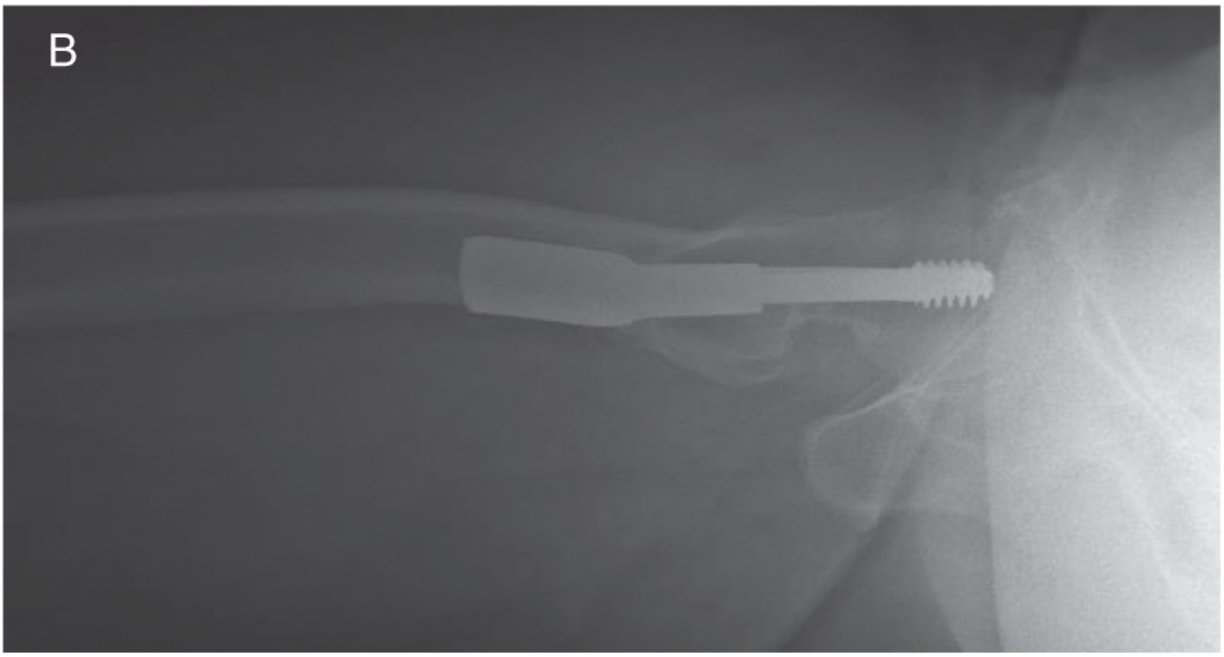


A



B

Figure 95.3 Six-month follow-up demonstrating interval healing and maintained reduction: (A) AP right hip; (B) lateral right hip.

Clinical comment

Proper management of displaced femoral neck fractures in young adult patients remains controversial. Treatment is associated with historically high complication rates including AVN, malunion, nonunion, and implant failure.[1–4] With the treatment goal being joint preservation, the most feared complication is AVN of the femoral head. Efforts have been made to reduce and stabilize the fracture in an urgent or emergent fashion to decrease this risk. However, there are currently no studies that can support the routine practice of emergent (<6 hours) surgical fixation in these patients.

Available literature and quality of the evidence

There is a lack of literature investigating optimal timing of fixation in young adult patients with femoral neck fractures. Recent literature includes a level I prospective randomized study comparing outcomes and complications in young patients with displaced femoral neck fractures.[5] Additionally, there is one retrospective cohort and one meta-analysis (level II), which both analyze the correlation of time to fixation with rates of AVN.[6,7]

Findings

Upadhyay and colleagues performed a prospective randomized multicenter study on 92 patients with Garden grades III and IV femoral neck fractures.[5] Patients aged 15–50 years who underwent closed or open reduction with internal fixation were followed clinically and radiographically for two years. Secondary measures

included risk factors affecting the development of AVN and nonunion. Forty-two patients had a delay of femoral neck fixation of >48 hours, and 15 femoral heads developed AVN. Of the 16 femoral necks that developed nonunion, 7 (43.8%) consisted of a delay of fixation of >48 hours (odds ratio [OR] = 1.37; 95% confidence interval [CI]: 0.20–9.50). They concluded that no factors investigated, including time of surgery, increased the risk of developing AVN.[5]

Razik et al. performed a retrospective study investigating effect of time delay to fixation in patients with femoral neck fractures.[6] Patients underwent fixation with either SHS, CS, or SHS with a de-rotation screw. Ninety-two patients under the age of 60 followed for a mean of two years were retrospectively analyzed. Time to fixation was divided into intervals including ≤ 6 hours, 6–12 hours, 12–18 hours, 18–24 hours, 24–48 hours, and >48 hours. The percentage of patients who developed AVN was 14.1%. Two had nondisplaced fractures and 11 had displaced fractures. Utilizing a binary logistic regression model, incidence of AVN did not increase significantly past the six-hour time to surgery interval, with no significant difference demonstrated between time intervals and rate of AVN.[6]

A meta-analysis performed by Papakostidis et al. reported on timing of internal fixation of femoral neck fractures.[7] Out of 492 studies that investigated outcomes of acute femoral neck fractures, seven met final inclusion criteria and six consisted of young adult patients. A meta-analysis was performed to compare time of internal fixation with rates of AVN and nonunion. Groups included fixation within six hours versus fixation after six hours, fixation within 12 hours versus fixation after 12 hours, fixation within 24 hours versus fixation after 24 hours, and fixation within 6 hours versus fixation after 24 hours. There was no association between AVN and any time interval. However,

the odds of nonunion tripled with patients who underwent internal fixation after 24 hours ($p = 0.004$).[7]

Resolution of clinical scenario

- In young patients with a femoral neck fracture, time to fixation may not be as crucial as previously thought.
- In young patients with a femoral neck fracture, time to fixation even >24 hours from injury has not been shown to increase the risk of AVN.
- Other factors should be considered to minimize complications including optimal operative environment and fixation method.

Question 2: In young adult patients with displaced femoral neck fractures, does treatment with open reduction provide superior outcomes compared to treatment with closed reduction?

Rationale

No standard of care exists regarding closed versus open reduction of femoral neck fractures. These fractures can be difficult to reduce and have high rates of osteonecrosis and nonunion if not reduced acceptably; for this reason, controversy remains regarding the best method of reduction.

Clinical comment

In the treatment of displaced femoral neck fractures in young patients, obtaining an anatomic reduction is

paramount, as a poorly reduced fracture is a major risk factor for nonunion and AVN.[5,8] While open reduction most easily facilitates anatomic fracture reduction, a closed reduction using fluoroscopy can often lead to a radiographically acceptable result without the need for direct open exposure. This leads to less invasive surgery, improved postoperative recovery, and results in indirect cost reduction.[9] Given that no consensus opinion exists on which method is superior, it is important to explore risks, benefits, and outcomes associated with each reduction method.

Available literature and quality of the evidence

Current literature includes a meta-analysis (level I) of closed versus open reduction investigating rates of union and AVN between reduction methods.[10] There is also a prospective, randomized study (level I)[5] and multicenter retrospective cohort study (level III)[11] comparing the results and complications between closed and open reduction in young adults with displaced femoral neck fractures.

Findings

A meta-analysis performed by Ghayoumi et al. investigated outcomes including nonunion, AVN, and deep infection after treatment of femoral neck fractures with ORIF or closed reduction with internal fixation (CRIF) in patients 50 years old or younger.[10] Twenty-one studies were included in the analysis. The incidence of nonunion and AVN was not found to be statistically significant between ORIF and CRIF ($p = 0.25$, 0.91, respectively). Incidence of deep wound infection was found to be higher in the ORIF patients compared to CRIF ($p = 0.0019$).[10] However, it is important to note possible bias in the included studies. Treating

surgeons are likely to perform closed reduction on minimally displaced fractures, which would likely go on to do well regardless of approach. Similarly, fractures with high degrees of displacement, which are more likely to do poorly, are more often treated with an open approach.

In a prospective, randomized study by Upadhyay et al., results and complications were compared after closed and open reduction with internal fixation in young adults with Garden grades III and IV femoral neck fractures.[5] Secondary outcomes included risk factors which influenced nonunion and development of AVN. There were 102 patients between 15 and 50 years who were randomized to receive closed or open reduction. There was no significant difference between fixation methods in union ($p = 0.93$) or AVN at two years ($p = 0.85$). Posterior comminution, poor reduction, and improper placement of the screws were the major risk factors which contributed to nonunion; however, incidence of AVN was not found to be influenced by these risk factors.[5]

A multicenter retrospective cohort study by Ishii et al. investigated 239 patients from 13 academic institutions that were treated with ORIF versus CRIF for OTA 31-B2 (femoral neck) or 31-B3 (basicervical) fractures with a minimum of six-month follow-up.[11] Primary outcome was reoperation with secondary outcomes including nonunion, malunion, AVN, infection, osteoarthritis, heterotopic ossification, and fracture fixation failure. There was no statistically significant difference in total reoperation rate between ORIF and CRIF (37.3% vs 27.4%, $p = 0.14$), although ORIF patients did show a higher incidence of reoperation due to nonunion when compared to CRIF patients (16.7% vs 5.3%, $p = 0.01$). Incidence of AVN (18.5% vs 8.7%) and post-traumatic osteoarthritis (12% vs 3.8%) was higher in the CRIF versus ORIF group ($p =$

0.034 and 0.027, respectively). When comparing the cohorts, CRIF patients were older, had more co-morbidities, and were more likely to have sustained OTA type B3 (displaced subcapital) injuries, while ORIF patients were more likely to have Pauwels type III injuries and coincident femoral shaft fractures.[11]

Resolution of clinical scenario

- In young adult patients with a displaced femoral neck fracture, open reduction has not been shown to decrease the risk of nonunion or AVN.
- Poor reduction of a displaced femoral neck fracture in a young patient, achieved by either open or closed reduction, is a risk factor for nonunion and poor outcome.
- Closed reduction and internal fixation will decrease overall risk of deep wound infection compared with open reduction.

Question 3: In young adult patients with displaced femoral neck fractures, does implant choice of cannulated screws (CS) result in higher complication rates when compared to an SHS?

Rationale

Controversy exists regarding the ideal implant for treatment of young patients with displaced femoral neck fractures. The two most commonly used devices are partially threaded 6.5 or 7.3 mm CS in an inverted triangle

configuration, and an SHS device with or without a de-rotational screw. The CS implant provides rotational control and are less invasive to perform, while the SHS provides axial compression along a fixed angle support. No consensus currently exists regarding which implant configuration is superior.

Clinical comment

Many young adult femoral neck fractures can undergo fixation with three cancellous screws in an inverted triangle formation with perpendicular placement to the fracture line. Proponents for this type of fixation reason that the orientation of three CS allows rotational stability while resulting in less bone loss than SHS if revision is required.

Significantly displaced femoral neck fractures are more controversial when considering fixation due to the degree of displacement and the desire for fixed angle support. Fixation with an SHS versus three CS has been shown to result in less inferior femoral head displacement, less shearing displacement, and greater load to failure in short-term follow-up studies.[12,13] While the fixed-angle SHS has been shown to be biomechanically superior to CS, this advantage is not demonstrated in current clinical studies.[12–15]

Available literature and quality of the evidence

There are two prospective randomized controlled trials (RCTs; level I) comparing fixation methods for nondisplaced femoral neck fractures. It is worth noting that patient population age was over 50 years in the FAITH trial.[16,17] Current literature beyond this is limited to retrospective cohort review studies (level III) comparing

outcomes of fixation methods for both nondisplaced and displaced young femoral neck fractures.[12]

Findings

In a prospective, international, multicenter, RCT by Nauth et al., known as the FAITH trial, 1108 patients with nondisplaced femoral neck fractures were recruited over six years.[16] Each patient was randomized to receive CS or SHS fixation and were followed up to two years postoperatively. Primary outcome was hip reoperation within 24 months after initial surgery. Analyses followed the intention-to-treat principle. AVN was more common in the SHS group compared to CS group (9% vs 5%; 95% CI: 1.06–3.44; p = 0.0319). Hip reoperation within 24 months did not demonstrate a statistically significant difference between methods of fixation (20% vs 22%; 95% CI: 0.63–1.09; p = 0.18). Similarly, nonunion rate, implant failures, infections, fracture shortening, and fracture healing did not show a statistically significant difference between surgical fixation method. Sub-group analyses favored SHS in patients with displaced fractures, fractures at the base of the femoral neck, and in those who were current smokers.[16]

In a second RCT by Siavashi et al., 58 patients with Garden type III or IV femoral neck fractures were randomized to receive CS or SHS treatment with minimum follow-up of one year evaluating union, AVN, infection rate, with clinical outcomes including Harris Hip Score (HHS).[17] There was a total of five (18%) versus zero patients that experienced reduction and fixation failures in the CS versus SHS treatment group (p <0.001). The patients who received CS fixation had statistically significant lower HHS outcomes compared to SHS (p <0.01). There was no statistically

significant difference between the rate of AVN and infection.

In a retrospective study by Gardner et al., early failure rates of SHS and CS constructs were evaluated in 68 patients aged <60 years. Primary aim was to compare rate of fixation loss in younger patients with displaced femoral neck fractures treated with either SHS or CS constructs.[12] A secondary aim was to identify risk factors associated with early or late fixation failure, AVN, or nonunion. Univariate comparisons suggested that CS fixation is associated with a significantly higher early fixation failure rate compared to SHS (21% vs 3%, p = 0.04). All early failures in the CS group were of intermediate verticality and were classified as Pauwels type II fractures. There was no significant difference between the two groups in nonunion rate (p = 0.39) and symptomatic AVN (p = 0.69).

Resolution of clinical scenario

- Nondisplaced femoral neck fractures treated with CS fixation provide a rotationally stable construct with less bony loss compared to SHS.
- Displaced femoral neck fractures treated with SHS fixation have shown lower rates of reduction loss and fixation failure when compared to CS.
- There is conflicting literature regarding complication rates in displaced femoral neck fractures treated with SHS versus CS. However, recent randomized controlled data suggest there is a higher rate of osteonecrosis in patients treated with SHS.

Summary of answers

- When treating femoral neck fractures in young patients, the current body of literature does not support emergent (<6 hours) fixation compared to fixation within 24 hours.
- Open versus closed reduction of a young femoral neck fracture should be based on fracture morphology with the goal being anatomic reduction. There are benefits to closed reduction; however, a closed reduction should not be performed at the cost of an acceptable reduction.
- SHS and CS fixation for young femoral neck fractures are both currently acceptable implant options, and there are pros and cons to both fixation methods.

Femoral Neck Fractures in the Elderly

Dylan McCreary BA, Brian P. Cunningham MD, and Marc Swiontkowski MD
Department of Surgery, University of Minnesota, Minneapolis, MN, USA

Clinical scenario

- You see a 71-year-old male patient who is a community ambulator and slipped while shoveling his driveway after a snowstorm. He was transported to the Emergency Department by emergency medical services. He is unable to bear weight. On examination, his right leg is shortened and externally rotated. He is neurovascularly intact.
- The patient's x-ray reveals a displaced femoral neck fracture (Garden type IV). You present treatment options to your patient: arthroplasty or internal fixation.

Top three questions

1. In patients over the age of 65 undergoing treatment of a displaced femoral neck fracture, does arthroplasty result in decreased mortality and re-operation rates compared to internal fixation?
2. In patients over the age of 65 undergoing internal fixation for a displaced femoral neck fracture, does use of cancellous screws result in reduced risk of

complications and re-operation compared to sliding hip screws (SHSs)?

3. In patients over the age of 65 undergoing arthroplasty for a displaced femoral neck fracture, does use of total hip arthroplasty (THA) result in decreased complications and improved outcomes compared to hemiarthroplasty?

Question 1: In patients over the age of 65 undergoing treatment of a displaced femoral neck fracture, does arthroplasty result in decreased mortality and re-operation rates compared to internal fixation?

Rationale

Maintaining the patient's original hip with a fixation device versus removing the femoral head and replacing the hip with a prosthesis has important implications for outcome and function. Current opinion is highly divergent among orthopedic surgeons on whether to fix or replace the hip.

Clinical comment

The disability adjusted life-years lost as a result of hip fractures ranks in the top 10 of all cause disability globally. Over 4.5 million persons sustain hip fractures around the world each year. By the year 2040, the number of people aged 65 or older will increase from 34.8 million to 77.2 million. The number of hip fractures is likely to exceed 500 000 annually in the United States and 88 000 in Canada over the next 40 years.[1–4] Hip fractures are associated with a 21% mortality rate at one year and

profound temporary, and sometimes permanent, impairment of independence, and quality of life.[5] Furthermore, approximately 30% of surgically treated hip fractures require revision surgery.[6] These revisions are associated with a large burden of morbidity and mortality. Arthroplasty has the potential to achieve reduced re-operation and mortality.

Available literature and quality of the evidence

Multiple randomized controlled trials (RCTs) have investigated the difference in mortality and re-operation rate between internal fixation and arthroplasty for displaced femoral neck fractures in patients over the age of 65. The most relevant literature consisted of a systematic review of the literature and meta-analysis (level I evidence).

Findings

In 2003, Bhandari et al. reported the results of a meta-analysis of 14 randomized trials comparing outcomes of internal fixation and arthroplasty (level I).[7] Nine trials (n = 1162 patients) provided postoperative mortality data at four months or less, twelve trials (n = 1767) provided one-year mortality data, and all 14 trials (n = 1901) provided information on revision surgeries. They found no difference in the risk of mortality between arthroplasty and internal fixation, but did find that arthroplasty was associated with significantly lower risk of revision and the results were consistent study to study (risk ratio [RR] = 0.23; 95% confidence interval [CI]: 0.13–0.42). Information on secondary outcomes of pain, function, and infection rate was available for some studies. Information on secondary outcomes was available for six studies (n = 1153 patients) reporting on pain relief and 12 on function (n = 1179

patients). Pain relief and function were similar in patients treated with arthroplasty or internal fixation (RR of no/little pain 1.12; 95% CI: 0.88–1.35 and good function 0.99; 95% CI: 0.90–1.10). Arthroplasty significantly increased the risk of infection (12 studies, n = 1822) compared to internal fixation (RR = 1.81; 95% CI: 1.16–2.85, p = 0.009, homogeneity p = 0.16). The risk difference between the two treatments was 3.4%. This meant that for every 29 patients treated with internal fixation one infection could be prevented (number needed to treat [NNT] = 1/0.034 = 29.4). Relatively fewer data were available for secondary outcomes of blood loss and surgical time. Four studies (n = 343 patients) reported on estimated blood loss, and five (n = 447 patients) and surgical time. Patients who underwent arthroplasty experienced greater blood loss than those who were treated with internal fixation (weighted mean difference = 176.4 mL; 95% CI: 132.4–220.4, p <0.05). Similarly, surgical time in the arthroplasty-treated patients was greater than the patients treated with internal fixation (weighted mean difference = 29.0 minutes; 95% CI: 23.2–34.8, p <0.05).

Overall, level I evidence suggests that arthroplasty is associated with significantly lower risk of re-operation compared to internal fixation, but there is no difference in risk or mortality.[7] Additionally, arthroplasty was associated with significantly greater blood loss, operative time, and risk of infection. There are limitations to these data though as they lacked the power to demonstrate whether there was an increased risk of mortality with arthroplasty. The review did raise a possible concern for increased risk of early mortality (relative risk of death at four months 1.27); however, this was not statistically significant.

Resolution of clinical scenario

- Level I evidence suggests that arthroplasty *does* significantly reduce the risk of revision surgery at one year compared to internal fixation.
- Level I evidence suggests arthroplasty *does not* result in significantly different risk of mortality at one year compared to internal fixation.
- Level I evidence suggests arthroplasty *does* significantly increase the risk of infection, blood loss, and operative time at one year compared to internal fixation.

Question 2: In patients over the age of 65 undergoing internal fixation for a displaced femoral neck fracture, does use of cancellous screws result in reduced risk of complications and re-operation compared to sliding hip screws (SHSs)?

Rationale

As much of the focus in the literature is concerned with comparing internal fixation to arthroplasty, what is less well understood is which method of fixation generates superior results. It is suggested that bias in certain study designs has caused outcomes for arthroplasty to fair better. For this reason, internal fixation cannot be overruled and further scrutiny of fixation methods are in order.[8]

Clinical comment

The literature has demonstrated that the most critical component to avoiding complication in femoral neck

fracture fixation is the quality of reduction. An optimal reduction far outweighs implant choice and it is our preference to perform an open reduction of all displaced femoral neck fractures that undergo internal fixation. With nondisplaced fractures, current opinion suggests that the majority of surgeons are using internal fixation with cancellous screws. When internal fixation is chosen for displaced fractures, SHS shows a reduced risk of re-operation.[9] It is important to understand the relative risks of complications, such as avascular necrosis (AVN), and re-operation to determine the optimal fixation method for patients; however, the quality of reduction must be the surgeons primary focus.

Available literature and quality of the evidence

Multiple RCTs have compared the use of SHSs and cancellous screws for fixation of displaced femoral neck fractures; however, many current studies lack methodological rigor. The most relevant current literature consisted of: (i) a systematic review of the literature with meta-analysis (level I evidence), (ii) a Cochrane review of the literature (level I evidence), and (iii) an international, multicenter, RCT (level I evidence).

Findings

A review from 2009 by Bhandari et al. summarized the results from four randomized trials (n = 516 patients) comparing SHSs to cancellous screws for fixation of displaced femoral neck fractures (level I).[8] They found no statistically significant difference in revision surgery using SHSs compared to cancellous screws (relative risk ratio [RRR] = 27%; 95% CI: 48 to −4). Similarly, a Cochrane review of internal fixation (using screws, pins and/or plates) in intracapsular hip fractures included 28 trials (n =

5547) (level I).[10] The authors concluded that due to the variability in study designs, outcomes, lack of methodological rigor, and small sample sizes no definitive statements could be made to support the use of certain types or methods of fixation over others. Pooled results from five trials (n = 565 patients) comparing SHS to cancellous screws showed that point estimates for AVN favor SHSs (RR = 0.62; 95% CI: 0.38–1.01). An international, multicenter, RCT by Bhandari et al. suggested SHSs reduced re-operations in patients with displaced fractures compared to cancellous screw fixation (re-operation 43/179 with SHS vs 57/167 with cancellous screws; hazard ratio [HR] = 0.57; 95% CI: 0.38–0.87) (level I).[9]

Overall, current studies comparing different implants for fixation of femoral neck fractures lack methodological rigor. While several studies did find significant results for certain outcomes, these results are questionable due to the multiple analyses performed. SHSs may reduce re-operations in patients with displaced fractures (level I).[8,10] SHSs have a tendency toward increased rates of AVN compared to cancellous screws (level I).[9]

Resolution of clinical scenario

- Current studies comparing different implants for fixation of femoral neck fractures lack methodological rigor. SHSs *may* reduce re-operations in patients with displaced fractures.
- Level I evidence suggests SHSs have a tendency toward *increased* rates of AVN compared to cancellous screws.

Question 3: In patients over the age of 65 undergoing arthroplasty for a displaced femoral neck fracture, does use of total hip arthroplasty (THA) result in decreased complications and improved outcomes compared to hemiarthroplasty?

Rationale

In making operative decisions about arthroplasty, it is important, for example, to know whether bipolar compared to unipolar hemiarthroplasty does in fact decrease acetabular wear and improve function. Also, what patient and implant risk factors should be considered when choosing between hemiarthroplasty and THA?

Clinical comment

Once arthroplasty has been chosen, it is important to select the technique that is most appropriate for the patient's age and functional status. Pre-existing hip pain and radiographic evidence of osteoarthritis has been an indication for THA. Determining the activity threshold when deciding between THA and hemiarthroplasty is nuanced, with the goal to avoid a second procedure in the future. THA is generally considered a better option for patients who are active and capable of following postoperative instructions. Hemiarthroplasty is more optimal for patients with limited demands or cognitive impairment due to the lower risk of hip dislocation compared with THA.

Available literature and quality of the evidence

Multiple systematic reviews are available to answer questions about arthroplasty in femoral neck fracture treatment. The most relevant current literature consisted of: (i) a Cochrane review of the literature (level I), (ii) another Cochrane review of current studies (level I), (iii) a meta-analysis of published RCTs (level I evidence), and (iv) a recently published large RCT (level I).

Findings

A Cochrane review of 19 trials (n = 2115) of arthroplasties in hip fractures provided the highest level of evidence (level I).[11] Two trials (n = 232 patients) compared uncemented hemiarthroplasty to THA. They found no difference in dislocation, re-operation, or failure to regain mobility. Additionally, one trial (n = 180 patients) found no difference in early mortality (3–4 months) or late mortality (one year). One trial (n = 135) did find a significant increase in postoperative residual pain following hemiarthroplasty compared to THA (RR = 34.91; 95% CI: 2.15–565.58). This trial compared the Austin Moore hemiarthroplasty to THA. A study by Ravikumar et al. (level I) also reported high rates of pain in patients with the Moore implant (27% at 1 year; 45% at 13 years) compared to hemiarthroplasty (0% at 1 year; 6% at 13 years).[12] The Austin Moore prosthesis was introduced in the 1950s as a monoblock cementless option for femoral neck fractures. With a lack of modularity as well as neither a fit and fill or wedge taper, the implant has had poor long-term results with thigh pain and loosening frequently reported. Cemented hemiarthroplasty was compared to THA in four trials (n = 415 patients).[11] They found significantly reduced rates of dislocation and minor re-operation associated with hemiarthroplasty compared to THA. A second Cochrane review of seven trials (n = 734) compared hemiarthroplasty to THA (level I).[13] They found similarly that

hemiarthroplasty was associated with lower risk of dislocation and minor re-operation compared to THA. Another meta-analysis from 2014 by Liu et al. summarized nine trials (n = 1100 patients) comparing unipolar and bipolar hemiarthroplasty (level I).[14] They found no difference in risk of complications, acetabular erosion, return to function, or mortality. Six clinical trials (n = 549 patients) compared cemented to uncemented arthroplasty in adults with hip fractures. The results revealed decreased risk of pain (RR = 0.51; 95% CI: 0.31–0.81) and failure to regain mobility (RR = 0.60; 95% CI: 0.44–0.82, respectively) in the cemented group. The Hip Fracture Evaluation with Alternatives of Total Hip Arthroplasty versus Hemi-arthroplasty (HEALTH) trial randomized 1495 patients to THA or HA and followed them for two years. They found no significant difference in the primary outcome of revision surgery (HR: 0.95; 95% CI: 0.64–1.40, p = 0.79). Patients in the THA group had significantly better function scores as measured on the Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC), though the difference was modest (mean difference = −6.37; 99% CI: −9.18 to −3.56).[15]

Overall, there is a lack of evidence of a difference in many outcomes between cemented or uncemented hemiarthroplasty and THA (level I).[11] There is, however, level I evidence that, when cemented and uncemented hemiarthroplasty is compared, cemented hemiarthroplasty is associated with a significantly lower risk of pain at one year post surgery and a significantly greater risk of failure to regain mobility (level I).[14] Additionally, there is no difference in outcome associated with unipolar versus bipolar hemiarthroplasty implants (level I).[14] The risk of dislocation and minor re-operation is higher in THA compared to hemiarthroplasty (level I).[11,13]

Resolution of clinical scenario

- Level I evidence demonstrates *increased risk* in dislocation and minor re-operation rates for THA versus hemiarthroplasty.
- Level I evidence demonstrates *no difference* between uncemented hemiarthroplasty compared to THA for any other outcome.
- Level I evidence demonstrates patients with the Moore implant were *significantly more* at risk for residual pain compared to those with THA.
- Level I evidence demonstrates patients with uncemented hemiarthroplasty were at *significantly increased* risk of residual pain and failure to regain mobility compared to cemented hemiarthroplasty.
- Level I evidence demonstrates there is *no difference* in the risk of complications, acetabular erosion, return to function, or mortality between unipolar and bipolar hemiarthroplasty in femoral neck fractures.

Summary of answers

- Arthroplasty does significantly reduce the risk of revision surgery at one year compared to internal fixation.
- Arthroplasty does not result in significantly different risk of mortality at one year compared to internal fixation.
- Arthroplasty does significantly increase the risk of infection, blood loss, and operative time at one year compared to internal fixation.

- Current studies comparing different implants for fixation of femoral neck fractures lack methodological rigor. SHSs may reduce re-operations in patients with displaced fractures.
- SHSs have a tendency toward increased rates of AVN compared to cancellous screws.
- THA is associated with an increased risk of residual pain at one year and minor re-operation compared to hemiarthroplasty.
- There is no difference between uncemented hemiarthroplasty compared to THA for any other outcome.
- Patients with the Moore implant were significantly more at risk for residual pain compared to those with THA.
- Patients with uncemented hemiarthroplasty were at significantly increased risk of residual pain and failure to regain mobility compared to cemented hemiarthroplasty.
- There is no difference in the risk of complications, acetabular erosion, return to function, or mortality between unipolar and bipolar hemiarthroplasty in femoral neck fractures.

97
Extracapsular Hip Fractures

Luke A. Lopas MD[1], Andrew F. Tyler MD PhD[2] and Samir Mehta MD[3]
[1]Indiana University School of Medicine, Indianapolis, IN, USA
[2]Vanderbilt University Medical Center, Vanderbilt Orthopaedic Institute, Nashville, TN, USA
[3]University of Pennsylvania, Philadelphia, PA, USA

Clinical scenario

- A 76-year-old community ambulatory female has a mechanical fall and sustains a right intertrochanteric hip fracture.
- The patient arrives at your Emergency Department that evening after a friend found her at home, complaining of right hip pain and unable to ambulate.

Top three questions

1. In patients with extracapsular hip fractures undergoing fixation, does a cephalomedullary nail (CMN) result in a lower rate of re-operation when compared with sliding hip screw (SHS) and stratified by fracture pattern?
2. In patients with extracapsular hip fractures, do comprehensive *orthogeriatric* co-management programs, compared to usual care, improve outcomes after hip fracture surgical fixation?

3. In patients with failed fixation of an extracapsular hip fractures, does revision fixation compared to arthroplasty lead to better long-term function?

Question 1: In patients with extracapsular hip fractures undergoing fixation, does a cephalomedullary nail (CMN) result in a lower rate of re-operation when compared with sliding hip screw (SHS) and stratified by fracture pattern?

Rationale

There are numerous implant options available and a growing trend toward the use of CMNs.[1] Implant options can be roughly separated into extramedullary implants (of which the SHS is the most common) and intramedullary implants (of which a CMN is the most common). Choosing the most appropriate implant for a specific patient allows the surgeon to optimize the patient's outcome while controlling cost.

Clinical comment

Many hip fracture failures stem from an inappropriate implant utilization, which leads to failure, typically represented by cutout, varus collapse, or medialization of the femoral shaft.

Available literature and quality of the evidence

Numerous prospective, randomized controlled trials (RCTs) have evaluated implants for treatment of extracapsular hip fractures. We focused on those carried out after the year 2000 to focus on current implant design.

Cephalomedullary nail versus sliding hip screw

- Level I data: 10 modern implant design prospective randomized clinical trials and 2 systematic reviews/meta-analyses.

Findings

Early studies suggested an increased rate of complications, specifically periprosthetic fractures, in hip fractures treated with a short CMN.[2,3] However, after design modifications were made to these devices, Bhandari et al. conducted a meta-analysis in 2009 to re-evaluate this.[4] They found in early studies (conducted before 2000) that short nails had an increased relative risk of fracture of 4.5 (95% confidence interval [CI]: 1.78–11.36), but that in studies performed after 2000 the relative risk (RR) was not significantly increased (RR = 1.65; 95% CI: 0.50–5.44, p = 0.41). They advise that early studies comparing nails to SHSs for the treatment of extracapsular hip fractures should be interpreted with caution as they may not be applicable to current technology.

Small differences or trends in secondary outcomes such as blood loss, operating room time, early mobilization, or pain have varied in significance depending on the study evaluated. However, our main outcome of interest (implant failure necessitating re-operation) has repeatedly been shown to be equivalent in most fracture patterns. Harrington compared a hip screw (n = 52) to an intramedullary device (n = 50) for unstable intertrochanteric hip fractures and found no difference in

the rate of re-operation relative to implant used.[5] They noted in all cases of cut-out the tip–apex distance was greater than 25 mm, suggesting surgical technique was more important than implant choice. Little compared a long, statically locked CMN (n = 92) to an SHS (n = 98) in a prospective randomized trial of AO/OTA type 31A fractures excluding only those with subtrochanteric extension. They found no difference in the rate of union, implant failure, or re-operation.[6] A Cochrane review of 43 trials performed in 2010 evaluated intramedullary versus extramedullary implants for extracapsular hip fractures. They found no compelling data to suggest intramedullary fixation provided better outcomes than the SHS, and instead found it may increase complications.[7]

Since this review, several RCTs have found no difference in revision or re-operation rates between CMN and SHS.[8–12]

A common belief is that fractures with subtrochanteric extension, reverse obliquity, an incompetent lateral wall, or incompetent calcar (the AO/OTA 31A3 fractures) benefit from intramedullary fixation. Sadowski et al. compared intramedullary versus extramedullary fixation in the treatment of AO/OTA 31A3 injuries.[13] Thirty-nine patients were randomized to CMN (n = 20) or a 95° fixed angle extramedullary device (n = 19). There were six implant failures and one nonunion in the 19 patients treated with the extramedullary device versus zero implant failures and one nonunion in the CMN group at one year (p = 0.007). Kuzyk et al. performed a meta-analysis of studies looking at subtrochanteric or intertrochanteric fractures with subtrochanteric extension.[14] They identified three level I studies and nine level IV studies. A pooled analysis of fixation failure in the level I studies trended toward a decreased risk of failure with intramedullary fixation (RR = 0.287; 95% CI: 0.062–1.327). Matre et al. reviewed the

Norwegian registry data of 2716 patients with AO/OTA 31–A3 or subtrochanteric fractures treated with an SHS (n = 1792) or an intramedullary nail (IMN) (n = 924).[15] At one year, the rate of re-operation was increased in the SHS (6.4%) than nail group (3.8%). A Cox regression analysis found the use of an SHS carried an RR of 1.43 for re-operation (95% CI: 1.01–2.03). Finally, in 2015, the American Academy of Orthopaedic Surgeons released evidence based clinical practice guidelines on the management of hip fractures in the elderly.[16] In their final report, they used three high and two moderate strength studies to conclude that there is strong evidence to support the use of a cephalomedullary device in the use of subtrochanteric and reverse obliquity intertrochanteric hip fractures.

Swart et al. used these data to ask whether cost-effective decision-making could guide implant choices based on fracture pattern. They used an expected-value decision-analysis model to compare SHS versus nail for the treatment of AO/OTA 31 injuries. Their model was sensitive to the failure rate and implant cost. For A1 fractures, the SHS and for A3 fractures the nail always provided more value.[17] For A2 injuries, there was discrepancy, depending on the fixation failure rate used, but under most conditions, the SHS was favored.

Lastly, Palm et al. reported an impressive series of data looking at 1000 geriatric hip fractures before and after the implementation of a defined treatment algorithm. Implant choice was dictated by fracture pattern with AO/OTA 31A1 and 31A2.1 injuries treated with an SHS and 31A2.2, 31A2.3, and 31A3 injuries treated with a short CMN. Total re-operation rate for extracapsular fractures was reduced from 13 to 7% (p = 0.002) with most of that decrease

coming from the unstable intertrochanteric fracture group (17% vs 8%, p <0.001).[18]

Resolution of clinical scenario

- In the absence of extenuating circumstances, AO/OTA 31A1 injuries should be treated with an SHS, and 31A3 injuries with an intramedullary device.
- For most 31A2 injuries, an SHS is the optimal implant, but certain patterns may benefit from intramedullary fixation, including severe posteromedial comminution.

Question 2: In patients with extracapsular hip fractures, do comprehensive orthogeriatric co-management programs, compared to usual care, improve outcomes after hip fracture surgical fixation?

Rationale

Geriatric hip fractures have a significant impact on patient morbidity and mortality. Coordinated care between orthopedic surgeons, geriatricians, endocrinologists, physical and occupational therapists, dieticians, and social workers may improve a variety of outcomes for older patients who suffer a hip fracture.

Clinical comment

Often, the decision to operate is the least complex aspect of managing a geriatric hip fracture patient. Optimizing a patient's medical and nutritional status, early mobilization, and appropriate transition to the next level of care may

play as large a role as surgical care in improving outcomes for these patients.

Available literature and quality of the evidence

- Level I: 3 systematic review/meta-analyses and 2 RCTs.
- Level II: 1 population-based longitudinal study.

Findings

A Cochrane review of five studies (n = 316) comparing enhanced rehabilitation care models (including orthogeriatric co-management teams) to usual care found a lower frequency of some complications (urinary tract infections, nutritional problems, postoperative delirium, recurrent falls), reduced length of stay, decreased risk of institutional placement at three months, better activities of daily living (ADLs) function, and higher probability of regaining preinjury walking capability. They found no differences in cognitive deterioration or mortality,[19] but admittedly was limited by inadequate reporting and low sample size. A second Cochrane review of 13 trials (n = 2498) comparing multidisciplinary rehabilitation models in geriatric hip fractures to usual care showed no difference in mortality at the end of follow-up.[20] Return to functional status, length of hospital stay, and costs varied between the studies.

Prestmo et al. reported a single-center RCT (n = 397) of patients 70 years or older able to walk 10 m before their fracture assigned to either comprehensive geriatric care or orthopedic care (usual care).[21] Those with comprehensive geriatric care demonstrated improved mobility at four months after surgery. Watne et al. randomized patients

(n = 329) to treatment in an acute geriatric ward or a standard orthopedic ward.[22] They found no significant difference in cognitive function or delirium rates four months after surgery.

A multicenter retrospective population-based longitudinal study (n = 33 152) demonstrated that introducing an orthogeriatrician decreased 30-day (hazard ratio [HR] = 0.73; 95% CI: 0.65–0.82) and one-year mortality (HR = 0.81; 95% CI: 0.75–0.87). Introduction of a nurse-led fracture liaison service had similar reduction on 30-day (HR = 0.80; 95% CI: 0.71–0.91) and one-year mortality (HR = 0.84; 95% CI: 0.77–0.93).[23] Grigoryan et al. conducted a meta-analysis of 18 studies (n = 9094 patients) and found a significant reduction in in-hospital mortality (RR = 0.60; 95% CI: 0.43–0.84) and long-term mortality (RR = 0.83; 95% CI: 0.74–0.94) with geriatric intervention during hospitalization for hip fractures.[24] A shared-care model also demonstrated a reduction in length of stay and time to surgery.

Resolution of clinical scenario

- Comprehensive care models, which include medical co-management, liaison services, and discharged planning, should be utilized in caring for geriatric hip fracture patients.
- Benefits appear to include improved functional status and decreased postoperative complications and may lead to decreases in mortality rates and length of hospital stay.

Question 3: In patients with failed fixation of an extracapsular hip fractures, does revision fixation compared to arthroplasty lead to better long-term function?

Rationale

Despite best efforts, some fixation failures of extracapsular hip fractures will result in patients who will need further surgical management.

Clinical comment

Deciding whether to attempt revision fixation or arthroplasty is a complex choice that often hinges on patient characteristics, remaining bone stock, and method of failure.

Available literature and quality of the evidence

- Numerous level III case series and retrospective reviews, 6 of which are reviewed below.
- No high-level data that directly compare attempted salvage to arthroplasty in similar patient populations.

Findings

Haidukewych et al. reported a case series of 20 failed intertrochanteric hip fractures treated with revision open reduction and internal fixation (ORIF) and bone grafting. Nineteen of the 20 patients ultimately went on to union and were ambulatory, demonstrating that success can be obtained with salvage procedures.[25] Haidukewych et al. also reviewed patients who underwent arthroplasty for

failed intertrochanteric fractures. Of the 44 patients available for follow-up, 39 had no or mild pain with ambulation and the implant survivorship at 10 years was 87.5% (95% CI: 67.3–100%).[26]

Yuan et al. reviewed 111 patients converted to arthroplasty after previous failed intertrochanteric fracture treated with an extramedullary device (n = 70) or an intramedullary device (n = 41). They found overall implant survivorship and function to be similar between groups. Complications were similar with the exception of increased intraoperative femoral fractures in the intramedullary group (12% vs 1%, p = 0.02).[27] Pui et al. looked at complications from conversion total hip arthroplasty (THA) following failed intertrochanteric hip fracture fixation. In a multicenter, retrospective review, they evaluated 91 conversion THA hips from a failed CMN (n = 31) or SHS (n = 60). Their primary outcome was Harris Hip Score, which showed no difference. The overall perioperative complication rate in CMN conversion was significantly higher (41.9% vs 11.7%, p = 0.001) as was the orthopedic complication rate (29.0% vs 8.3%, p = 0.014).[28] However, Zeng et al. reviewed patients who underwent conversion THA from either failed SHS (n = 70) or CMN (n = 72) and found contradictory results. They found a higher rate of complications in those converted from SHS (42.9% vs 20.8%, p = 0.003), specifically for periprosthetic fracture (15.7% vs 4.2%, p = 0.021).[29]

Said et al. reviewed 26 patients with failed SHS fixation of intertrochanteric hip fractures.[30] Eighteen patients underwent revision fixation and eight underwent arthroplasty (for irreparable femoral head and/or acetabular damage). All patients in the revision fixation group eventually achieved union at an average of 17 weeks, with one patient having avascular necrosis. Six of the eight

patients who underwent arthroplasty had good outcomes with pain-free gait.

Resolution of clinical scenario

- Revision fixation and arthroplasty are both options in the case of a failed original ORIF for a hip fracture.
- There is mixed evidence as to whether conversions from a failed CMN or SHS are at higher risk of failure.

Summary of answers

- Appropriate implant choice based on fracture pattern can reduce the rate of failure and help reduce cost.
- Multidisciplinary care models improve a variety of outcomes in geriatric hip fracture patients.
- Both revision fixation and conversion arthroplasty can produce good results. Surgeons should be aware of the risk of intra-operative fracture with respect to revision of CMNs.

Clinical scenario

- A 45-year-old obese patient who is otherwise well presents to the Emergency Department after a motor vehicle accident.
- X-rays show a proximal femur fracture (Figure 98.1a and b). There is significant abduction, external rotation, and flexion deformity of the proximal fragment in relation to the distal fragment. The AO/OTA classification is a 31A3.1.

Top three questions

1. In patients with subtrochanteric femur fractures treated with an intramedullary nail (IMN), does a trochanteric start point provide superior outcomes to a piriformis fossa start point?
2. In patients with subtrochanteric femur fractures treated with an IMN, does a nonanatomic reduction result in higher failure rates and higher mal/nonunion rates than anatomic reduction?

3. In patients with subtrochanteric femur fractures treated with an IMN, does open reduction lead to increased complication rates (i.e. infection, nonunion) when compared to closed reduction and intramedullary nailing?

Question 1: In patients with subtrochanteric femur fractures treated with an intramedullary nail (IMN), does a trochanteric start point provide superior outcomes to a piriformis fossa start point?

Rationale

When performing intramedullary nailing of subtrochanteric fractures, there has been debate over different aspects of the surgical technique including the starting point.

Clinical comment

The insertion site for anterograde nailing of subtrochanteric femur fractures can be located in the piriformis fossa or the tip of the trochanter. It should be noted that the term *piriformis fossa* is actually a misnomer and anatomically incorrect, although this has been propagated as the start point for femoral nailing in the literature for decades.[1,2] The correct name is the *trochanteric fossa*, but to keep the nomenclature consistent with North American literature we have chosen to keep with the term *piriformis fossa*.

A piriformis fossa starting point offers colinear access to the shaft for reaming and nail insertion of a straight nail and possible decreased risk of varus malalignment.

Fracture reduction is important when dealing with a subtrochanteric femur fracture; however, this insertion site may involve more soft tissue compromise than a start point at the tip of the trochanter.[3,4] A start point at the tip of the trochanter may be technically easier to obtain; however, anatomic variability in the start point and varying proximal nail geometry may add complexity when choosing this start point. One study observed that the tip was ideal as a start point in only a minority of cases, and recommended preoperative templating of the contralateral intact femur to identify the appropriate start point to prevent malreduction of the fracture.[5,6]

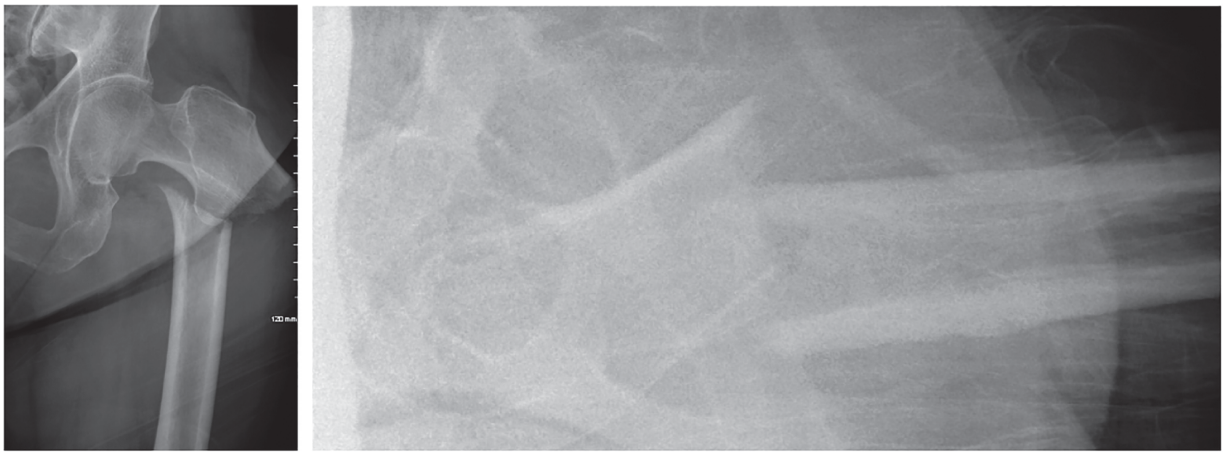

Figure 98.1 AP and lateral x-ray of a proximal femur fracture. This is an OTA 31A3.1 type femur fracture with typical noted deformity.

Available literature and quality of the evidence

There is one prospective randomized trial (level I), one prospective cohort study (level II), and one retrospective cohort study (level III) that specifically addresses this question.

Findings

The only randomized study to date included 34 patients who were randomized to one of two implants that had a piriformis start or a trochanteric start respectively (level I).[7] This study was powered to detect a significant difference (200 mL) in blood loss and there was no difference between the two groups in this regard. With respect to varus malalignment, this study showed 2 of 17 patients in the piriformis fossa group and 4 of 17 patients in the trochanteric group had varus malalignment on follow-up x-rays. This was not statistically significant; however, this study was underpowered for this outcome. Several other outcomes were compared, including duration of surgery, union rate, complication rate, and functional outcomes, and there were no differences between the two groups for these outcomes in this small patient sample.

The other prospective study was a multicenter cohort study that included 108 patients treated with a single implant that differed only in proximal lateral bend which was used either through a piriformis or trochanteric entry.[8] This study showed that piriformis entry nails had a mean 12-minute longer operative time – 75 minutes (range 31–131) versus 62 min (range 14–193), ($p = 0.08$) – and a 61% increase in fluoroscopic time – 153 seconds (range 16–662) versus 95 seconds (range 20–375). These differences were amplified in obese patients where operative time was 30% longer and fluoroscopy time was 73% higher. There were no varus malreductions in either group and only one patient in each group needed further intervention (exchange nailing) for nonunion. Functional outcomes were recorded using the lower-extremity measure which showed no difference between the groups at any time point (4, 6, and 12 months). It should be noted that the authors used a modified greater trochanteric (GT) start point (either slightly medial or lateral to the tip of the GT) that was individualized for each patient, taking into account the

anatomy of the patient's proximal femur as well as the geometry of the nail. This idea of a variable trochanteric start point is supported in other anatomic and radiographic studies, and it is accepted that a correct trochanteric entry point is slightly medial to the tip of the greater trochanter in the anteroposterior (AP) view and slightly posterior in line with the shaft on the lateral view (due to the anterior offset of the GT).[5,6,9,10]

There is one retrospective cohort study that compared the two starting points with respect to nerve and muscle function postoperatively with outcomes out to a mean of 22 months.[11] This study included only 17 patients (9 in the piriformis group and 8 in the trochanteric entry group). They looked at whether the patients had a Trendelenburg gait, electromyographic (EMG) changes in their hip musculature, differences in their Harris Hip Score and Visual Analog Scale (VAS), magnetic resonance imaging (MRI) changes of the soft tissues, and differences in muscular endurance around the hip. Overall, five patients in the piriformis group had a Trendelenburg gait and four had EMG evidence of injury to the superior gluteal nerve which had since recovered. The piriformis group had decreased endurance on the isokinetic testing of the hip range of motion; however, the clinical relevance is unknown. Overall, this was a very small retrospective study with fragile results and the clinical relevance is questionable, although it does fuel the need for larger studies.

Resolution of clinical scenario

- Both start points can be used and varus malalignment is relatively uncommon with either start point. Anatomical differences may require modification of the

GT start point from the radiographic tip to a position slightly medial and posterior.

- With modern intramedullary implants, there is no conclusive evidence that one start point leads to a better outcome with respect to blood loss, fracture healing, and complication rates when variations in proximal femoral anatomy and nail geometry are accounted for.
- Trochanteric start nailing may decrease operative and fluoroscopy time, especially in obese patients.
- There is very weak evidence that a piriformis entry point, when compared to a GT entry, causes some weakness (neuromuscular and tendon injury) around the hip but the clinical relevance of this has not been definitively shown.
- In this obese patient, a trochanteric start nail, with a slightly medial and posterior starting point, may be ideal.

Question 2: In patients with subtrochanteric femur fractures treated with an IMN, does a nonanatomic reduction result in higher failure rates and higher mal/nonunion rates than anatomic reduction?

Rationale

Because of the difficulty of treating this fracture and the relatively high failure rate of fixation in early studies, there

has been focus on trying to improve these results with emphasis on the importance of fracture reduction.

Clinical comment

In 2018, intramedullary nailing is the preferred method of treatment for subtrochanteric femur fractures. Many plating options exist and are useful for fractures that extend into the nail insertion site or femoral neck; however, proximal femoral locking plates have been shown to have high failure rates and blade plates are technically demanding, especially in an already challenging fracture pattern.[12,13] When consideration is given for nailing these fractures, the short proximal segment, capacious size of the metaphyseal component, and the multidirectional deforming forces create a perfect environment for a less-than-ideal reduction. But does an anatomic reduction matter when you are aiming for relative stability and secondary bone healing with an intramedullary implant? So, the question remains, does a nonanatomic reduction result in higher failure rates when compared with an anatomic reduction for subtrochanteric fractures treated with an IMN?

Available literature and quality of the evidence

There are two retrospective studies (level III) that specifically address reduction quality in intramedullary fixation of subtrochanteric femur fractures.

Findings

Shukla et al. performed a retrospective review that included 60 patients treated with a cephalomedullary nail.[14] They examined the effect of coronal plane (varus/valgus) reduction on union and complication rates. They found that 19 out of 60 fractures were malreduced in

varus (>10° as compared to the contralateral femur). Of these, 74% (n = 14) had a complication of malunion (n = 9), nonunion (n = 3), or hardware failure (n = 2). This was in contrast to the anatomically reduced group which only had one complication (a varus malunion) in 41 cases.

Riehl et al. performed a retrospective cohort study of 35 patients who were treated with an IMN for a subtrochanteric femur fracture and compared those nailed with a malreduction and those without.[15] Their main outcome measure was fracture healing. They found 7 of 35 fractures had a malreduction, either varus >10° (n = 2), flexion (n = 4), or both (n = 1). Of the fractures with a malreduction, all developed a delayed union (n = 6) or nonunion (n = 1). The presence of a malreduction greater than or equal to 10° in any plane significantly increased the rate of delayed or nonunion (p = 0.0005).

Resolution of clinical scenario

Malreduction (especially varus malreduction) of subtrochanteric fractures increases implant failure rates, increases malunion rates, and increases nonunion rates.

Question 3: In patients with subtrochanteric femur fractures treated with an IMN, does open reduction lead to increased complication rates (i.e. infection, nonunion) when compared to closed reduction and intramedullary nailing?

Rationale

In subtrochanteric femur fractures, the personality of the fracture is determined by the deforming forces of muscular action on the proximal and distal fragments (Figure 98.2) and closed reduction is often unable to achieve a satisfactory reduction. An open reduction would be needed to obtain a more accurate reduction.

Clinical comment

Malreduction is associated with higher delayed and nonunion rates as well as hardware failure (see Question 2). Open reduction can improve the reduction to acceptable parameters; however, it has been suggested that open reduction techniques (clamping, provisional plating [PP], cerclage wires/cables) may be associated with increased infection rates as well as increased nonunion rates secondary to soft tissue stripping.

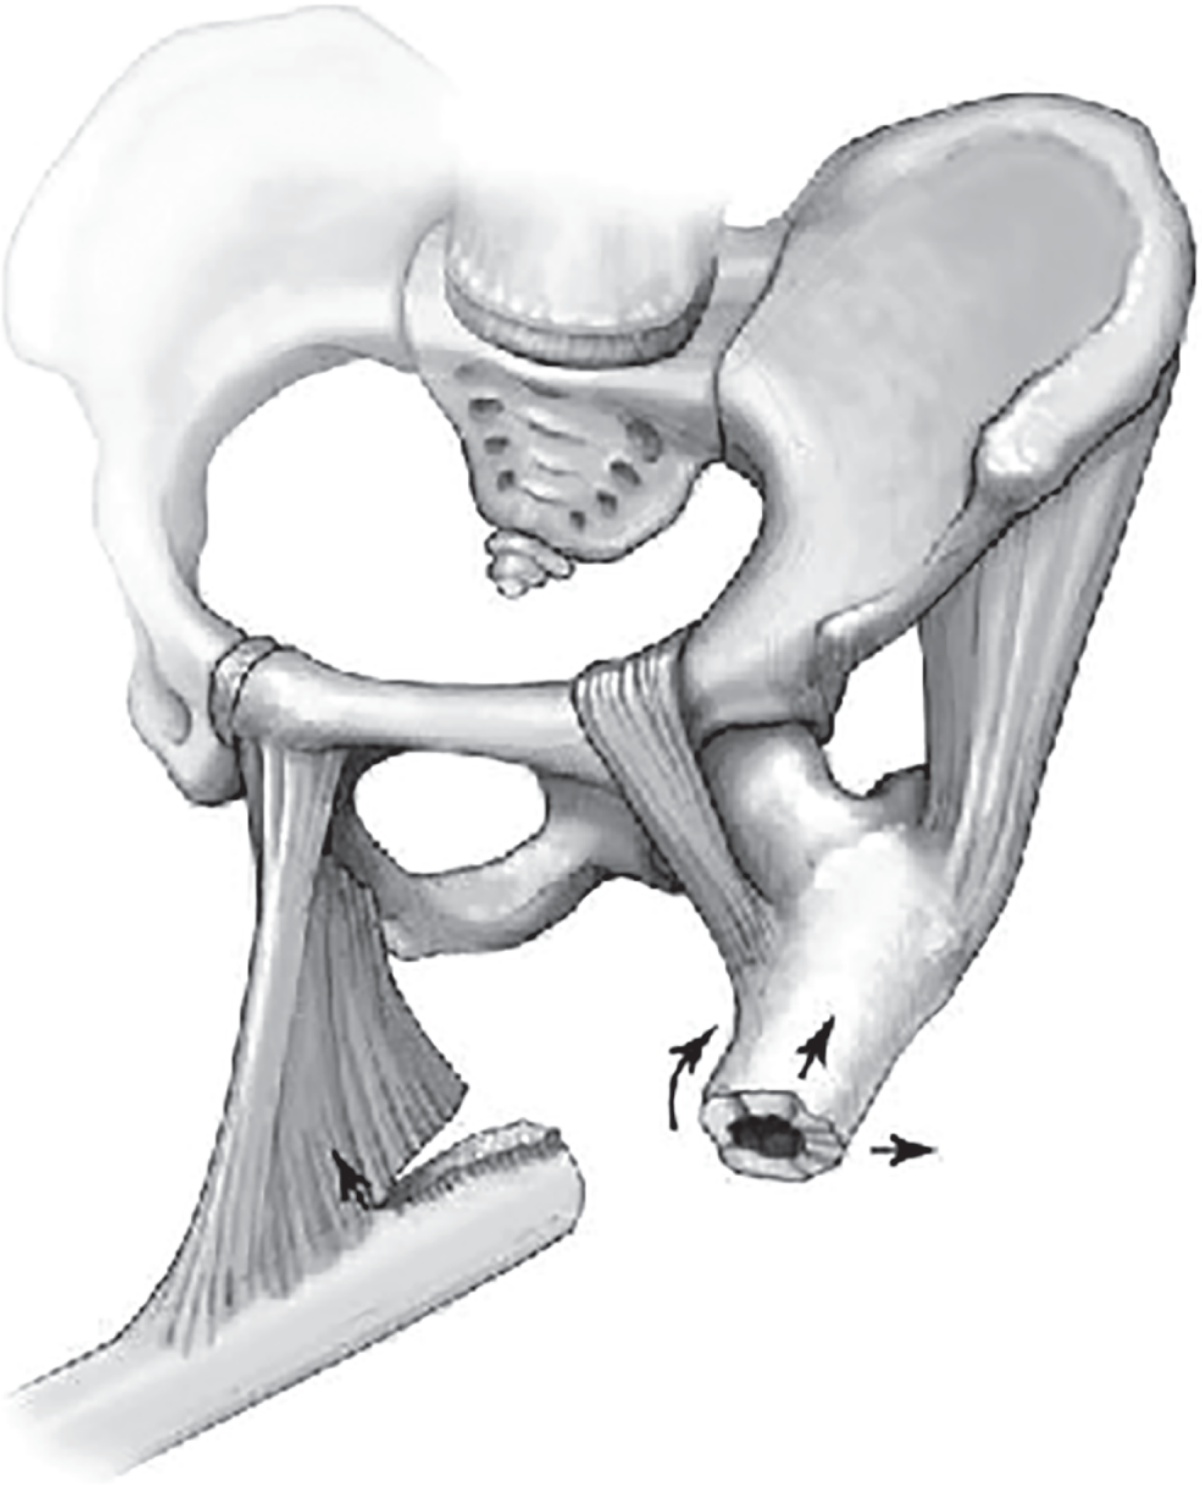

Figure 98.2 Schematic diagram of the muscular forces that deform a typical subtrochanteric femur fracture.

Available literature and quality of the evidence

There have been several recent studies examining open reduction techniques of subtrochanteric femur fractures including three retrospective cohort studies (level III) and four case series (level IV).

Open reduction

Three studies looked at open reduction and nailing with the highest-quality study (level III) from Beingessner et al.[16] This was a retrospective cohort study including 56 patients who underwent open reduction and intramedullary fixation compared to 40 that underwent closed reduction and intramedullary (IM) fixation. There were no nonunions or infections in the open group, whereas the closed group had one nonunion and one early fixation failure. There was no difference in time to union.

A retrospective case series by Afsari et al. of 44 patients treated with clamp-assisted nailing (either clamp reduction of oblique or spiral fractures or simply clamp control of the proximal segment fractures not amenable to clamp reduction).[17] Nonunion was only reported in 1/44 cases (2.3%) and there were no reported infections or wound complications.

Another retrospective series, by Mingo-Robinet et al., looked at open reduction of 26 geriatric subtrochanteric fractures and had no cases of nonunion and one case of deep infection.[18]

Open reduction and cerclage wire

Cerclage wiring was once considered orthopedic trauma heresy due to periosteal stripping and strangulation of bony vascularity; however, it is gaining momentum as an adjunct to intramedullary nailing of subtrochanteric fractures. There are three recent studies that support the use of open reduction and cerclage wiring. Hoskins et al.

provided a retrospective cohort study of 134 cases of which 20 were treated with cerclage wire.[19] Of these, there were no major complications (nonunion, loss or failure of fixation, or cutout). If a cerclage wire was not used there was a major complication rate of 11.4%. This study did not look at infection. Another retrospective cohort study examined the use of cerclage wiring and nailing compared with closed nailing in a geriatric cohort of 90 patients and found that there was a significantly superior reduction in the cerclage group (n = 30). There were no differences in the complication profile between the two groups and the cerclage group had a significantly shorter time to union (4.4 months vs 6.9 months p <0.001).[20]

Open reduction and provisional plating

One retrospective cohort study examined their series of 22 cases of open reduction and PP in the lateral position compared with 48 cases of closed reduction.[21] There were no malunions in the PP group; however, there was a 27.7% rate of malreduction (defined as >5° of angulation on postoperative radiographs) in the closed nailing group. There was no difference in time to union and there was only one case of nonunion in each group. However, there was increased blood loss (392 vs 293 mL, p = 0.007) and operative time (128 vs 105 min) in the PP group.

Resolution of clinical scenario

In patients with displaced subtrochanteric fractures where closed manipulation does not achieve a satisfactory reduction, evidence suggests open reduction and the use of reduction adjuncts such as clamps, wires, or provisional plates:

- Reduces the risk of malunion.

- Does not increase the risk of nonunion.
- Does not increase the risk of infection.

Summary of answers

- When treating subtrochanteric femur fractures with an IMN, reduction of the fracture prior to nail insertion and a proper start point are essential.
- There is no difference between a piriformis and trochanteric start point implant; however, when choosing a trochanteric start point the surgeon must pay close attention to the start point as this commonly *does not* correspond to the tip of the trochanter and is usually slightly medial and posterior.
- Malreduction (especially varus malreduction) of subtrochanteric fractures increases implant failure rates, increases malunion rates, and increases nonunion rates. One should strive for anatomic reduction, and if an open reduction is necessary, be reassured that, with respectful soft tissue principles, infection and nonunion rates are not increased.

Femoral Shaft Fractures

Costas Papakostidis MD[1] and Peter V. Giannoudis MD FACS FRCS[2]
[1]Limassol General Hospital, Nikaias, Polemidia Kato, Limassol, Cyprus
[2]Academic Department of Trauma & Orthopaedics, School of Medicine, University of Leeds, Leeds, Yorkshire, UK

Clinical scenario

- A 30-year-old male victim of a road traffic accident (RTA) is admitted to the Emergency Department.
- He is suffering from bilateral femur fractures, one of them being Gustilo II open, minor contusion of the right lung, and his Glasgow Coma Scale is 14/15.
- He is cleared of any other injuries of his abdomen and pelvis.
- Femoral shaft fractures frequently occur within the context of polytrauma and might result in considerable morbidity and mortality.
- Bilateral as well as open femur fractures constitute high energy injuries and have been associated with higher mortality and morbidity rates as compared to unilateral femur fractures.
- The optimal timing and type of definitive treatment of femoral shaft fractures in the above scenario are still controversial.

Top three questions

1. In polytrauma patients with femoral shaft fractures, does early definitive fixation of the femoral fracture result in lesser systematic complications and decreased mortality compared to the damage control orthopedics (DCO) approach?
2. Does early, simultaneous intramedullary nailing (IMN) of bilateral femur fractures predispose the patient to increased complication rates compared to the DCO approach?
3. In open femur fractures, does early IMN result in increased complication rates compared to delayed IMN?

Question 1: In polytrauma patients with femoral shaft fractures, does early definitive fixation of the femoral fracture result in lesser systematic complications and decreased mortality compared to the damage control orthopedics (DCO) approach?

Rationale

Multiply injured patients with concomitant femoral shaft fractures are at increased risk of systemic complications that could cause considerable morbidity and mortality.[1,2] These adverse outcomes could be attributed not only to the patient's related factors (such as age, co-morbidities, associated injuries, etc.) but also to the type of the initial therapeutic intervention.[3] There is a diversity of recommendations regarding the optimal treatment plan in this cohort of patients. Neither early total care (ETC), entailing early internal fixation of femur fractures, nor DCO, combining initial temporary stabilization of the femoral fractures by means of external fixation and secondary conversion of the ex-fix to definitive internal fixation, have emerged as the unequivocal treatment methods for all trauma patients.

Clinical comment

DCO combines the benefits of early fracture stabilization, allowing for ongoing patient resuscitation, with the minimal risks of complications.[4] However, some skepticism exists with the DCO practice for potential septic complications at the stage of conversion of the temporary external fixation to definitive IMN.[5,6] On the other hand, early definitive fixation of femoral fractures leads to decreased rates of pulmonary complications (adult respiratory distress syndrome [ARDS], fat embolism, pulmonary embolism, and pneumonia), shorter duration of ventilation, decreased length of hospital stay (LOS), and overall lesser costs of treatment.[7] Emphasis has also been given on the detrimental effect of early fixation in the presence of subclinical tissue hypoperfusion as this might increase systemic complications.[8–10]

Table 99.1 Results by outcome of interest. Source: Modified from El-Menyar et al.[11]

Outcome	n-studies (refs)	n-pts Early IMN	n-pts Delayed IMN	Odds ratio (95% CI)	p	I^2	Favors
ARDS	10	2133	791	0.39 (0.26, 0.57)	p <0.0001	0%	Early IMN
FE	4	1150	420	0.65 (0.26,1.62)	0.35	0%	ns
Pneumonia	5	1468	399	0.71 (0.21, 2.39)	0.58	0%	ns
PE	2	1440	428	0.39 (0.21, 0.71)	0.002	11%	Early IMN
MOF	2	502	155	0.34 (0.03, 3.95)	0.39	90%	ns
Mortality	11	6370	2230	0.46 (0.26, 0.82)	0.008	51%	Early IMN

ARDS: Adult Respiratory Distress Syndrome, CI: confidence interval, FE: fat embolism, PE: pulmonary embolism, MOF: multiple-organ failure.

Available literature and quality of the evidence

The most relevant current literature consisted of:

- Level III: 1 systematic review of the literature and meta-analysis.[11]
- Prognostic level II: 1 prognostic study (statistical modeling based on retrospective database.[12]

Findings

The systematic literature review and meta-analysis attempted to critically assess early versus delayed IMN of femur fractures in polytrauma patients.[12] It included relevant studies up to mid-2016. Based on eligibility criteria, the authors recruited 15 component studies (2 RCTs and 13 retrospective cohort studies). The distinction between early and delayed IMN across component studies was based on variable timeframes, but 24 hours was the most frequently used cutoff. The main results of the study, categorized per outcome of interest, are shown in Table 99.1.

The study documented significantly reduced odds of ARDS, pulmonary embolism, and mortality in the group of early IMN compared with delayed IMN (Table 99.1). As for fat embolism, pneumonia and MOF, no statistically significant difference between the two groups could be established. Based on the GRADE (Grading of Recommendations, Assessment, Development and Evaluations) system, the strength of evidence for every outcome of interest of this meta-analysis was low.

Finally, in the prognostic study mentioned above, a protocol termed *early appropriate care* (EAC) was developed aiming at quantifying the response of the multitrauma victim to the resuscitative measures for the management of metabolic acidosis.[12] A complex statistical model, incorporating univariate and multivariate analysis of variance, logistic predictive analysis and calculation of receiver operating characteristic (ROC) curves, was developed and showed that correction of metabolic acidosis within the first eight hours, as indicated by lactate levels <4.0 mmol/L, pH >7.25, or BE less than −5.5 mmol/L was associated with a reduced risk of pulmonary complications. Early (within 36 hours of injury) definitive fixation of unstable fractures in adequately resuscitated polytrauma patients reduces systematic complications, shortens LOS, and reduces costs of treatment. If metabolic acidosis persists despite resuscitative measures, a DCO approach is recommended.

Resolution of clinical scenario

- Early (within 24 hours from injury) definitive fixation of femur fractures in stable polytrauma patients reduces the risks of systematic complications and mortality.
- Optimal timing of definitive femoral fracture fixation in trauma patients should be balanced between patient physiologic condition and adequacy of resuscitation.
- A delay of definitive fracture treatment of up to 36 hours is justified in order to correct metabolic acidosis, due to occult tissue hypoperfusion.

Question 2: Does early, simultaneous intramedullary nailing (IMN) of bilateral femur fractures predispose the patient to increased complication rates compared to the DCO approach?

Rationale

Respiratory complications in the form of fat embolism, ARDS, pulmonary embolism, or pneumonia occur in approximately 2–3% of patients with isolated femur fractures and up to 10–75% of polytrauma patients with femur fractures, following IMN. Two independent risk factors for developing serious respiratory complications following IMN of the femur have been identified: thoracic injury and multiple IMN procedures in the same sitting.[13] Furthermore, a statistical predictive model was developed to predict the likelihood of respiratory failure (RF) in the presence of the above parameters. According to this model, only 2% of patients with femur fractures are likely to develop RF when both risk factors are absent, 33% will develop RF following multiple nailing procedures and in the absence of thoracic injury, whereas the likelihood of developing RF increases dramatically to 95% in the presence of both risk factors.[13]

Clinical comment

Simultaneous IMN of bilateral femoral fractures, particularly in trauma victims with concomitant thoracic injuries, could potentially predispose to systemic complications and increased mortality.

Available literature and quality of the evidence

The most relevant current literature included:

- Level IV: 4 retrospective comparative studies.[14–17]
- Level III: 1 longitudinal cohort study.[18]

Findings

All four retrospective studies[14–17] provided data of direct comparison between patient cohorts with bilateral and unilateral femoral fractures. We performed a pooled analysis of the following outcomes of interest: intensive care unit/high dependency unit (lCU/HDU) stay, LOS, ARDS, and mortality (Table 99.2).

Table 99.2 Results of pooled analysis.[14–17]

		Participants					
Outcome	**Studies**	**BFF**	**UFF**	**Statistical method**	**Effect estimate**	**Heterogeneity (I^2)**	**Favors**
ICU/HDU stay	3[15–17]	186	1505	Mean Difference (IV, Fixed, 95% CI)	3.30 (1.82–4.77)	0%	UFF
LOS	3[15–17]	186	1505	Mean Difference (IV, Fixed, 95% CI)	5.22 (2.30–8.13)	11%	UFF
ARDS	3[14,15,17]	171	1365	Odds Ratio (M-H, Random, 95% CI)	2.71 (1.39–5.29)	53%	UFF
Mortality	4[14–17]	271	2305	Odds Ratio (M-H, Fixed, 95% CI)	2.44 (1.71–3.49)	0%	UFF

BFF: bilateral femur fracture, UFF: unilateral femur fracture, IV: inverse variance, Fixed: fixed effects model, Random: random effects model, M-H: Mantel-Haenszel analysis method.

Table 99.3 Comparison of outcomes among DCO, ETC, and mixed approach for bilateral femur fractures.[18]

	DCO	ETC	Mixed	P (DCO vs ETC)
ISS, mean (SD)	31.1 (15.0)	23.5 (12.0)	19.9 (10.9)	<0.001
NISS, mean (SD)	37.5 (12.9)	31.2 (9.9)	42.5 (16.4)	<0.001
ICU stay, mean (SD), d	19.4 (25.6)	11.5 (9.9)	13.3 (15.1)	<0.001
Ventilation time, mean (SD), days	11.6 (15.6)	7.3 (9.4)	11.3 (14.9)	
OF (%)	55.3	39.6	37.5	0.02
MOF (%)	40.2	25.3	23.2	0.016
Sepsis (%)	21.6	12.0	13.5	0.081
Hospital mortality, n (%)	26 (13.5)	8 (8.4)	1 (1.7)	

The results of the pooled analysis demonstrate that the odds of ARDS and mortality are about 2.5 times higher in patients suffering from bilateral femur fractures as compared to patients with unilateral femur fractures. Moreover, patients with BFF have significantly protracted ICU/HDU and LOS stay compared to UFF patients.

A longitudinal cohort study conducted over a 15-year period (1993–2008), and based on the German registry for polytrauma patients, investigated the effect of the initial therapeutic approach on the final outcome of polytrauma patients suffering from bilateral femur fractures.[18] All included patients had been managed with a risk-adapted approach, meaning that there was a trend for primary definitive osteosynthesis of both fractured femora in less injured patients and for DCO in more severely injured ones. Thus, out of the initial cohort of 379 multiply-injured patients with bilateral femur fractures, almost half of them (51%, n = 193 patients) had been treated with DCO (bilateral temporizing ex-fix of both femora), 25% of them (n = 95 patients) with ETC (primary definitive IMN of both femora), 15.6% (n = 59 patients) with IMN on one side and temporary ex-fix on the other side (mixed subgroup), while 32 patients (8.4%) had not received any osteosynthesis of their fractured femora, because of their critical condition (*No* subgroup).

Compared with the ETC and mixed groups, patients of the DCO group were more severely injured (increased Injury Severity Score [ISS] and New Injury Severity Score [NISS] and more severe thoracic injuries) and required significantly longer stay in the ICU, significantly longer time of ventilation, while their complication and mortality rates were increased. Adjusted for injury severity, the standardized mortality rates between DCO and ETC subgroups did not differ significantly. Based on their results the authors

concluded that it was reasonable to treat the clearly stable patient with primary IMN of both femora (Table 99.3). It would be better to treat the potentially unstable patient with the DCO approach. When in doubt, it seems to be safer to use DCO as a risk-adapted approach.

Resolution of clinical scenario

- Bilaterality of femur fractures is a clear risk factor for systemic complications, and increased mortality.
- Adequately resuscitated, stable patients suffering from bilateral femur fractures could be safely treated with simultaneous IMN of both fractured femora.
- For the potentially unstable patient with bilateral femoral fractures, or when in doubt, the best treatment option seems to be a DCO approach.

Question 3: In open femur fractures, does early IMN result in increased complication rates compared to delayed IMN?

Rationale

Open femur fractures constitute high-energy injuries usually occurring within the context of polytrauma. Their prevalence among the cohort of multiply-injured patients with femur fractures has been recently estimated as high as 23%.[19] In this longitudinal cohort study including 5761 individuals with femoral fractures (77% closed and 23% open fractures) open femoral fractures demonstrated increased incidence of hemorrhagic shock in the prehospital setting, and required significantly more IV fluids and transfusions compared with the closed femur fractures.[19] Moreover, open femur fractures were associated with longer hospital and ICU stay, and increased risk of MOF. In a further subgroup analysis, based on the Gustilo classification, an increasing risk of sepsis, mortality, and MOF with increased grade of open injury was documented.

Clinical comment

While IMN is the gold standard treatment of closed femur fractures even in multiply-injured patients, its role in the subgroup of open femur fractures has to be critically evaluated.

Available literature and quality of the evidence

The most recent evidence on this topic was provided by:

- Level IV: 1 systematic review of the literature and meta-analysis.[20]

Findings

This review included 17 primary studies, mostly retrospective observational, with only two prospective studies reporting on the treatment of open femur fractures with intramedullary nails. The study documented a summarized estimate of union rate at 97% (95% confidence interval [CI]: 94–99%, I^2 = 68.5%). As for complication rates, the pooled estimates of effect size for deep infection and malunion rates were 6% (95% CI: 1.5–6%) and 3% (95% CI: 1–5.6%), respectively. The overall rate of bone grafting was 3.5% (95% CI: 1.8–5.8%, I^2 = 34.5%).

Timing of nail fixation (*early fixation*– within 72 hours of injury vs *delayed fixation* –after 72 hours of injury) did not seem to affect the final outcome in terms of union or infection rates. However, increasing Gustilo grade of the open injury resulted in an increase of the odds of infection (3.5 times for Gustilo III open fractures as compared to grade I + II open femur fractures).

This review provided a low level of evidence due to the inclusion of low-quality component studies. However, these studies were the only available relevant material in the current literature.

Resolution of clinical scenario

- Treatment of open femoral fractures with IMN results in satisfactory union and acceptable infection rates, comparable to those observed in the management of closed counterparts.
- Scheduled secondary grafting, when needed due to traumatic bone loss, should be promptly addressed and, if so, satisfactory healing should be expected.
- While early IMN does not adversely affect union or infection rates, Gustilo grade III injuries predispose to higher deep infection rates, and strict adherence to established surgical debridement and fixation protocols is advocated.

Summary of answers

- Optimal timing of definitive femoral fracture fixation in trauma patients depends on the patient's physiologic condition and adequacy of resuscitation. A protocol of early (within 36 hours) definitive stabilization of femoral fractures after appropriate management of occult tissue hypoperfusion (and subsequent metabolic acidosis) seems to be feasible in most trauma patients. In the small proportion of patients not responding early to the resuscitation measures, a DCO approach is preferable.
- Bilateral femur fractures can be treated with simultaneous IMN, provided the patient is adequately resuscitated and physiologically stable. In case the patient's physiologic stability is in doubt, the DCO approach should be undertaken.

- Immediate IMN is the hallmark of the treatment of open femur fractures. Extreme vigilance should be paid in in Gustilo III open femur fractures as their odds of being infected is 3.5 times higher than Gustilo I + II open fractures.

100
Distal Femur Fractures

Graeme Hoit MD[1], Amir Khoshbin MD[1] and Rudolf W. Poolman MD PhD[2]
[1]Department of Orthopaedic Surgery, University of Toronto, Toronto, ON, Canada
[2]Leiden University Medical Center, Amsterdam, The Netherlands

Clinical scenario

- A 66-year-old woman presents to the Emergency Department with significant pain and deformity to her right lower thigh after falling off a step ladder. X-rays demonstrate a distal femur fracture. You are consulted as the orthopedic surgeon on call.
- She would like to know what the best way to fix her fracture is and is quite insistent on doing everything possible to avoid a second operation.
- She has also recently heard about the expedited surgery of hip fracture are receiving on the news and wonders if this is applicable to her as well.

Top three questions

1. In patients undergoing distal femoral fixation, do locking plates result in less construct failures and nonunions than nonlocking constructs?
2. In geriatric patients with distal femur fractures, does early surgery result in improved morbidity and mortality in comparison with delayed surgery?

3. In patients undergoing lateral locking plate fixation, are some patient and surgical factors, such as patient BMI, plate length, etc., more likely to result in nonunion and mechanical failure compared to other factors?

Question 1: In patients undergoing distal femoral fixation, do locking plates result in less construct failures and nonunions than nonlocking constructs?

Rationale

Locking plates have become widely used throughout trauma orthopedics because of their assumed increased stability, ability to find fixation in osteoporotic bone, and often their precontoured nature.[1] However, there is concern regarding a potential for nonunion when applied to distal femoral fractures.

Clinical comment

Distal femoral fractures have been reported to go onto nonunion at a rate of 6–24%.[1–3] Nonunions have been demonstrated to have devastating consequences for patients' physical, psychosocial, and financial wellbeing as well as lead to significant healthcare system costs.[4–6] Additionally, mechanical failure (often contributory to nonunion) has been identified as a significant problem in distal femoral fractures, resulting in the need for re-operation in 4% of cases.[7] With this in mind, the surgical techniques used to fix distal femoral fractures should

attempt to minimize the nonunion rate and requirement for re-operation.

Available literature and quality of the evidence

A 2015 Cochrane review by Griffin et al. (level II) for distal femoral fractures included six studies examining surgical fixation methods, including preliminary data from two studies that compared locking plates versus intramedullary (IM) nailing and the dynamic condylar screw (DCS), respectively.[8] No differences were found between locking plates and other interventions in this review in terms of union rates or mechanical failures. Similarly, a small randomized controlled trial (RCT) (level II) by the Canadian Orthopaedic Trauma Society of 52 patients with distal femoral fractures were randomized to either locked plating with the Less Invasive Stabilization System (LISS) or DCS.[9] Significantly more DCS patients achieved bony union without subsequent intervention in comparison to LISS plating.

A meta-analysis (level II) by Koso et al. synthesized the results of 11 level II and 3 distal femoral fracture studies including 505 patients.[7] They found no significant differences in nonunion rates, reoperation rates, or mechanical failures when comparing plating constructs versus IM nails – they did not differentiate between locking and nonlocking plates. The LISS was compared specifically to other constructs, which included IM nails, other locking plates, DCS, and nonlocking plate constructs and was found to have significantly fewer mechanical failures.

The Southeast Fracture Consortium compared locking compression plating to LISS for distal femoral fixation in a retrospective review (level III) of 339 patients.[10] No significant difference was found between the two constructs for mechanical failure or nonunion rates.

Findings

Based on the current available evidence, it is unclear if locking plates provide any benefit over other constructs. This is especially apparent as the predominant locking plate option reported on in the literature is the LISS, which is no longer as widely used with the advent of other commercial locking plates that are marketed as less rigid to avoid nonunion.[9,11] There is a need for high-quality evidence examining the optimal fixation method for distal femoral fractures.

Resolution of clinical scenario

- Level II and III evidence provides mixed results for the benefit of locking plates over other constructs for distal femoral fractures. Given the current literature, no resolution was reached.

Question 2: In geriatric patients with distal femur fractures, does early surgery result in improved morbidity and mortality in comparison with delayed surgery?

Rationale

Increasingly, attention has been drawn to the effect of surgical delay on the morbidity and mortality of geriatric orthopedic patients. Definitive evidence to this effect for hip fracture patients has changed the clinical landscape with clinical practice guidelines recommending early surgery.[12,13] Whether or not a similar action should be applied to distal femur fractures in the geriatric population is an important question to answer.

Clinical comment

Distal femur fractures occur in a bimodal distribution in the population, with an increased frequency in young trauma patients and in elderly patients with osteoporotic bone.[14,15] The patient profile of low-energy distal femur fractures is similar to the hip fracture population in terms of demographics and comorbidities. Elderly patients who suffer a distal femur fracture are at significant risk of postoperative complications and/or mortality. The one-year mortality rate has been reported as up to 38% post distal femur fracture,[16–18] which is similar to hip fractures.[19] Several studies have evaluated patient and surgical factors affecting mortality of patients with distal femoral fractures, including surgical delay.

Available literature and quality of the evidence

Evidence from retrospective reviews has produced mixed results as to whether surgical timing has an impact on patient mortality for distal femur fractures. In 2018, Myers et al. reviewed 283 elderly patients with distal femur fractures (level III) and found significantly higher 30-day, 60-day, and one-year mortality when surgery occurred more than two days after admission.[20] Moloney et al. also examined 176 elderly patients with distal femur fractures in a retrospective cohort (level III) and similarly found a significantly higher one-year mortality in patients with delay to surgery greater than two days.[21] Streubel et al. (level III) found a similar association between surgery delayed more than four days from injury and six-month and one-year mortality in their review of 92 elderly patients with distal femur fractures.[16]

However, the impact of surgical delay on mortality has not been found consistently by other studies; however, a 2017 retrospective study using the Danish fracture database

(level III) examined 90-day mortality of patients aged >50 and found no association with surgical timing.[22] Kammerlander et al. (53 patients, level III) and Brogan et al. (80 patients level III) also did not demonstrate a mortality difference between early and delayed surgery.[23,24]

Findings

Based on the current available evidence, it is unclear if early surgery provides any mortality benefit for geriatric patients with distal femur fractures. There is a need for large, multicenter, population-based studies examining surgical timing, as well as meta-analyses of the currently available data for a more conclusive answer to this problem.

Resolution of clinical scenario

- Level III evidence provides mixed results if delay to surgery affects postoperative mortality in geriatric patients with distal femur fractures. Thus, given the current literature, no resolution can be reached.

Question 3: In patients undergoing lateral locking plate fixation, are some patient and surgical factors, such as patient BMI, plate length, etc., more likely to result in nonunion and mechanical failure compared to other factors?

Rationale

The postoperative nonunion rate in distal femoral fractures has been estimated to be 6–24%.[1–3] Significant attention should be given to ways to reduce nonunions in these patients, and as such an understanding of patient and provider risk factors for developing nonunion must be understood.

Clinical comment

In recent years, lateral locked plating has become the predominant means of fixation for distal femoral fractures over previously popular fixed angle devices such as DCS, blade plates, and retrograde IM nails.[25] Early results of studies examining lateral locking plates showed very promising results with possible improvements in nonunion rates in comparison to other fixed angle devices.[26,27] However, other studies have since reported higher nonunion rates and called into question whether locking plate are contributory to nonunions in this patient population.[28–30] Understanding patient and surgical risk factors for developing nonunion, as well as strategies to mitigate these factors are important in avoiding postoperative complications.

Available literature and quality of the evidence

Several large retrospective reviews and biomechanical studies have examined risk factors for nonunion after distal femoral fixation with a lateral locking plate. A large population-based review by Ricci et al. (level III) of 335 patients found that diabetes and open fractures were risks for developing nonunion, and that open fractures, smoking, obesity, and shorter plate length (eight or fewer holes) to be associated with implant failure.[25] Similarly, Rodriguez et al. (level III) performed a retrospective case control study of 283 distal femoral fracture patients after lateral locked plate fixation.[31] They found that obesity, open fracture, and

occurrence of infection were patient risk factors for developing nonunion. Additionally, the use of stainless-steel plates resulted in significantly more nonunions than titanium plates attributable to construct rigidity. In a separate analysis on a similar dataset, the authors examined other construct factors and once again demonstrated the use of stainless steel as a risk factor but did not find a significant difference for screw density or plate length.[3]

Peschiera et al. (level III) examined surgical factors that contributed to nonunions in 116 distal femoral fractures and found that malreduction, particularly with varus malalignment, as well as medial cortical bone defect were associated with developing nonunion.[2] This led to the authors' recommendation that if medial cortical bony contact could not be achieved with primary fixation bone grafting be used to avoid nonunion, though this method itself has not been well studied.

Findings

Level III studies are the best available evidence for answering which factors are more likely to lead to nonunion in distal femoral fractures. Patient factors of obesity and smoking result in more nonunions and mechanical failures, respectively. Injury factors such as open fractures and the development of infection have also been shown to increase the likelihood of nonunions. Stainless-steel plates, failure to obtain adequate reduction, and the lack of medial cortical support are surgical factors that have been shown to increase nonunion rates.

Resolution of clinical scenario

- Level III evidence demonstrates obesity, smoking, open fractures, infection, medial cortical gaping, and use of

stainless-steel plates result in a greater risk of nonunion and/or mechanical failure after locked plating for distal femoral fractures.

Summary of answers

- A lack of high-quality evidence exists comparing lateral locked plating of distal femoral fractures with other constructs.
- The effect of using locking plates on the nonunion rates for distal femoral fractures is unclear.
- Based on current literature, it is unclear if delay to surgery affects postoperative mortality of geriatric patients with distal femur fractures.
- Obesity, smoking, open fractures, infection, malunion, medial cortical gaping, and use of stainless-steel plates result in greater risk of nonunion and/or mechanical failure after locked plating for distal femoral fractures.

Division of Orthopaedic Surgery, Department of Surgery, Sunnybrook Hospital, University of Toronto, Toronto, ON, Canada

Clinical scenario

- You are an orthopedic staff on call and are asked to see a 48-year-old male who has fallen from a ladder. He has sustained a closed injury to his right proximal tibia. Radiographs reveal a bicondylar tibial plateau fracture.
- You review the case and decide that this patient will require an operation. When considering the operative treatment options, you wonder if treatment with external fixation leads to a decreased rate of complications when compared to open reduction and internal fixation.
- When considering treatment for this patient, you anticipate he will require bone graft to fill a bone defect after reducing the fracture fragment. Should you use bone substitute, iliac crest bone graft, or neither?
- Lastly, you are describing the likely postoperative course for this patient. He asks if he will return to having full preoperative range of motion (ROM). Unsure, you review the most recent evidence on

predictive factors for postoperative knee stiffness in patients treated operatively for tibial plateau fractures.

Top three questions

1. Amongst adult patients presenting with bicondylar tibial plateau fracture, does open reduction and internal fixation, when compared to external fixation with use of limited open techniques, lead to fewer operative complications?
2. Amongst adult patients who have proximal tibial fractures with metaphyseal bone defects, does iliac crest bone grafting (ICBG), when compared to bone substitute (calcium phosphate or other), improve patient-reported and radiographic outcomes?
3. Amongst adult patients who have undergone operative treatment for a tibial plateau fracture, what patient and injury-specific factors, when compared to the general population, yield improvement in knee ROM at one-year follow-up?

Question 1: Amongst adult patients presenting with bicondylar tibial plateau fracture, does open reduction and internal fixation, when compared to external fixation with use of limited open techniques, lead to fewer operative complications?

Rationale

There are a number of treatment options for complex proximal tibia fractures.1 External fixation, combined with limited open techniques can potentially reduce complications but potentially limit the ability to obtain optimal reductions.2 Open plating techniques can allow a more precise reduction, but risk complications. When performing an open reduction and internal fixation (ORIF), the surgeon must consider choice of incision and approach(es) to achieve surgical goals while limiting complications as well as considering the need for future procedures.

Clinical comment

In patients with orthopedic injuries, it is often a challenge to decide amongst treatment options, as it is often unknown which treatments offer the lowest acceptable rate of complications, while still remaining a cost-effective option. Treatment with ORIF with two plates inserted via an anterior or two incisions may have a higher complication and re-operation rate. Patients often prefer to avoid the prolonged use of external devices as is necessary compared with limited ORIF with circular external fixator. There is insufficient evidence to definitively guide choice between ORIF, hybrid external fixation, and unilateral locked plating in proximal tibia fractures.

Available literature and the quality of the evidence

Level I: 2 prospective comparative trials were identified in the literature.

Level II: 1 meta-analysis of both randomized and nonrandomized trials.

Findings

A trial from the Canadian Orthopaedic Trauma Society (COTS) compared closed/limited open reduction and circular external fixation with ORIF via midline or two-incision methods using nonlocking implants.[3] The patients were limited to high-energy fractures classified as Schatzker 5/6 injuries (AO 41-C). The authors identified Hospital for Special Surgery knee scores at two years postoperatively as their primary outcome with an a priori power calculated to predict a 25% difference with their sample size of 82 patients. There was no significant difference in HSS knee scores at two years (primary outcome) between groups ($p = 0.31$). However, the external fixation group was found to have a trend to earlier functional recovery with better HSS knee scores at six months postoperatively ($p = 0.064$). The ORIF group was found to have a 17% (8/40) infection rate versus 4.7% (2/43) in the external fixation group ($p = 0.032$). The ORIF group was found to have a larger number of unplanned procedures (37 vs 16, $p = 0.001$) which were often of significant magnitude, including one above-knee amputation. Other secondary outcomes of Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC) scores, quality of reduction, development of osteoarthritis, and Short Form 36 (SF-36) scores were similar between groups.

Jiang et al. randomized 84 patients with bicondylar tibial plateau fractures to either double plating through two incisions or lateral locked plating with the LISS device.[4] Some limitations of this study include concerns that details of the randomization process were not clear and that a priori primary and secondary outcomes were not discussed. However, a power calculation for HSS scores was presented, which is presumably the primary outcome. This group found no significant difference in HSS score at 12 or 24 months postoperatively ($p = 0.215$ and $p = 0.84$). They

also found no significant difference in infection rate (2/43 using double plating vs 3/41 using LISS p = 0.96) or other complications.

A recent meta-analysis was completed comparing patients receiving external fixation versus ORIF for complex tibial plateau fractures.[5] In summary, patients treated with external fixation tended to return to preinjury level faster than those treated with ORIF, but ultimately there was no difference in functional score at final follow-up. Conversely, ex-fix patients had higher pooled rates of superficial infection (odds ratio [OR] = 1.93; 95% confidence interval [CI]: 0.17–22.53; p = 0.01), venous thromboembolism (OR = 1.56; 95% CI: 0.49–4.96; p = 0.45) and higher re-operation rate (OR = 0.77; 95% CI: 0.40–1.49; p = 0.44) and lower rates of compartment syndrome (OR = 0.61; 95% CI: 0.12–3.20; p = 0.56). However, only superficial infection risk was found to be significantly different between groups.

There is insufficient evidence to recommend external fixation with limited open reduction over open reduction and internal fixation (overall quality: moderate).

Resolution of clinical scenario

- The best available data suggest no obvious difference between limited open reduction with external fixation versus formal open reduction.
- Surgeon experience and patient choice can be used to determine a preferred approach for each particular patient scenario
- Large prospective studies are required to determine which groups of patients will do better with each intervention

Question 2: Amongst adult patients who have proximal tibial fractures with metaphyseal bone defects, does iliac crest bone grafting (ICBG), when compared to bone substitute (calcium phosphate or other), improve patient-reported and radiographic outcomes?

Rationale

Proximal tibia fractures are often associated with a component of joint surface depression.6 Elevation of the joint surface to its anatomic location leaves behind a metaphyseal bone void of variable size. It is common practice to fill this resultant void with supportive material to augment internal fixation and support elevated articular bone fragments.7 Autograft bone, usually from the iliac crest, has been used historically. Several bone graft substitute materials have been introduced recently, in part due to the known morbidity of bone graft harvest.8

Clinical comment

The development of substitutes is a widely developing practice with multiple companies offering various branded options. However, the safety of these bone substitutes, as well as their effectiveness, remains unclear. ICBG is widely considered the gold standard for filling substantial bone defects, though the donor site morbidity is significant. The choice to use one or the other presents a challenging decision for the patient and the surgeon.

Available literature and quality of the evidence

- Level I: 2 randomized controlled trials (RCTs).
- Level II: 1 systematic review and meta-analysis of comparative studies.
- Level II: 4 prospective cohort studies.
- Level IV: multiple case series and case reports.

Findings

Multiple recent trials have compared use of bone substitutes, of various kinds, to ICBG. In 2008, Russell et al. published a prospective RCT comparing calcium phosphate bone substitute to ICBG.[9] In this trial, 120 acute tibial plateau fractures were randomized to either ICBG or alpha-BSM (a type of calcium phosphate bone substitute). In this study, alpha-BSM was significantly more likely to prevent radiographic subsidence of the tibial plateau ($p = 0.009$, no CI: reported). However, no patient-reported outcomes were measured or compared.

Nusselt et al. . completed an RCT in 2014 comparing a bioabsorbable calcium phosphate cement to ICBG.[10] Unpublished results from conference abstracts relay that this bone substitute was noninferior to ICBG in SF-12 scores at six-month follow-up.

Lastly, the most recent systematic review evaluating use of bone substitutes used in the management of bone defects in the tibial plateau fractures was completed in 2013.[11] This review described that overall subsidence rates were lowest in calcium phosphate substitutes (3.6%) and highest in calcium sulphate groups (11.1%) when a radiographic cut-off of >2 mm was used to qualify as subsidence (no p values or CI: were reported). The rate of complications was not measurably different between groups, while patient pain scores in the early postoperative period favored bone

substitute. Overall, the review supported the use of bone substitutes in depressed tibial plateau fractures.

Resolution of clinical scenario

- Level I evidence support the use of calcium phosphate bone graft over ICBG to improve radiographic subsidence. Additionally, the donor site morbidity from ICBG should remain a consideration when choosing bone substitute. Similar results would be expected when evaluating allograft ICBG, though minimal head-to-head evidence exists.
- Level IV evidence suggesting patient functional scores are equivocal when considering bone substitute or ICBG.

Question 3: Amongst adult patients who have undergone operative treatment for a tibial plateau fracture, what patient and injury-specific factors, when compared to the general population, yield improvement in knee ROM at one-year follow-up?

Rationale

Knee stiffness following operative fixation of tibial plateau fractures is an unfortunate but relatively common complication.[12] Knee stiffness can result from injury to the soft tissue envelope, muscle atrophy, or arthrofibrosis.[13] Significant intra-articular adhesions may require a secondary arthroscopic lysis of adhesions to improve ROM.

Clinical comment

Stiffness is always considered a potential complication of any articular or periarticular injury, particularly those involving the tibial plateau. Patient and injury-specific factors could provide insight into which patients will predictably have better or worse recovery of knee ROM.

Available literature and quality of the evidence

- Level II: 1 prospective cohort study.
- Level II/III: 2 retrospective cohort studies.
- Level II /III: 2 systematic reviews of nonrandomized studies.
- Level III: 2 case control studies.

Findings

Kugelman et al. reported on a prospectively collected cohort of patients followed at a single academic center over 11 years.[14] The 266 patients involved in this study completed a mean of 17 months of follow-up. After regression analysis, bilateral injuries ($p = 0.02$, 1.16–9.12), increasing age ($p = 0.004$; 95% CI: −0.71 to −0.15), postoperative deep infection ($p = 0.003$; 95% CI: −15.12 to −3.01) were all significantly associated with decreased ROM, while increased time in external fixator ($p < 0.0001$; 95% CI: 1.29 to −1.7) reduced knee stiffness. A total of 10 patients (3.7%) required secondary procedure for arthrofibrosis.

Konda et al. examined 293 patients in a retrospective case series of patients with tibial plateau fractures, and found that patients with associated tibial eminence fractures had poorer ROM and functional scores at three months, six months, and one-year following injury than a matched

cohort of patients without tibial eminence fractures (p <0.01; ROM of 118.7 vs 126.9).[15] Reahl et al. described risk factors for postoperative knee stiffness in a case-control study.[16] The 110 patients who underwent subsequent surgery for knee stiffness following a tibial plateau fracture were matched with 319 patients who did not have any postoperative stiffness. Weeks in an external fixator (OR = 1.5 per week; 95% CI: 1.3–1.7; p <0.001) and presence of bilateral tibial plateau fractures (OR = 3.3; 95% CI: 1.2–9.1; p = 0.02) were implicated as significant risk factors for postoperative stiffness. Gittings et al. described in a retrospective case series that patients who underwent arthroscopic lysis of adhesions for knee stiffness following surgery for periarticular fractures improved significantly immediately postoperatively (from 72° to 127°).[17] However, these patients lose approximately half of their gains in ROM by final follow-up (mean ROM of 104°).

Christiano et al. reported on 117 patients assess in a case series.[18] In this group, patients were able to measurably increase short musculoskeletal functional assessment (SMFA) scores (p <0.01) until a plateau at six months – with no subsequent improvements afterwards (p = 0.92).

Resolution of clinical scenario

- Level II evidence that tibial eminence fractures, age, and deep infection are risk factors for postoperative knee stiffness in patients undergoing operative treatment for tibial plateau fractures. There is conflicting evidence on length of use of external fixators and whether it leads to better or worse postoperative ROM.
- Level IV quality evidence suggests patients continue to improve functional scores (SMFA) until six months

postoperatively (overall quality: low).

Summary of answers

- There is no measurable difference in outcomes between ORIF when compared to external fixation with limited open reduction for management of tibial plateau fractures.
- Bone substitute provides lower rates of plateau subsidence than ICBG without differences in complications.
- Tibial eminence fractures, bilateral tibial plateau fractures, older age, and presence of deep infection are risk factors for postoperative knee stiffness following fixation for tibial plateau fractures.

Tibial Shaft Fractures

Taylor Yong MD MS[1], Ilda Molloy MD MS[1], and Leah Gitajn MD[1]
Dartmouth-Hitchcock Medical Center, Dartmouth Geisel School of Medicine, Lebanon, NH, USA

Clinical scenario

- A 32-year-old male presents to the Emergency Department following a motorcycle collision.
- On examination, swelling and deformity of the left lower extremity are noted. There is a small open wound that probes to fracture.
- Neurovascular exam is normal, and there are no signs of acute compartment syndrome.

Top three questions

1. In tibial shaft fractures, does intramedullary (IM) nailing offer better outcomes compared with open reduction and internal fixation (ORIF)?
2. In open tibial shaft fractures, does IM nailing offer improved outcomes compared to external fixation?
3. In tibial shaft fractures (open and closed), what is the effect of reamed versus unreamed intramedullary (IM) nailing in the rates of major re-operations and secondary complications?

Question 1: In tibial shaft fractures, does intramedullary (IM) nailing offer better outcomes compared with open reduction and internal fixation (ORIF)?

Rationale

Although the patient in the example provided has an open tibial shaft fracture, it is important to know which intervention (casting, external fixation, plating, IM nailing) is supported by the evidence across a variety of clinical scenarios.

Clinical comment

Tibial shaft fractures are among the most common long bone fractures encountered by orthopedic surgeons with almost 500 000 occurring annually.[1,2] Tibial shaft fractures often represent high-energy injuries and account for a significant proportion of open fractures.[3,4] The management of these injuries is challenging, and complication rates can be high. Further, the economic impacts, in terms of disability and utilization of healthcare resources, are broad.[5,6] Thus, command of current literature is critical with respect to the provision of safe and effective care to patients with tibial shaft fractures. This enables the clinician to choose the best intervention for the patient and clinical scenario while offering appropriate counseling and education regarding the treatment options.

Available literature and quality of the evidence

There is limited literature available that directly compares ORIF to IM nailing in closed, diaphyseal tibial shaft fractures. In general, IM nailing has supplanted ORIF as the preferred method of treatment for the majority of practicing orthopedic surgeons as ORIF has been associated with significant soft tissue concerns.[2,7] It should be noted that there is additional controversy in the setting of extra-articular proximal and distal metaphyseal tibial fractures due to higher rate of malunion with IM fixation.

This question was answered based on three systematic reviews/meta-analyses and two randomized clinical trials with limitations:

- Level I: 3 systematic reviews/meta-analyses.
- Level II: 2 randomized controlled trials (RCTs) with limitations.[8,9]

Findings

The two reviews utilized pooled data from primarily observational studies to evaluate treatment options in closed tibial shaft fractures. With regard to surgical options, Littenberg et al. demonstrated faster time to union in plate fixation without differences in rates of nonunion. Rates of deep infection were lower with the use of IM nail.[10] Coles and Gross performed a systematic review and meta-analysis, including 13 studies with 895 tibial shaft fractures.[11] They reported that plate fixation resulted in lower rates of delayed union and nonunion (2.6% with plate fixation, 8.0% with reamed nailing, and 16.7% with unreamed nailing), but higher rates of infection (9% for plate fixation, 2.9% for reamed nailing, and 0.5% for unreamed nailing).[11] In general, survey data suggest that the benefits in terms of time to union do not offset the

perceived risks of soft tissue and infectious complications.[7] As a result, IM nailing is the preferred method of operative treatment for closed diaphyseal tibial shaft fractures.

With regards to distal metaphyseal tibial shaft fractures, data are derived from one systematic review of 11 randomized control trials evaluating ORIF versus IM nail.[12] This systematic review demonstrated that there were no significant differences between IM nail and locking plate fixation with regards to nonunion, delayed union, deep infection, union time, AOFAS score, and Disability Rating Index. However, IM nail fixation was associated with a higher rate of malunion (relative risk [RR] = 1.76; 95% confidence interval [CI]: 1.21–2.57; p = 0.003), a lower rate of superficial infection (RR = 0.29; 95% CI: 0.13–0.63; p = 0.02), and a higher foot function index (mean difference [MD] = 0.09; 95% CI: 0.01–0.17; p = 0.02).[12]

Resolution of clinical scenario

Although ORIF is associated with lower rates of nonunion and faster time to union, IM nailing is the consensus surgical option for the management of closed diaphyseal tibial shaft fractures primarily due to concerns regarding soft tissue and infection. The quality of the evidence is poor as direct comparative studies are limited.

Question 2: In open tibial shaft fractures, does IM nailing offer improved outcomes compared to external fixation?

Rationale

Open tibial shaft fractures are challenging injuries faced by orthopedic surgeons regularly. These injuries are often

associated with significant soft tissue injury as classified by the Gustilo and Anderson system. It is imperative that surgeons are aware of evidence-based treatment options to avoid complications and disability.

Clinical comment

There are many controversies in the treatment of open tibial shaft fractures. High-energy open tibia fractures present a significant clinical challenge with high rates of hospital re-admission for complications and poor longer-term outcomes associated with these complications.[13,14] Traditional treatment protocols typically utilize IM nails or plates for fracture fixation, which has the disadvantage of placing metal within the fracture site. Multiple studies demonstrate that infection rates tend to increase whenever hardware is placed within a wound[15,16] Use of definitive external fixation (either traditional uniplanar frames or circular multiplanar frames) for treatment of open tibial shaft fractures does not place any hardware at the fracture site. However, in the past, there have been issues with malunion, nonunion, and limitations in patient mobility.[17] It is important to consider the relative risks and benefits of these treatment options in an effort to avoid complications which can be prevalent with these injuries.

Available literature and quality of the evidence

This question was answered based on a systematic review and meta-analysis, one randomized trial, and two prospective studies.

- Level I: 2 systematic reviews and meta-analyses, 1 randomized trial.[18–20]
- Level II: 2 prospective cohort studies.[21,22]

Findings

Foote et al. conducted a recent meta-analysis primarily evaluating the rate of re-operation for different fixation strategies in open tibial shaft fractures.[19] Five studies assessing unreamed IM nailing versus external fixation were included. These studies demonstrated a lower odds of re-operation in the unreamed nailing group compared to external fixation (OR = 0.38; 95% CI: 0.23–0.62). They also completed a meta-regression to assess the effect of Gustilo grade on odds of re-operation in these groups which revealed no difference in effect (p = 0.84), indicating consistency across Gustilo grades. These findings were consistent with a prior systematic review and meta-analysis by Bhandari and colleagues in 2001.[18]

Inan et al. performed a randomized trial of type IIIA open tibial shaft fractures treated by circular wire external fixation versus unreamed IM nails.[20] Their results demonstrated shorter time to union (19 weeks vs 21 weeks; p = 0.04) and fewer knee contractures in the IM nail group. They did not detect a significant difference in the rate of deep infection. Kakar and Tornetta performed a prospective cohort study of 143 type I–III open tibial shaft fractures treated with immediate unreamed IM nails that showed a low incidence of deep infections (3%) and implant failures (3.5%).[21] Henley et al. demonstrated decreased risk of re-operation without difference in infection rate in a quasi-randomized comparative study of type II, IIIA, and IIIB open tibial shaft fractures.[22] There is good evidence to support the use of IM nailing in open tibial shaft fractures. This should be applied with caution with regard to injuries with more extensive soft tissue damage such as types IIIB and IIIC as further study is warranted.

O'Toole et al. in association with the Major Extremity Research Consortium (METRC) is actively enrolling patients into a randomized pragmatic trial designed to address this issue in severe open tibia fractures.[23] In this

study patients with severe open tibia fractures are randomized into circular external fixation versus internal fixation arms (IM nail and/or plate). Patients who decline randomization may enroll into the observation arm of the study in which the patient chooses their fixation strategy (external vs internal fixation) and identical follow-up data are collected. The primary outcome is rehospitalization for major limb complications and secondary outcomes include infection, fracture healing, limb function, and patient-reported outcomes regarding function and pain. This study, with its rigorous methodology, will provide important high-quality guidance regarding optimal management of these severe injuries in coming years.

Resolution of the clinical scenario

- In the case of open diaphyseal tibial shaft fractures, IM nailing is supported overuse of plating or external fixation due to lower re-operation rates and shorter time to union without changes in rate of deep infection.
- Extent of soft tissue injury is an important consideration. Further studies are required with regard to more severe soft tissue damage in type IIIB and IIIC injury patterns.

Question 3: In tibial shaft fractures (open and closed), what is the effect of reamed versus unreamed intramedullary (IM) nailing in the rates of major re-operations and secondary complications?

Rationale

The patient has an open tibial shaft fracture that will be treated with IM nailing. You are unsure whether reaming will result in better outcomes for your patient.

Clinical comment

The use of reamed versus unreamed IM nailing of long bone fractures has long been a topic of discussion. Unreamed nails may preserve endosteal blood supply and improve fracture healing rates. Reamed nails, however, offer greater mechanical stability at the fracture site due to their larger size at the expense of the endosteal blood supply.

Available literature and quality of the evidence

Several randomized control studies and the pooled results of a meta-analysis were used to address the question.

- Level I: 3 systematic reviews/meta-analyses (one includes all long bones – tibia and femur).[24–26]
- Level I: 3 randomized trials (level I).[13,15,27]

Findings

Multiple level I studies show no clear difference in major re-operations or complications between reamed and unreamed IM nailing of combined open and closed tibial shaft fractures. Sub-analyses between open and closed fractures, however, have shown that reamed closed tibial fractures may have a reduction in re-operation compared to open fractures. Studies measuring patient function and quality of life corroborate these findings.[24–27]

- Moderate quality evidence has shown no statistically significant differences between reamed and unreamed tibial nailing groups for combined open and closed

fractures in “major” re-operations (RR = 0.88; 95% CI: 0.64–1.21; five trials), or in the secondary outcomes of nonunion, pain, deep infection, malunion, and compartment syndrome. Subgroup analysis, however, suggests that reamed nailing reduces the incidence of re-operations related to nonunions in closed fractures compared to open fractures.[25]

- Benefits of reaming for closed fractures were also supported by a large multicenter RCT that found a 33% reduction in having a re-operation with reamed versus unreamed IM (RR = 0.67; 95% CI: 0.47–0.96; p = 0.03) in closed tibial fractures. This reduction was largely due to differences in dynamization.[15]
- No significant differences in adverse effects were found between reamed and unreamed nails in open tibial fractures. A pooled meta-analysis of four studies found no difference in healing rate, secondary surgery rate, implant failure rate, compartment syndrome, and infection between reamed and unreamed nails in open tibial fractures (p >0.05 for all outcomes).[26]
- There were no differences between the reamed and unreamed groups at 12 months for either the Short Form 36 (SF-36) physical component score (42.9 vs 43.4; 95% CI: 22.1–1.1; p = 0.54) or the short musculoskeletal functional assessment (SMFA) dysfunction index (18.0 vs 17.6; 95% CI: –2.2 to 2.9; p = 0.79).[13]

Resolution of clinical scenario

- There is no difference in major re-operations or complications between reamed and unreamed IM nailing of tibial shaft fractures (combined open and closed).

- Closed tibial fractures treated with a reamed IM nail appear to have decreased re-operations related to nonunions.

Summary of answers

- IM nailing is the preferred method of operative treatment for closed diaphyseal tibial shaft fractures.
- IM nailing is the preferred method of treatment for open diaphyseal tibial shaft fractures.
- There is no demonstrable difference in major re-operations or complications between reamed and unreamed nails for tibial shaft fractures (combined open and closed). Subgroup analyses, however, show reamed nails appear to have a lower risk of re-operation for closed fractures.

103
Intra-Articular Distal Tibia (Pilon/Plafond) Fractures

Luc Rubinger MD[1], Seper Ekhtiari MD MSc[1], and Peter J. O'Brien MD[2]
[1]Division of Orthopaedic Surgery, Department of Surgery, McMaster University, Hamilton, ON, Canada
[2]Department of Orthopaedic Surgery, University of British Columbia, Vancouver, BC, Canada

Clinical scenario

- A 30-year-old man who was involved in a motor vehicle accident comes in as a trauma team activation. He has been cleared on primary and secondary survey. He has suffered an isolated injury to his right ankle. His chief complaint is pain, swelling, and inability to weightbear on his right lower extremity. He is diagnosed with a distal tibia intra-articular fracture (i.e. *pilon* or *plafond*) on x-ray.
- On physical examination, there are no open wounds, there are intact dorsalis pedis and posterior tibial pulses with only moderate swelling. Computed tomography (CT) scan confirms an intra-articular multifragmentary distal tibia fracture with proximal displacement of the talus, an AO43 type C fracture.[1]
- As the most responsible physician caring for this patient, you consider the most appropriate management plan in terms of operative approach, immediate versus delayed fixation, and the use of external fixator in the treatment for pilon fractures.

Top three questions

1. In patients undergoing operative management for distal tibia intra-articular fractures, does staged open reduction and internal fixation (ORIF) result in better clinical and postsurgical outcomes compared to acute fracture management?
2. In patients undergoing operative management for distal tibia intra-articular fractures, does definitive management with limited internal fixation with external fixation result in better clinical and postsurgical outcomes compared to ORIF (early or delayed)?
3. In patients undergoing operative management for distal tibia intra-articular fractures, does any specific surgical exposure result in better clinical and postsurgical outcomes compared to other exposures?

Question 1: In patients undergoing operative management for distal tibia intra-articular fractures, does staged open reduction and internal fixation (ORIF) result in better clinical and postsurgical outcomes compared to acute fracture management?

Rationale

Intuitively, ORIF is easiest to perform immediately after injury and before the development of organizing hematoma, soft tissue contraction, callus formation, and inflammatory osteopenia. However, the timing of definitive surgery depends on soft tissue integrity. Appropriate surgical

timing decreases the risk of wound complications, including skin slough and superficial and deep infection.

Clinical comment

The decision on when to operate depends on multiple factors such as age, general and current health, soft tissue integrity, and other injuries that influence the safe administration of anesthesia.[2]

Surgical intervention during maximal soft tissue swelling will lead to a higher risk of wound necrosis and infection. Early surgical intervention or delayed surgery as part of two-stage management is carried out when the soft tissue envelope is *favorable*. Specific clinical signs that help the surgeon decide if the soft tissue is ready include resolution of edema and fracture blisters and the return of skin wrinkling.

Available literature and quality of the evidence

Overall, there is limited high-quality evidence on the topic of acute versus delayed management of pilon fractures. There is one prospective cohort study (level II) and two retrospective cohort studies (level III) that specifically seek to answer this question.

Tang et al. retrospectively compared a cohort of 46 patients with closed type C pilon fractures who underwent surgery either within 36 hours of injury or had delayed treatment (level III).[3] Sajjadi et al. retrospectively studied 41 closed tibial pilon fractures, half of which were treated definitively within 24 hours, and the other half of which were treated with an external fixator within 24 hours then subsequent ORIF once soft tissues were amenable (level III).[4] In a prospective cohort study, Conroy et al. reported the results of early ORIF in 32 patients who suffered from open type B (21 patients) and type C pilon fractures (11 patients) (level

II).[5] They followed a *fix and flap* protocol by managing pilon fractures with early bone stabilization and flap coverage at the same time. In this study 28 patients were managed with early ORIF and early coverage using free muscle flaps and split skin graft, and four patients were managed with application of external fixation.

Findings

In their retrospective cohort (level III), Tang et al. found that there was no significant difference between groups regarding the rate of soft tissue complications, fracture union, and final functional outcome score. Further, the early fixation group had a significantly shorter mean time to fracture union and hospital stay.[3] Sajjadi et al. (level III) reported no significant difference in rate of infection (superficial or deep infection, osteomyelitis), malunion/nonunion, and patients' satisfaction with American Orthopaedic Foot and Ankle Society (AOFAS) score. Similar to Tang's study, Saijadi et al. reported significantly decreased length of stay with early ORIF.[4] In their study, Conroy et al. (level II) reported two amputations (6.2%), two deep infections (6.2%), and three malunions (9.3%).[5] After exclusion of the two amputees, all 30 remaining patients progressed to clinical and radiological union. They concluded their *aggressive protocol* showed excellent union rate, low rate of infection, and good functional outcome.

At least two major differences can be identified between the studies above that endorse the use of early ORIF, and the lower-quality studies that historically reported much higher complication rates[6–9]: the mechanism of injury and status of the soft tissues. In the more recent, higher-quality evidence, when soft tissue integrity and fracture type are taken into account, early ORIF represents a reasonable and comparable option to delayed fixation.

The approach most commonly used to treat high-energy pilon fractures is a two-stage procedure involving initial reduction and application of external fixator followed by definitive fixation about 10–21 days later when the soft tissue envelope is amenable (level II–III). There is, however, mounting moderate-quality evidence that tibial pilon fractures treated acutely within 12–24 hours, without evidence of extensive soft tissue trauma, do as well as those treated in delayed fashion (level II–III).

Resolution of clinical scenario

- Level II–III evidence suggests that acute ORIF of pilon fractures is a viable treatment option if: definitive management occurs within 48 hours, the injury is relatively lower energy (or torsional) with amenable soft tissues, by an experienced surgeon at a well-resourced facility with ability for *flap* management of soft tissue coverage issues.
- Level II evidence suggests acute ORIF decreased hospital length of stay.
- Two-stage protocol involves an ankle-spanning external fixation and delayed internal fixation once the soft tissue injury resolves.
- A two-stage approach is most appropriate for high-energy injuries with extensive soft tissue disruption including open injuries and those with extensive hemorrhagic fracture blisters (level II–III).

Question 2: In patients undergoing operative management for distal tibia intra-articular fractures, does definitive management with limited internal fixation with external fixation result in better clinical and postsurgical outcomes compared to ORIF (early or delayed)?

Rationale

In high-energy pilon fractures, the soft tissue envelope has been damaged by the injury. A second insult from surgical dissection may increase soft tissue complications. Maintenance of fracture length and stability decreases soft tissue swelling by helping to maintain vascular flow. In addition, with minimal dissection, the surgeon will avoid more insult to the vulnerable soft tissue envelope.

Clinical comment

As mentioned above, historically, poor outcomes have been reported with primary ORIF of high-energy pilon fractures and external fixation, and therefore became a popular treatment alternative. Fracture reduction through ligamentotaxis will maintain fracture length, provide fracture stabilization, and eventually promote soft tissue healing. Limited ORIF of the joint surface is utilized for articular fragments not anatomically reduced by ligamentotaxis.

Available literature and quality of the evidence

Two downgraded prospective randomized controlled trials (RCTs) and one meta-analysis (all level I) aim to answer this question.

In their RCT, Wyrsch et al. compared 18 patients who were treated with ORIF between 2 hours and 10 days of index injury, with 20 patients who were treated with external fixation with limited internal fixation. Patients were randomized using a quasi-random method (odd and even numbers) (level II).[10] Wang et al., in their 2015 meta-analysis in comparing ORIF and limited internal fixation combined with external fixation, analyzed nine studies (three RCTs and six non-RCTs) with 498 fractures (level II).[11] Wang et al. most recently evaluated patients closed B3- and C-type tibial pilon fractures randomized to either two-stage ORIF (27 patients) or limited incision and external fixation (29 patients)(level II).[12]

In their RCT, Wyrsch et al. reported 15 major complications in seven patients who had ORIF, necessitating 28 additional operations.[10] In the external fixation group there were four major complications in four patients, necessitating five additional operations. The authors found no significant difference in post-traumatic arthritis and concluded that external fixation with limited internal fixation was a satisfactory method of treatment of pilon fractures and was associated with fewer complications than early ORIF. Wang et al.'s meta-analysis found no significant differences in bone healing complications (risk ratio [RR] = 1.17; 95% confidence interval [CI]: 0.68–2.01; p 1/4 0.58]), nonunion (RR = 1.09; 95% CI: 0.51–2.36; p 1/4 0.82), malunion or delayed union (RR = 1.24; 95% CI: 0.57–2.69; p 1/4 0.59), superficial (RR = 1.56; 95% CI: 0.43–5.61; p 1/4 0.50), or deep (RR = 1.89; 95% CI: 0.62–5.80) infections, arthritis symptoms (RR = 1.20; 95% CI: 0.92–1.58; p 1/4 0.18), or chronic osteomyelitis (RR = 0.31; 95% CI: 0.05–1.84; p 1/4 0.20) between the two groups.[11]

Finally, in their RCT of 56 patients, Wang et al. reported two wound infections, one requiring reoperation, and one pin-tract infection in the two-stage ORIF group compared to no wound infections and 12 pin-tract infections in the limited incision and external fixation group ($p < 0.05$).[12] The external fixation group had higher rates of malunion, delayed union, and arthritis symptoms, but no statistical significance was demonstrated. Both groups resulted in similar ankle joint function. Logistic regression analysis, however, indicated that smoking ($p < 0.01$), increasingly severe fracture pattern ($p < 0.01$), and age ($p = 0.026$) were the factors significantly influencing the final outcomes.

Findings

When considered in the context of the aforementioned meta-analysis, there is no clear treatment that can be strongly recommended. External fixation appears to have fewer deep wound complications than ORIF, but it may be more prone to impaired union. Wang et al.'s more recent, methodologically sound quasi-RCT, however, suggested a trend toward a treatment advantage for ORIF, however not significant, over external fixation.[12] This study also illustrated that a number of variables important to the final outcome are not within the surgeon's locus of control, including the degree of fracture comminution, smoking status, and age.

Resolution of clinical scenario

- External fixation with limited internal fixation is a widely accepted mode of definitive treatment in pilon fracture management.
- The existing literature suggests that outcomes are better with ORIF at the expense of elevated infection

events, compared to the elevated malunion/nonunion events associated with external fixation and limited ORIF (level III/IV).

- There is not enough evidence to conclude whether two-stage ORIF or definitive management with an external fixator is superior; this is likely fracture-, surgeon- and patient-dependent.

Question 3: In patients undergoing operative management for distal tibia intra-articular fractures, does any specific surgical exposure result in better clinical and postsurgical outcomes compared to other exposures?

Rationale

The ankle soft tissue envelope is thin and vulnerable to wound complications.[13] Extensive soft tissue dissection may result in wound breakdown. The approach that allows for satisfactory fixation while causing the least amount of soft tissue compromise should be chosen.

Clinical comment

The surgical approach to a pilon fracture is primarily dictated by the fracture pattern and soft tissue status. The CT scan must be reviewed carefully as part of surgical planning for both reduction and fixation strategies. The goal is to achieve anatomic reduction of the joint surface, restoration of axial alignment of the nonarticular component, and application of appropriate fixation with meticulous soft tissue handling.

The classic approaches to distal tibia and fibula are: (i) anteromedial (1cm lateral to the anterior tibial crest), (ii) anterolateral (between the peroneal and extensor muscles), (iii) posterolateral (Harmon), (iv) posteromedial, (v) anterior, and (vi) direct lateral. The traditional surgical approach, described and recommended by the AO Group, is the *anteromedial approach* for the tibia and lateral for the fibula.[1]

Available literature and quality of the evidence

A prospective cohort (level II) and a comprehensive systematic review (level IV) have assessed the impact of surgical approach on wound and fracture healing in pilon fractures.

Howard et al. performed a prospective cohort (level II) which reported a low rate of wound complications in 46 pilon fractures with less than a 7 cm skin bridge between two or three skin incisions.[14] The authors concluded that, with careful attention to soft tissue management and surgical timing, incisions for pilon fractures may be placed less than 7 cm apart, allowing the surgeon to optimize exposures on the basis of the injury pattern.

More recently, Liu et al. (2016) conducted a systematic review (level IV) on the same topic. A total of 733 patients were included with type B and C fractures. The anterolateral approach was most common, accounting for one-third of the entire study population. The anterior approach had one of the lowest complication rates with a patient base that had a high proportion of type C fractures. The posterolateral and anteromedial approaches had markedly higher complication rates, although no formal statistics were displayed in that review.[15]

Findings

Weak evidence suggests that there are decreased complications associated with the anterior approach to pilon fractures. Nonetheless, given the weak evidence and complexity of these fractures, the approach to the fracture should be dictated by the fracture pattern and surgeon comfort.

Resolution of clinical scenario

- The surgical approach is dictated by anatomy of fracture and the status of the soft tissue.
- Careful physical examination and review of the CT scan will help the surgeon to choose the most appropriate surgical approach. Weak evidence suggests that the anterior approach is useful for type C fractures and is associated with lower complication rates (level IV).

Summary of answers

- Acute ORIF of tibial pilon fractures is a viable treatment option if: definitive management occurs within 48 hours, relatively lower energy (or torsional) injury with manageable soft tissue status.
- A two-stage approach is most appropriate for high-energy injuries with extensive soft tissue disruption including open injuries and those with extensive hemorrhagic fracture blisters.
- External fixation with limited internal fixation is a widely accepted mode of definitive treatment in pilon fracture management.
- The surgical approach is dictated by anatomy of fracture and the status of the soft tissue.

- Weak evidence suggests that the anterior approach is useful for type C fractures and is associated with lower complication rates.

Malleolar Fractures

Daniel Axelrod MD[1], and David W. Sanders MD FRCSC[2]
[1]Division of Orthopaedic Surgery, Department of Surgery, McMaster University, Hamilton, ON, Canada
[2]Division of Orthopaedic Surgery, Western University, London, ON, Canada

Clinical scenario

- You are on call and are asked to see a 23-year-old male who has suffered a rotational ankle injury after slipping on ice. The triage nurse asks if he should receive an x-ray before you see him and what clinical tools might be appropriate to decide that.
- Once the x-rays have been completed and you speak to the patient, you mention that he may have an injury to his ankle syndesmosis. The patient asks what various options there may be for treatment.
- You also notice on the lateral x-ray that the patient has a small posterior malleolus fracture. You are unsure if you should fix the posterior malleolus as it seems small. You wonder if adding additional fixation will improve this patient's outcomes.

Top three questions

1. Amongst adult patients presenting with low-energy inversion ankle injuries, are the Ottawa Ankle Rules (OAR), when compared to other ankle injury screening

tools, more accurate in diagnosing patients with ankle fractures?

2. Amongst adult patients, who have syndesmotic injuries proven with intraoperative stress testing, do novel suture button devices, when compared to standard screw fixation, improve the reduction of syndesmosis and patient-reported outcomes?
3. Amongst adult patients who have posterior malleolar ankle fracture, at what percentage of articular surface involvement does operative intervention, when compared to nonoperative management, yield improvement in patient-reported outcomes at one-year follow-up?

Question 1: Amongst adult patients presenting with low-energy inversion ankle injuries, are the Ottawa Ankle Rules (OAR), when compared to other ankle injury screening tools, more accurate in diagnosing patients with ankle fractures?

Rationale

Ankle injuries are among the most common reasons for visits to the Emergency Department.[1] Many patients do not require radiographic imaging, adding unnecessary cost and increasing wait times in the Emergency Department. Multiple screening tools have been developed to triage which injuries are at high risk for fractures and will require radiological investigation.[2]

Clinical comment

In order to deliver healthcare effectively, it is important to identify which patients require imaging in the Emergency Department and those that can be managed conservatively and discharged immediately. Furthermore, the most utilized decision-making tool (the OAR) was initially validated more than 25 years ago and primarily used at that time by emergency physicians.[3] Modern primary care involves associated healthcare professionals, including nurse practitioners and physiotherapists. Accordingly, the most accurate screening tool needs to be one that is appropriately utilized by all healthcare professionals.

Ottawa Ankle Rules[3]

Ankle radiographs are indicated if there is pain in the malleolar area and any of the following:

- Bone tenderness along the distal 6 cm of the posterior edge of the tibia or tip of the medial malleolus.
- Bone tenderness along the distal 6 cm of the posterior edge of the fibula or tip of the lateral malleolus.
- An inability to bear weight, both immediately and in the Emergency Department, for four steps.

Available literature and the quality of the evidence

The most relevant current literature consisted of:

- Level I: 2 randomized trials.[2,4]
- Level I: 2 systematic reviews of the literature and meta-analysis of comparative studies.[5,6]

Findings

Various decision-making tools regarding ankle fracture assessment have been reviewed in a number of prospective studies and a recent systematic review. In a 2015 randomized controlled trial (RCT), the OAR were shown to have better specificity than the Bernese Ankle Rules, at 0.97 and 0.69.[2] In a 2018 RCT, triage nurses using the OAR were able to detect ankle fractures more often than physicians using expertise alone.[3] Additionally, the proportion of ankle fractures missed was lower in the triage nurse group than the physician group. This study highlighted the ability to apply the OAR to a variety of healthcare professionals, not just emergency room physicians.[4]

Additionally, 66 studies evaluating the OAR were included in the most recent systematic review and meta-analysis.[5] Overall sensitivity of the OAR was found to 99.4%, while use of the OAR was found to reduce unnecessary medical imaging by ~30% across all settings and by 49% in sports centers.

When compared to other screening tools, a recent meta-analysis showed the OAR, Bernese Ankle Rules, and the Malleolar Zone Algorithm to result in a negative likelihood ratio of 0.12, 0.14, 0.39, and 0.23, respectively – highlighting that the OAR remains the most accurate decision tool for excluding fractures in the setting of an acute injury.[6]

Resolution of clinical scenario

- Level I evidence that the OAR are an accurate screening tool to exclude fracture in adult patients presenting with ankle fractures. These rules decrease use of radiography with a low likelihood of missing a fracture (overall quality: high).

- Level I evidence that the OAR are superior to other screening tests in excluding ankle fractures(overall quality: high).

Question 2: Amongst adult patients, who have syndesmotic injuries proven with intraoperative stress testing, do novel suture button devices, when compared to standard screw fixation, improve the reduction of syndesmosis and patient-reported outcomes?

Rationale

One of the promising aspects of suture button fixation for syndesmotic injuries is the ability to maintain reduction while allowing a small degree of motion of the syndesmosis once patients begin to weight bear, and a relative reduction in hardware-related complication compared to screw fixation.[7] Accordingly, it is important to understand if suture button fixation achieves its purported goals.

Clinical comment

The distal tibiofibular syndesmosis is a primary stabilizer of the ankle joint. Instability of this articulation has been shown to significantly increase joint contact pressures and thus predispose to secondary arthrosis and poor functional outcomes.[8] Suture button fixation is a relatively novel technique that has shown excellent functional outcomes when using in other operations, including anterior cruciate ligament reconstruction and distal biceps repairs.[9]

Common complications following syndesmotic fixation in ankle fractures with screws include failure to maintain reduction and hardware failure.[10] It has been proposed that a suture button technique allows for a more physiologic relationship between the distal tibia and fibula and thus retains syndesmotic reduction once patients begin to weight bear. However, the per-unit cost of a given suture button system far exceeds that of typical screw fixation and thus excellent evidence is required to support the use of this implant.

Available literature and quality of the evidence

The most relevant current literature consisted of:

- Level I: 3 randomized trials.[11–13]
- Level I: 1 systematic reviews of the literature and meta-analysis of comparative studies.[14]

Findings

There has been significantly increased interest in suture or dynamic fixation of the syndesmosis in the past 10 years. A recent multicenter RCT found dynamic fixation of acute ankle syndesmosis to result in better clinical and radiographic outcomes at minimum two-year follow-up, with lower re-operation rates.[11] Laflamme et al. described the results following their prospective RCT. They noted that dynamic fixation of acute ankle syndesmosis rupture with a suture button device seems to result in modestly better clinical outcomes (Olerud Molander scores 93.3 vs 87.6, $p = 0.046$) and lower rate of hardware failure (36.1% vs 0%, $p < 0.05$).[12]

In 2015, Kortekangas published an RCT comparing suture button and screw fixation for accuracy and maintenance of syndesmotic reduction assessed with bilateral computed

tomography. Twenty-one patients were randomized to TightRope (a type of suture button fixation), while 22 were randomized to syndesmotic screw fixation. They reported that syndesmotic screw and suture button fixation had similar postoperative malreduction rates. Neither the incidence of ankle joint osteoarthritis nor the functional outcome significantly differed between the fixation methods. The results of the study pointed to similar overall outcomes in all techniques.[13]

Additionally, a recent meta-analysis commented that suture button fixation yielded improvement in functional scores over screw fixation, but clinical significance is doubtful.[14] Future trials are in progress, and an updated meta-analysis will be required to answer this clinical question.

Resolution of clinical scenario

- Level I evidence suggests that screw fixation is not inferior to suture button fixation when focusing on clinical outcomes, though it may lead to worse radiographic outcomes when measuring syndesmotic reduction.

Question 3: Amongst adult patients who have posterior malleolar ankle fracture, at what percentage of articular surface involvement does operative intervention when compared to nonoperative management, yield improvement in patient-reported outcomes at one-year follow-up?

Rationale

A high proportion (>10%) of rotational ankle injuries will involve a bony injury to the posterior malleolus.[15] The clinical importance of this fragment remains unclear. Biomechanical studies have suggested that the posterior malleolus can prevent posterior tibial subluxation over the talus,[15] but should all posterior malleolar fractures be treated? Is there a meaningful clinical benefit to patients?

Clinical comment

It is generally accepted that fractures involving the posterior malleolus have a worse prognosis than those with intact posterior malleoli.[16] The literature remains divided with respect to the indications for surgical intervention. Open reduction and internal fixation (ORIF) of this piece often requires a separate incision and approach than the standard bimalleolar fracture approaches. Given the potential morbidity and complications associated with a longer and more complex operation, should all posterior malleolar fractures be anatomically reduced and undergo internal fixation? Is there an optimal size to which the fragment can be successfully treated without an operation? Lastly, if treated with ORIF, should one use screw fixation from anterior to posterior or buttress plating from a posterolateral approach?

Available literature and quality of the evidence

The most relevant current literature consisted of:

- Level I: 1 randomized trial.[17]
- Level III: 1 systematic review and meta-analysis of biomechanical studies.[18]
- Level III: 1 systematic reviews of the literature and meta-analysis of both comparative and noncomparative

studies.[19]

- Level III: 1 retrospective cohort with medium to high risk of bias.[20]

Findings

Biomechanical studies

In a recent meta-analysis,[18] eight biomechanical studies were reviewed. Unfortunately, the findings of the studies were very heterogenous. Scheidt et al. showed that a posterior malleolar fragment 25% of the articular led to posterior tibial subluxation, and that subsequent fixation reduced instability.[21] In contrast, other studies found that osteotomized as much as 40% of the posterior malleolus did not change tibiotalar alignment.[18] However, more recent literature supports fixation of the posterior malleolus to regain stability of the syndesmosis.[22,23] Miller et al. described that fixation of posterior malleolus offered stability to the syndesmosis due to the ligamentous attachments to the malleolus itself,[22] while Fitzpatrick et al. demonstrated in a cadaveric study that malreduction of the posterior malleolus led to malreduction of the syndesmosis itself.[18]

Clinical studies

Fragment size

No randomized or prospective cohort studies have been undertaken to compare operative and nonoperative treatment of posterior malleolar fractures at a given size of the articular surface. Mingo-Robinet conducted a retrospective cohort study of 45 patients, and found that patients with small fragments (defined as less than 25% of the articular surface on a lateral radiograph) had similar outcomes regardless of whether they had an anatomic or

nonanatomic reduction.[20] However, in a meta-analysis comprising 12 other nonrandomized studies, the decision to pursue nonoperative treatment was based on fragment size, though that was only defined in 2 of 12 studies.[16] Additionally, no retrospective studies have shown a relationship between fragment size and development of osteoarthritis. Higher-level evidence is required to definitively state that certain fragment sizes can be treated with or without an operation.

Fixation strategy

O'Connor randomized 37 patients with posterior malleolar fractures to either anterior to posterior screws or an ORIF with a posterolateral buttress plate. Though the study was small, buttress plating was shown to have superior clinical outcomes at follow-up.[17] A recent meta-analysis supported this finding, but commented that the postoperative articular step was the most important predictor of clinical outcomes,[19] and that posterolateral plating offered a lowered risk of leaving an articular step.

Resolution of clinical scenario

- Level III evidence that surgical fixation for fragments that are nondisplaced, with no articular step-off, regardless of size, may not affect patient outcomes (overall quality: poor).
- Level III evidence that malreduction of a displaced posterior malleolus fragment may lead to malreduction of the syndesmosis (overall quality: poor).
- Level III evidence that posterior malleolar fractures comprising less than 25% of the articular surface may not require operative fixation (overall quality: poor).

- Level II evidence supporting use of posterolateral buttress plate over anterior to posterior screws for fixation of posterior malleolar fragments (overall quality: moderate).

Summary of answers

- The Ottawa Ankle Rules are a reliable tool for determining which patients require ankle radiographs, and are superior to other tools used for the same purpose.
- Suture button and screw fixation for syndesmotic disruption have similar clinical outcomes.
- For posterior malleolar fractures requiring operative fixation (usually >25% articular surface), posterolateral buttress plates are preferred over anterior to posterior screws.

105
Talus Fractures

Pablo Mery MD[1] and Carlos Prada MD MHSc[2]
[1]Department of Orthopaedic Surgery, Pontificia Universidad Católica de Chile, Santiago, Chile
[2]Division of Orthopaedic Surgery, Department of Surgery, McMaster University, Hamilton, ON, Canada

Clinical scenario

- A 21-year-old male suffered a motor vehicle accident. He presents to the Emergency Department with a painful and swollen left ankle but no other injuries.
- Edema and tenderness over left hindfoot is noted. The skin has some small blisters but otherwise the physical exam is normal. X-rays show a displaced talar neck fracture with a subtalar joint dislocation.

Top three questions

1. In patients with displaced talar neck fractures, does urgent definitive fixation result in better outcomes and fewer complications, compared with delayed definitive fixation?
2. In patients with displaced talar neck fractures, does surgery with dual approaches (anteromedial and anterolateral) result in better outcomes and fewer complications, compared with surgery with percutaneous fixation or arthroscopic-assisted reduction and fixation?

3. In patients with displaced talar neck fractures, does plate fixation result in better biomechanical stability compared with fixation using only screws?

Question 1: In patients with displaced talar neck fractures, does urgent definitive fixation result in better outcomes and fewer complications, compared with delayed definitive fixation?

Rationale

Talar neck displaced fractures have been historically considered surgical emergencies due to their frequent association with peritalar joint dislocations or subluxations. It is also believed that early surgery will decrease vascular impairment and subsequent risk of osteonecrosis.[1] However, given the high-energy characteristics commonly associated with this injury, soft tissue conditions make immediate definitive fixation challenging and significantly increases complications.[2]

Clinical comment

Even when displaced talar neck fractures are considered to need an urgent surgery, there has recently been a trend toward performing a closed reduction of the fracture-dislocations and wait until soft tissues are in a good enough condition to perform a delayed final open reduction and internal fixation (ORIF). There is a need to analyze which treatment paradigm has better outcomes and fewer complications.

Available literature and quality of the evidence

This search produced no systematic reviews or randomized controlled trials. There are five retrospective studies (level III). Whenever possible, these level III studies will be used to answer the question.

Findings

Lindvall et al. compared different aspects of 26 talar body and neck fractures (8 body and 18 neck) treated within six hours from injury or after six hours and found no difference regarding American Orthopaedic Foot and Ankle (AOFAS) score, nonunions, osteonecrosis or post-traumatic arthritis.[3] Sanders et al. review 70 cases of displaced talar neck fractures and although they did not list the detailed times in which surgeries were performed, they stated that surgical timing showed no difference in the need of secondary procedures.[4]

Vallier et al. reviewed 60 displaced talar neck fractures. Although the numbers in the study were small, no correlation was found between the timing of reduction and the development of osteonecrosis.[5] Despite this, the authors advocate for urgent reduction because it may help to preserve any remaining blood supply. Once reduction has been achieved, a delay in fixation could be done and potential complications derived from severe soft tissue injury as skin necrosis, wound dehiscence, and infection could be avoided.

In another more recent cohort, Vallier et al. reviewed 81 talar neck fractures. This cohort had 2 Hawkins type I fractures, 44 Hawkins type II fractures – 21 were type II-A (without subtalar joint dislocation) and 23 were type II-B (with subtalar dislocation) – 32 Hawkins type III fractures, and 3 Hawkins type IV fractures.[6] Treatment consisted of emergent closed reduction for dislocation patterns.

Irreducible dislocations and open fractures underwent definitive surgical treatment immediately. From the total cohort, 46 (57%) were treated with urgent definitive fixation and 35 (43%) were treated with delayed ORIF. They found that emergent closed reduction within 6, 8, 12, or 18 hours did not correlate with osteonecrosis and the time to definitive fixation did not correlate with avascular necrosis (AVN) rates. Actually, patients who developed osteonecrosis underwent ORIF earlier than those without AVN (1.7 days vs 4.8 days; $p < 0.001$). Authors believed that this difference might be attributed to a difference in the severity of fractures in both groups as there were more open fractures in the group that underwent urgent fixation. They declared that their analysis did not account for that potential confounding effects.

In addition, even when prior studies have suggested no association between the timing of definitive fixation and osteonecrosis,[3],[5] none of those studies specifically included the timing of reduction. Because of the small sample they were unable to determine an association between the timing of the reduction of dislocations and the development of osteonecrosis, but they stated that achieving an expeditious closed reduction is mandatory.[6]

Similarly, another study reviewed 106 talus fractures and fracture-dislocations and found that there was no effect from the time since the injury to surgical reduction on rates of AVN and posttraumatic osteoarthritis.[7] However, all these studies are retrospective and have relatively small sample sizes, so statistical power to reject the correlation between complication rates and surgical timing is limited.[8] In spite of this, these series consistently show that displaced talar neck fractures might not need to be treated as surgical emergencies. However, if dislocations are present, they must be reduced even if this requires an open reduction.

Resolution of clinical scenario

Even when urgent reduction and definitive fixation has been advocated for talar neck fractures, current evidence suggests that there is no difference in AVN rates, post-traumatic arthritis, union rate, or AOFAS hindfoot scores. Moreover, it seems that urgent open management gives rise to concerns regarding wound complications given the often severely traumatized soft tissues. With this in mind, in this case it seems reasonable to perform a closed reduction and, if congruence of the subtalar joint is restored, wait for the soft tissues to recover before performing the definitive fixation.

Question 2: In patients with displaced talar neck fractures, does surgery with dual approaches (anteromedial and anterolateral) result in better outcomes and fewer complications, compared with surgery with percutaneous fixation or arthroscopic-assisted reduction and fixation?

Rationale

Different surgical approaches have been used during the last decades to achieve better talar neck fracture reduction with the hope of reducing AVN rates and post-traumatic arthritis. Nevertheless, there is controversy about which surgical approach should be used. Some authors advocate for internal fixation under direct visualization by utilizing two surgical approaches, and others prefer smaller

percutaneous surgical approaches to preserve the soft tissues with the idea to protect vascular supply to the talus.

Clinical comment

Talar neck fractures often occur in high-energy trauma context so they are commonly presented as either fractures associated with some degree of soft tissue damage or as open fractures. However, nowadays there is no agreement about which surgical approach is better to perform the reduction and fixation, but there is a trend toward doing less-invasive approaches.

Available literature and quality of the evidence

This search produced no systematic reviews or randomized controlled trials. There are three retrospective studies (level III) related to this question. Whenever possible, these level III studies will be used to answer the question.

Findings

Even when there are not specific studies addressing this specific clinical question, different studies have been published showing the functional outcomes and complication rates with the different aforementioned techniques.

Beltran et al. did a retrospective review of 24 patients with talar neck fractures treated with a percutaneous posterior-to-anterior (PA) screw fixation finding an average AOFAS hindfoot score of 78.5 (range 28–100), an average Visual Analog Scale (VAS) for daily pain of 0.8 (range 0–4) and a Short Form 36 (SF-36) mental component score (MCS) and physical component score (PCS) averaging 49.1 ± 13.1 and 47.5 ± 12.4, respectively.[9] They reported one superficial surgical site infection, five transient, and one permanent numbness and paresthesias of the sural nerve. Besides,

62% of the patients developed subtalar arthrosis and 42% showed AVN but without joint collapse. These outcomes compare favorably to a previously published systematic review and meta-analysis.[10]

Xue et al. followed 28 patients treated with plate fixation through dual approaches for an average period of time of 25 months.[11] Their cohort showed a mean AOFAS hindfoot score of 78 (range 65–91). SF-36 PCS and MCS domains averaged 68 (range 59–81) and 74 (range 63–85), respectively. Although SF-36 scores differ between both series and are higher in the group of patients treated with dual approaches compared with the group that underwent percutaneous fixation, both populations are not comparable because they did not have the same fracture characteristics (Beltran et al. series had four open fractures and one Hawkins type IV fracture, compared with no open fractures or Hawkins type IV fractures in Xue et al.'s series).

Wagener et al. published a case series of seven patients with a Hawkins type II talar neck fractures treated arthroscopically.[12] Patients did not suffer any complications or AVN at a mean follow-up of 2.2 years. Unfortunately, they did not report on SF-36 or AOFAS scores, so it makes it hard to compare the results with previous published series.

Resolution of clinical scenario

As current evidence does not allow for a precise conclusion of which intervention has better functional outcomes and fewer complications for displaced talar neck fractures, probably the best recommendation for surgeons is that they should perform the surgical fixation they feel more comfortable with and experienced at until new evidence arises on less invasive methods (overall quality: low).

Question 3: In patients with displaced talar neck fractures, does plate fixation result in better biomechanical stability compared with fixation using only screws?

Rationale

Varus malunion is a common source of late morbidity from talar neck fractures. Rates higher than 30% have been reported.[4,13] Varus malunion shortens the medial column, locking the hindfoot in varus and internal rotation causing altered gait patterns and lateral column overload.[14]

As little as 3° of malunion produces a significant loss of motion in the subtalar joint.[14] Avoiding this problem is essential in talar neck fracture management and in order to do so there is a need to achieve stable fixation. Controversy exists whether screws or plates have better biomechanical properties to treat these fractures, both with and without associated comminution.

Clinical comment

Traditionally, it has been taught that these fracture fixations have a tension failure side (simple fracture pattern) and a compression failure side (comminuted fracture patterns). It is believed that screws are good for simple fracture patterns and comminuted fracture patterns are better fixed using a plate over the comminuted side.

Available literature and quality of the evidence

This search produced no systematic reviews or randomized controlled trials. There are five mechanical studies comparing different fixations techniques (level II).

Findings

Swanson et al. compared four different fixations (crossed 2.0 mm Kirschner wires [K-wires], two anterior-to-posterior [AP] 4.0 mm screws, two PA 4.0 mm screws, and one PA 6.5 mm screw plus a 2.0 antirotatory K-wire) on a model with minimal dorsal comminution.[15] Yield load, yield deformation, stiffness, and energy absorbed were significantly higher for both PA techniques with the best results for the two screws technique ($p < 0.001$).

Charlson et al. assessed the biomechanical properties of either 4.0 mm partially threaded cancellous screws placed PA and a four-hole 2.0 mm mini-fragment plates secured with 2.7 mm screws on a comminuted talar neck model.[16] PA screw fixation had statistically higher load to failure (120.7 ± 68.5 N vs 89.7 ± 46.6 N; $p < 0.05$) in a model of comminuted dorsal talar neck fractures. Nevertheless, the magnitude of the difference of around 30 N might not be that relevant (about six pounds). Interestingly, they compared the ultimate strength with previousfindings[15] and noticed that comminution greatly decreased construct strength by an order of magnitude.

Attiah et al. compared three techniques: three AP screws (one 3.5 mm cortical, and two 4.0 mm cancellous screws), two PA 4.0 mm cannulated cancellous screws and one 4.0 mm cancellous screw with a medially applied 2.7 mm mini-fragment blade plate (BP) on a model with dorsal medial comminution.[17] They did not find any statistical difference but a 25% decrease in fixation strength was observed in the group of three AP screws compared to the other two methods of fixation. The yield points (kN) for AP screws, PA screws, and BP were 1.48 ± 1.06 vs 1.88 ± 0.49 vs 1.83 ± 0.96, respectively ($p > 0.05$). Loads to 3 mm deformation were 1.26 ± 0.88 vs 1.48 ± 0.47 vs 1.41 ± 0.66 for the AP, PA, and BP groups, respectively ($p > 0.05$).

Capelle et al. performed biomechanical testing in a talar neck fracture model comparing headless variable-pitch screws with conventional screws.[18] The interventions compared were: fixation of the talar neck fractures with two cannulated headless variable-pitch 4/5 screws or two 4.0 mm conventional screws. In all cases the screws were inserted from AP. Results showed that fixation with headless variable-pitch screws had significantly lower failure displacement than the conventional screws. Besides, no significant differences were found between both fixation techniques for the energy absorbed, failure stiffness, or load at failure. However, differences in stiffness ($p = 0.058$) and energy absorption ($p = 0.065$) between screw types were quite large and very close to statistical significance favoring headless variable-pitch screws.

Karakasli et al. compared mechanical properties of headless screw fixation and locking plate fixation for talar neck fractures on a model with a simple transverse fracture.[19] They used two AP cannulated headless variable-pitch 4 mm/5 mm screws and a 2.7 mm locking plate. Headless variable-pitch screw fixation had lower failure displacement than the locking plate fixation. There were no significant differences in failure stiffness, yield load, yield stiffness ($p = 0.065$), or ultimate load between the two fixations techniques.

Resolution of clinical scenario

Many fixation options have been compared showing similar biomechanical properties. PA screws are superior to AP screws, and they seem to have at least similar biomechanical stability compared to plate fixation, even in comminuted talar neck models. Also, there is some evidence showing that headless variable-pitch screws might be superior to traditional cancellous screws.

With current evidence, it appears that talar neck fracture fixation using either plates or screw-only constructs provide appropriate biomechanical stability (overall quality: low).

Summary of answers

- Best current evidence shows that there is no difference in AVN rate, post-traumatic arthritis, union rate, or AOFAS hindfoot scores when comparing urgent versus delayed ORIF in displaced talar neck fractures.
- Urgent ORIF seems to be related with increased early wound complications so, even when the quality of evidence is low, currently it is reasonable to wait for the soft tissues to recover before performing the definitive fixation in patients with displaced talar neck fractures, if peri-talar joints are congruent.
- Existing evidence does not allow for precise conclusion of which kind of approach results in better outcomes and fewer complications in patients with displaced talar neck fractures.
- PA screws are biomechanically superior to AP screws in talar neck fracture models.
- Both plates and screw fixation provide appropriate biomechanical stability for displaced talar neck fractures.

106
Calcaneal Fractures

Richard E. Buckley MD FRCSC
University of Calgary, Calgary, AB, Canada

Clinical scenario

- A 35-year-old male construction worker is brought to the Emergency Department following a 3 m fall at work. He complains of left heel pain and is unable to weight bear on the left.
- Initial trauma workup reveals an isolated injury to the left calcaneus, with no spinal or ipsilateral lower limb fractures. His left foot is very swollen and tender posteriorly with a few blisters.
- This man has no medical problems except he has smoked one pack/day for 20 years.

Top three questions

1. In adults with displaced intra-articular calcaneal fractures, does nonoperative treatment provide long-term functional outcomes as good as operative care (open reduction and internal fixation [ORIF])?
2. In adults with displaced intra-articular calcaneal fractures, does minimally invasive reduction and percutaneous fixation provide long-term functional outcomes as good as ORIF?
3. In adults with displaced intra-articular calcaneal fractures, does primary fusion provide long-term functional outcomes as good as ORIF?

Question 1: In adults with displaced intra-articular calcaneal fractures, does nonoperative treatment provide long-term functional outcomes as good as operative care (open reduction and internal fixation [ORIF])?

Rationale

Operative treatment of calcaneal fractures is associated with a significant risk of serious complications. As such, it is important that both the treating surgeon and the patient are aware of the expected outcome of the three options of operative treatment (ORIF, minimally invasive reduction, and primary fusion) and nonoperative treatment so that this can be accurately balanced against the risks involved with the chosen treatment.

Clinical comment

Most trauma surgeons would currently suggest operative treatment of a displaced intra-articular calcaneal fracture in an otherwise healthy young male manual worker. Clinical features that would push a surgeon to do an ORIF in a patient with a displaced intra-articular calcaneal fracture are young age, active lifestyle, simple fracture, good soft tissue envelope, nonsmoker, and good clinical expertise.

Available literature and quality of the evidence

A literature search provided us with eight randomized controlled trials (RCTs)[1–8] and four meta-analyses.[9–12] All of these RCTs are of level II strength (as they each have some methodologic flaws) and none of them is of the size to accurately answer this tough problem alone. However, together they create a good body of work and can provide some clinical direction to answer this tough question.

The four meta-analyses were done between 2009 and 2017 and thus reflect the difference in timing of the appearance of the above RCTs.[9–12] When combined, these four papers have very similar summaries.

Findings

These papers state that we are still in need of a large RCT to answer this question definitively.[1–12] They also state that surgical complications are the big downside of ORIF but that clinical outcomes are somewhat better with ORIF.

Pooled results of the eight RCTs showed that patients managed nonoperatively failed to resume pre-injury work (risk ratio [RR] = 0.60; 95% confidence interval [CI]: 0.37–0.98; p = 0.04). However operative intervention was associated with more complications (RR = 1.74; 95% CI: 1.28–2.37; p = 0.0005). There was no statistically significant difference in residual pain (RR = 0.73; 95% CI: 0.40–1.36; p = 0.33) and re-operation (RR = 0.75; 95% CI: 0.48–1.16; p = 0.20) between the two groups.

Surgically managed patients are more likely to resume their pre-injury work. Buckley et al. noted that patients with light-to-moderate work may lead to better recovery with surgery.[4] However, patients with heavy workloads are unlikely to recover well regardless of the treatment type. Buckley et al. and others reported better functional results and less pain when Bohler's angle was restored and anatomic reductions were achieved. On the other hand, Ibrahim et al. found no association between radiographically measured restoration of the angle and clinical outcome.[5]

Operatively managed patients had fewer problems while wearing shoes. This may be due to the fact that surgery results in the restoration of preinjury calcaneal width. Patients who underwent surgery were likely to have less pain as compared to those who underwent nonoperative management, although the difference did not reach statistical significance.

Although operative intervention showed good outcomes, they also had a significantly higher incidence of complications. Complication rates were much higher with surgery with the most frequent complication being infection with rates between 5 and 15%.

Resolution of clinical scenario

- Complications must be avoided for the best results when managing these patients (RR = 1.74; 95% CI: 1.28–2.37, p = 0.0005).
- Operative care is slightly better in younger patients as they have fewer complications than the older patient with more medical problems (overall quality: moderate).
- Functional outcome is slightly better in the operatively managed patient provided complications are not encountered (overall quality: moderate).
- Return to heavy labor is unlikely after a displaced intra-articular calcaneal fracture regardless of treatment type; return to work may be improved with operative treatment (overall quality: moderate).
- Better restoration of anatomy can lead to a better clinical result as footwear is easier to manage in the operatively treated patient (overall quality: moderate).

- No statistically significant difference in pain or functional outcome between operative treatment modalities and nonoperative treatment (overall quality: moderate).
- Subtalar arthrodesis rates are significantly decreased after operative treatment (overall quality: moderate).
- This young laborer should undergo ORIF of his calcaneal fracture.

Question 2: In adults with displaced intra-articular calcaneal fractures, does minimally invasive reduction and percutaneous fixation provide long-term functional outcomes as good as ORIF?

Rationale

With minimally invasive reduction and fixation techniques becoming widely accepted in orthopedic trauma practice, the role of this technique in calcaneal fracture fixation is becoming clearer. Complications certainly are less with smaller incisions, and with less surgery, range of motion may be better, providing better long-term outcomes for patients.

Current opinion

Currently, over the last five years, there has been a real swing in popularity for surgeons to routinely use minimally invasive techniques for the treatment of displaced intra-articular calcaneal fractures rather than the classic extensile lateral calcaneal exposure. Fewer complications and better range of motion with less postoperative pain are pushing surgeons to move toward less invasive surgery to accomplish the same goals for patients.

Available literature and quality of the evidence

A literature search provided us with:

- Level II: 5 randomized trials[13–17] and 2 systematic reviews.[18,19]
- Level III: 3 prospective cohort or retrospective reviews.[20–22]

Findings

There are no level I studies comparing minimally invasive techniques to any other form of treatment but there are 10 level II or III studies and 2 systematic reviews.

The most recent RCT provided these findings: operative time in the minimally invasive percutaneous osteosynthesis (MIPO) group was 52.5 ± 11.1 min, which was significantly shorter than 82.8 ± 16.2 min in the conventional treatment group ($p < 0.001$).[17] One week postoperatively, the Visual Analog Scale (VAS) value was 3.2 ± 1.4 in the MIPO group, which was lower than that in the conventional treatment group, 3.9 ± 1.3 ($p = 0.038$). In the conventional treatment group, 13 of 35 fractures (37.1%) had wound healing problems, whereas this issue occurred in only 2 of 29 fractures (6.7%) in the MIPO group ($p = 0.004$). In the MIPO group, deep and superficial infections occurred in none of the cases and 1 of 29 (3.4%) patients, respectively. Length of incision in the MIPO group was shorter than that in the conventional treatment group (4.2 ± 0.6 vs 10.9 ± 1.5 cm; $p < 0.001$). Hospital stay was 9.7 ± 2.8 days in the MIPO group and 11.7 ± 2.6 days in the conventional treatment group ($p = 0.004$). At the last follow-up, the Short Form 36 (SF-36) scores and AOFAS scores in the two groups were comparable ($p > 0.05$). The postoperative radiographic data, the Bohler's angle, Gissane's angle, and calcaneal height, width, and length in the two groups were comparable ($p > 0.05$).

A systematic review states that the results from the current data appear to be promising;[18] however, the lack of statistical power and inconsistent documentation have made it difficult to determine any superiority. The complication rates were much lower than those with open procedures, regardless of the technique. The percutaneous fixation technique appears to be a favorable option for displaced intra-articular calcaneal fractures.

Resolution of the clinical scenario

- At present, there is strong and growing evidence regarding the use of minimally invasive techniques for calcaneal fracture fixation.
- Functional outcomes are at least equal, complications are much less with smaller incisions, time in hospital is less, and early postoperative pain is also less.
- The sinus tarsi approach is the approach of choice for reduction of the joint with percutaneous fixation with screws and/or plates and screws.
- This 35-year-old laborer (also a smoker with potential wound problems) should have minimally invasive reduction with percutaneous fixation using the sinus tarsi approach.

Question 3: In adults with displaced intra-articular calcaneal fractures, does primary fusion provide long-term functional outcomes as good as ORIF?

Rationale

Should the preoperative CT scan demonstrate that this patient has a Sanders type IV comminuted displaced intra-articular calcaneal fracture, then besides the option of ORIF, this patient may be served by a primary subtalar fusion. The more severe the fracture, the more that this option can become relevant because of the difficulty with obtaining a satisfactory ORIF.

Clinical comment

It is difficult to obtain an anatomic reduction in this type of fracture. Some surgeons would recommend immediate subtalar arthrodesis given that this fracture pattern is often associated with poor functional results after an ORIF and a high rate of late subtalar arthrodesis regardless. The argument is that why would a surgeon ever do an ORIF for a patient with a Sanders type IV fracture if a second operation (secondary fusion) is needed in a high percentage of patients anyway.

Available literature and quality of the evidence

- 2 level II studies[23,24]
- 2 level III studies[25,26]
- 3 level IV studies[27–29]
- 1 systematic review.[30]

Findings

There are two level II studies that compare reconstruction and primary subtalar arthrodesis (PSTA) with reconstruction for severe (Sanders type IV) fractures. In a study by Buckley, 26 patients (26 displaced intra-articular calcaneal fractures) were followed

for a minimum of two years (81% follow-up).[23] No statistical difference was found between the results for ORIF compared with ORIF + PSTA: the mean SF-36 physical component scores were, respectively, 30.2 (standard deviation [SD] = 11.4) and 37.8 (SD = 10.4) ($p = 0.10$); the mean Musculoskeletal Functional Assessment Survey scores were 44.2 (SD = 25.6) and 37.9 (SD = 21.5) ($p = 0.50$); the mean Ankle-Hindfoot Scale scores were 62.5 (SD = 19.6) and 65.8 (SD = 19.2) ($p = 0.68$); and the mean VAS scores were 36.8 (SD = 34.7) and 36.0 (SD = 30.7) ($p = 0.82$). A Korean study showed that the results for ORIF did not differ from those for PSTA based on the last follow-up AOFAS scores or the VAS scores ($p > 0.05$).[24] However, patient satisfaction was significantly higher in the PSTA group ($p = 0.008$). Secondary subtalar arthrodesis was conducted in five patients (45.5%) of the ORIF group within two years postoperatively.

Resolution of clinical scenario

- There is some evidence to support acute subtalar arthrodesis as an appropriate treatment for Sanders type IV displaced calcaneal fractures.
- It can help prevent late secondary fusion after primary ORIF, and when done primarily, results in earlier return to work with good satisfaction.
- This patient should not have a subtalar fusion unless he has a Sanders type IV fracture.

Summary of answers

- No statistically significant difference in pain or functional outcome between operative treatment modalities and nonoperative treatment (overall quality: moderate).
- Minimally invasive surgery creates less complications and less pain with equal late functional outcomes (overall quality: moderate).
- Subtalar arthrodesis is a viable option for Sanders type IV fractures and prevents the need for secondary fusion (overall quality: moderate).
- Current evidence suggests that treatment of displaced intra-articular calcaneal fractures be tailored to the individual, as summarized in Table 106.1.

Table 106.1 Important recent studies of high quality about displaced calcaneal fractures.[9]

Study year	Country	Cases Operative (O)/Nonoperative (NO)	Sex Male/ Female	Mean Age O/NO Years	Followup Years O/NO	Important conclusions of study	Jadad Score (quality of study)
O'Farrell 1993[1]	Ireland	12/12	20/4	33/38	1.3/1.2	Surgery improved functional results	2
Parmar 1993[2]	UK	25/31	48/8	48/48	2.1/1.8	No difference in functional outcomes between groups	2
Thordarson 1996[3]	USA	15/11	21/5	35/36	1.4/1.2	Improved walking ability after surgery	5.5
Buckley 2002[4]	Canada	206/218	381/43	41/39	3.0/3.0	No difference between outcome in the two groups but trends evident in RCT	6.5
Ibrahim 007[5]	UK	15/11	21/5	61/58	15.2/14.8	No difference between groups	4
Nouraei 2011[6]	Iran	31/30	No data	46/52	3.0/3.0	Surgery group more likely to resume pre-injury work	4
Griffin 2014[7]	UK	73/78	127/24	45/48	2.0/2.0	No difference between outcome in the two groups but more complications in the operative group	6

Study year	Country	Cases Operative (O)/Nonoperative (NO)	Sex Male/ Female	Mean Age O/NO Years	Followup Years O/NO	Important conclusions of study	Jadad Score (quality of study)
Agren 2013[8]	Sweden	42/40	59/23	49/48	10.0/10.0	No difference with short-term outcomes but operative group was superior over time	7

Lisfranc Injuries

Robin R. Elliot MA FRCS, Nicholas B. Jorgensen MBBS, and Terrence S. Saxby MBBS FRACS
Brisbane Foot and Ankle Centre, Brisbane, Queensland, Australia

Clinical scenario

- A 19-year-old motorbike rider attempts a large jump whilst off-road racing in a country competition.
- He lands poorly and feels his right foot get hyperextended with his foot against the foot pedal as he hits the ground and falls from his bike.
- There is immediate pain and he is unable to fully weight bear. He then rides home in pain, and walks with difficulty for the next few days until seeking medical attention. The local doctor sees a swollen foot with bruising on the plantar surface and does an x-ray that shows an avulsion fracture at the base of the second metatarsal but no obvious displacement.
- He is then placed in a controlled ankle motion (CAM) walker, allowed to weight bear as tolerated, and asked to present to the local fracture clinic in several weeks' time.

Top three questions

1. In a patient with a Lisfranc injury, does an anatomical reduction and fixation result in better outcomes than primary arthrodesis?

2. In a patient with a Lisfranc injury, does delayed or misdiagnosis adversely affect the outcomes compared to successful diagnosis and treatment?
3. In the active patient with a Lisfranc injury does, operative treatment allow for return to preinjury level of sport compared to nonoperative treatment?

Question 1: In a patient with a Lisfranc injury, does an anatomical reduction and fixation result in better outcomes than primary arthrodesis?

Rationale

A Lisfranc joint fracture dislocation is relatively rare, 0.1–0.9% of all fractures.[1] It is associated with significant morbidity and it is reported up to one-third of these injuries are missed. In contrast, midfoot sprains are commonly seen in athletes.[2] Unfortunately, a Lisfranc injury is a commonly missed diagnosis and this type of injury has the potential to lead to significant morbidity.[3] Key to this is the reduction of the articulation between the second metatarsal and the middle cuneiform and fixation which replicates the function of the Lisfranc ligament, tying the medial cuneiform to the second metatarsal.

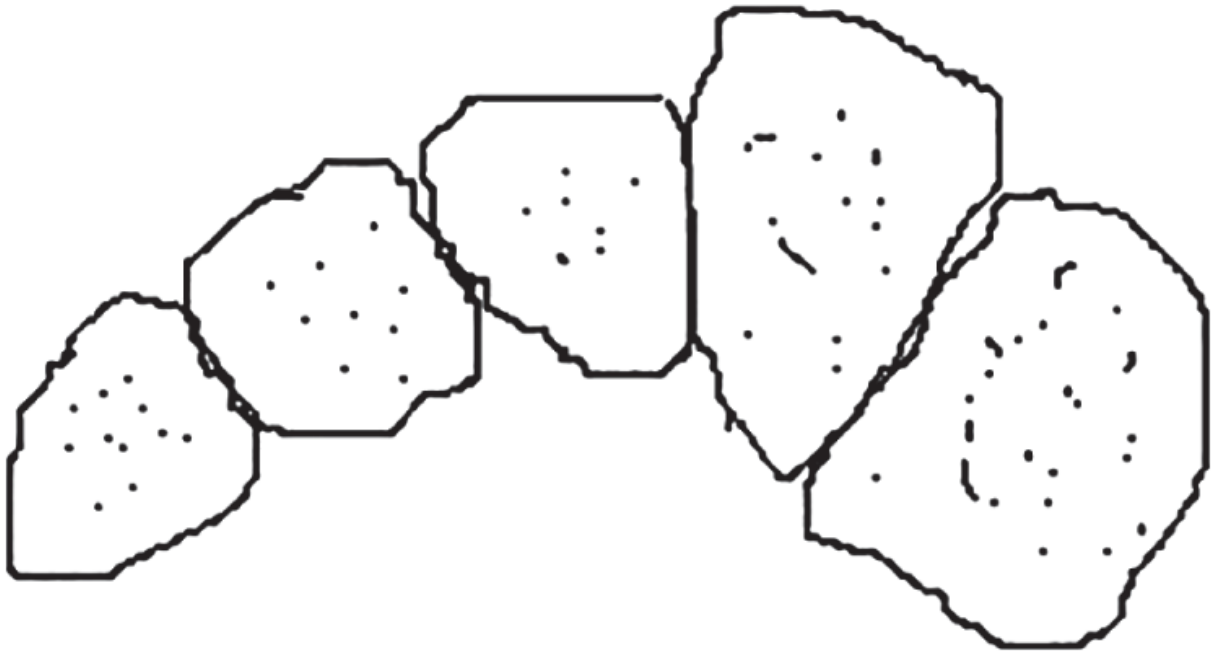

Figure 107.1 The Roman arch configuration of the Lisfranc complex.

Figure 107.2 Anteroposterior view showing alignment of the lateral borders of the first metatarsal and the medial cuneiform as well as the medial borders of the second metatarsal and the middle cuneiform.

Clinical comment

Lisfranc injuries require prompt anatomical reduction and surgical fixation with plates and screws. There is some debate regarding the effectiveness of primary arthrodesis as treatment for these injuries, but this has not become mainstream treatment. It is important to recognize purely ligamentous Lisfranc injuries, as these can be underappreciated, and there is emerging evidence to suggest primary arthrodesis can have a more favorable outcome in these select patients.

Available literature and quality of the evidence

A recent meta-analysis (level I) concluded that there was no difference in outcomes or quality of anatomic reduction between open reduction and internal fixation (ORIF) and primary arthrodesis.[4] Three studies were considered eligible for inclusion, and demonstrated similar patient reported outcomes, revision surgery rates, and anatomic reduction. It was demonstrated that there are greater rates of hardware removal with the ORIF group, which needs to be considered in the discussion with the patient,[4] which is also supported by other studies.[5]

Figure 107.3 30° oblique view showing alignment of the medial borders of third metatarsal and the lateral cuneiform as well as the medial borders of the fourth metatarsal and the cuboid bone.

A prospective randomized study (level I) has also demonstrated no difference,[5] whereas a similarly constructed prospective, randomized study by Ly and Coetzee have shown improved short- and medium-term outcomes in the arthrodesis group.[6] Ly and Coetzee compared 41 patients with primarily ligamentous injuries for 42.5 months, and demonstrated an improved AOFAS midfoot score of 88 in the arthrodesis group and 68.6 in the open-reduction group ($p < 0.005$). The primary arthrodesis group estimated that their postoperative level of activities was 92% of their preinjury level, whereas the open-reduction group estimated that their postoperative level was only 65% of their preoperative level ($p < 0.005$).[6]

A comparative cohort study (level III) by Rammelt et al. compared 44 patients that underwent primary open reduction (22 patients) with delayed, corrective arthrodesis (22 patients) with a follow-up of 22 months and found that the primary fixation leads to improved functional results, earlier return to work, and greater patient satisfaction than secondary corrective arthrodesis ($p = 0.03$).[7]

Figure 107.4 Weightbearing views showing instability of the left first and second tarsometatarsal joints and widening of the space between the first and second rays.

Numerous level IV case series are available to demonstrate the importance of accurate reduction and internal fixation. In Myerson's case series of 55 patients the major determinant of unacceptable results was identified as the quality of the initial reduction.[8] Goossens and De Stoop's case series of 20 patients showed that 70% of patients who were treated conservatively in an unreduced position had a poor outcome compared with only 18% of those who had reduction and pinning.[9] Arntz et al. showed in a consecutive series of 40 patients that good or excellent results were obtained in 95% of patients with an anatomical reduction but only 20% of those in whom the

reduction was nonanatomic.[10] One case series suggested that anatomical reduction was not a guarantee of satisfactory outcome: Teng et al. reported that the subjective functional outcome in their series of 11 patients was not very good despite successful restoration of normal anatomy.[11]

Findings

Overall, level I evidence has shown mixed support for undertaking a primary arthrodesis for Lisfranc injury. Ly and Coetzee have demonstrated favorable outcomes for patients with a primarily ligamentous injury treated with a primary arthrodesis with a significant improvement in midfoot AOFAS scores in the arthrodesis group at two years.[6] Whereas, Henning et al. demonstrated in 40 patients no significant difference in Short Form 36 (SF-36) and short musculoskeletal functional assessment (SMFA) score.[5]

Level III evidence also demonstrates no difference in outcomes or quality of anatomic reduction between ORIF and primary arthrodesis.[7] Level IV studies have demonstrated the need for anatomical reduction and rigid internal fixation has been shown to be an important factor in the eventual outcome.[5–11]

Resolution of clinical scenario

- Level IV evidence suggests restoration of normal anatomy and surgical fixation gives the best chance of a favorable long-term outcome.
- Level I evidence suggests similar outcomes can be expected with anatomic reduction and primary arthrodesis, though a higher rate of removal of hardware in the anatomic reduction group.

- Level I evidence suggests that, in the primarily ligamentous injury group, consideration for primary arthrodesis should take place.

Question 2: In a patient with a Lisfranc injury, does delayed or misdiagnosis adversely affect the outcomes compared to successful diagnosis and treatment?

Rationale

Lisfranc injury is a commonly missed diagnosis in the acute setting, and although it is a rare injury, the potential for a poor outcome is significant, especially if mismanaged.[12,13] A missed Lisfranc injury is reported to lead to progressive planovalgus deformity, instability, and post-traumatic arthritis.[14]

Clinical comment

In this case, the diagnosis was not significantly delayed, surgical intervention would not be recommended before the swelling had settled, and there is only evidence in the literature that a significant delay (six months) in treatment would affect outcome (level IV).[15] Nevertheless, clinicians who regularly attend to patients with acute foot trauma should always be alert to the possibility of a Lisfranc injury in order to expedite prompt further investigation and management. Clues to aid in diagnosis include a mechanism of injury including hyperplantarflexion (toe catching the ground in a motorbike, foot plantarflexing of a rigid surface like stairs/curbside, or caught in a horse's stirrup), midtarsal pain, swelling, and plantar ecchymoses.[16]

Lisfranc injuries often occur with significant trauma to the foot. Most specialists would advocate a period of elevation, icing, and observation in the initial 24–48 hours. At the same time further investigations should be arranged, if necessary, to assess tarsometatarsal stability. Plain radiographs and weightbearing/stress radiographs are appropriate initial investigations. If these are normal or equivocal and there is ongoing clinical suspicion of a Lisfranc injury then further investigation with computed tomography (CT) or magnetic resonance imaging (MRI) should be arranged. Both study mediums are more sensitive in identifying midfoot fractures and malalignments than plain and stress radiographs.[17]

Available literature and quality of the evidence

Multiple case reports and case series have reported on the sequelae of delayed or missed diagnosis in Lisfranc injuries (level IV). Loss of range of movement in the midfoot is well recognized after this injury. Wilson found that almost all patients in his series displayed some degree of stiffness and this was related to the quality of the initial reduction.[18] Complex regional pain syndrome (CRPS) has been reported in 25% of the patients in his series, and missed or delayed diagnosis was thought to be an important factor in many of those cases.[9] Disruption of the Lisfranc complex can result in a planovalgus deformity. There is conflicting evidence as to whether this is significant in terms of outcome. Aitken and Poulson reported good functional outcomes in their case series despite obvious residual deformity.[19] This is contrary to the findings of Faciszewski et al., who reported that maintenance of the longitudinal arch is a major determinant of outcome.[20] Post-traumatic arthritis is the most common long-term complication in Lisfranc injuries. In many series this is reported to occur in a significant number of cases and is a significant cause of long-term

morbidity.[8,21] Calder et al. retrospectively analyzed 46 patients with Lisfranc injury and demonstrated there was a worse outcome in terms of return to work when there was delay in diagnosis of greater than six months ($p = 0.01$), with age, gender, mechanism, or occupation prior to injury not appearing to affect outcome.[15]

Findings

Overall, published data reporting on the sequalae of missed diagnosis are restricted to case reports and small case series (level IV). These studies demonstrate that postinjury stiffness is related to the quality of initial reduction.[18] Missed or delayed diagnosis of injury can have an important influence on the development of CRPS,[9] planovalgus deformity,[19,20] and post-traumatic arthritis.[8,21]

Resolution of clinical scenario

- Level IV evidence Lisfranc injuries are best treated acutely to avoid potential problems associated with missed or delayed diagnosis.
- Level IV evidence suggests that missed or delayed diagnosis can have an important influence on the development of CRPS, planovalgus deformity, post-traumatic arthritis, and ability to return to work.

Question 3: In the active patient with a Lisfranc injury does, operative treatment allow for return to preinjury level of sport compared to nonoperative treatment?

Rationale

Managing expectations is an important aspect of treating surgical patients, and a thorough knowledge of prognosis helps in this respect.

Clinical comment

Return to a preinjury level of sporting activity is difficult to predict with Lisfranc injuries, and become increasingly less likely in those with missed diagnosis of a Lisfranc injury.

Available literature and quality of the evidence

Retrospective cohort studies (level III) have demonstrated high rates of return to sport (and preinjury levels) in both operatively and nonoperatively treated Lisfranc injuries. Nunley and Vertullo reported on 15 patients with Lisfranc injuries sustained playing sport.[22] Seven of these injuries were diagnosed as sprains and treated conservatively and eight required operative treatment. All patients in their series returned to sport (average 15.2 weeks) and an excellent result in 93%.[22] McHale et al. found that of 28 NFL athletes treated for a Lisfranc injury 26 returned to sport, though at longer time period compared to other studies, up to 15 months. Those that were treated nonoperatively (six patients) returned at a mean of 6.2 months compared to those treated operatively (22 patients) returning at a mean of 11.1 months. Importantly, their study reported on performance (Offensive Power Rating, Defensive Power Rating), positional demands and durability matched against 162 players in a control group.[23]

Multiple level IV studies have assessed return to preinjury levels of function with mixed levels of success. Hawkinson et al. published a retrospective review of 171 military personnel treated for Lisfranc fracture/dislocation.[16] Of 111 who had complete data, 91 underwent an ORIF and 20

a primary arthrodesis. Overall 75 (68%) returned to full active duty, 5(4%) to limited duty, and 31 (28%) were discharged from service due to pain and/or disability. This study had many limitations, no radiological or surgical records were available to the authors, the information they had was limited to medical notes through the military database.[15] Other level IV studies have reported a case series including five gymnasts with Lisfranc injuries, only one returned to full competition[24] and a reported 3 of 19 patients with Lisfranc injury were unable to return to their sports.[25]

Doel et al. undertook a retrospective review of English premier league and championship rugby players, with 16/17 surgically managed players returning to full competition between 21–31 weeks post injury (level IV).[26] The authors attribute the excellent outcomes to avoiding metalware across joint surfaces and access to prompt, high-quality rehabilitation.

Findings

Overall, there is difficulty in predicting postinjury levels of activity and satisfaction. There is, however, level III and level IV evidence that suggests elite level athletes who have sustained an injury in their sport have high rates of returning to preinjury levels.[22,23,26] However, other level IV evidence suggests that these rates of return are not as reliable in predicting return to preinjury levels of ability.[16,24,25] This may reflect the difference in injury mechanism, injury type, treatment type and postinjury rehabilitation access, as well as study design and quality. Recent studies are becoming more optimistic in predicting outcomes after Lisfranc injury, which may reflect improved imaging, increased suspicion for injury, and a focus on anatomic reduction and surgical technique.

Resolution of clinical scenario

- The outcome of Lisfranc injuries is not predictable from the current literature, although recent studies are more optimistic than older ones.
- Level III and level IV evidence suggests that those patients injured playing sport can have reasonable expectations to return to similar levels of preinjury ability and satisfaction, though this may take up to 15 months.

Summary of answers

- Lisfranc injuries are best treated acutely to avoid potential problems associated with missed or delayed diagnosis.
- In treating Lisfranc injuries restoration of normal anatomy and surgical fixation gives the best chance of a favorable long-term outcome.
- Primary arthrodesis is a viable treatment option, and has less cases of a need to remove hardware than those patients treated with internal fixation.
- Primary arthrodesis should be considered in the primarily ligamentous Lisfranc injuries.
- Awareness of the immediate and late complications of Lisfranc injuries is essential.
- Patients injured playing sport can have reasonable expectations to return to similar levels of preinjury ability and satisfaction

Fifth Metatarsal Fractures

Robin R. Elliot MA FRCS, Nicholas B. Jorgensen MBBS, and Terrence S. Saxby MBBS FRACS
Brisbane Foot and Ankle Centre, Brisbane, Queensland, Australia

Clinical scenario

- A 30-year-old football player attempts a tackle and “rolls” her ankle in the process.
- She has immediate pain but manages to finish the game with a limp.
- The pain worsens on the lateral border of the foot over the next few days and she presents to the Emergency Department complaining of pain, swelling, and difficulty mobilizing.
- A radiograph is taken showing a base of fifth metatarsal fracture and she is given a controlled ankle motion (CAM) walker to weight bear in for the next six weeks.
- She is gradually weaned from the CAM walker and finds she still has pain with weightbearing at the three-month mark with no radiological signs of fracture union.

Top three questions

1. In patients with a proximal fifth metatarsal fracture, does the pattern of injury affect the clinical and radiological outcome?

2. In patients with a proximal fifth metatarsal fracture, does operative fixation result in better outcomes than nonoperative management?
3. In patients with a proximal fifth metatarsal fracture, does intramedullary screw fixation lead to better biomechanical and clinical outcomes than other operative treatment options?

Question 1: In patients with a proximal fifth metatarsal fracture, does the pattern of injury affect the clinical and radiological outcome?

Rationale

Fractures of the fifth metatarsal are the most common fractures sustained in the foot.[1,2] Fractures of the base are classified into three zones, which have been found important for prognosis and determining fracture management.[2,3]

Clinical comment

The classification and description of fractures of the proximal fifth metatarsal can be confusing and central to this has been the regular mis-use of the term *Jones' fracture*. Sir Robert Jones was one of the forefathers of British orthopedics and founder of the British Orthopaedic Association. In 1902, he wrote a case series on fractures of the fifth metatarsal, one of which was his sustained through dancing.[3,4] A zone 1 (avulsion) fracture is proximal to the fourth/fifth intermetatarsal joint and represents an avulsion of the tuberosity. A zone 2 (Jones) fracture is in the vascular watershed zone between the diaphysis and metaphysis, at the level of the intermetatarsal joint. A zone

3 (diaphyseal stress) fracture is distal to this in the proximal diaphysis (Figure 108.1).2 Zone 3 fractures were qualified further by Torg et al., who described a classification system with a type 1 indicating an acute fracture, a type 2 representing delayed union with a wide fracture line and intramedullary sclerosis, and type 3 is a nonunion with a wide fracture line and extensive intramedullary sclerosis.5 Further work has differentiated fractures into complete and incomplete fractures, where an incomplete fracture is more likely to progress to nonunion in weightbearing as there are tensile forces over the lateral cortex and compressive forces medially.6

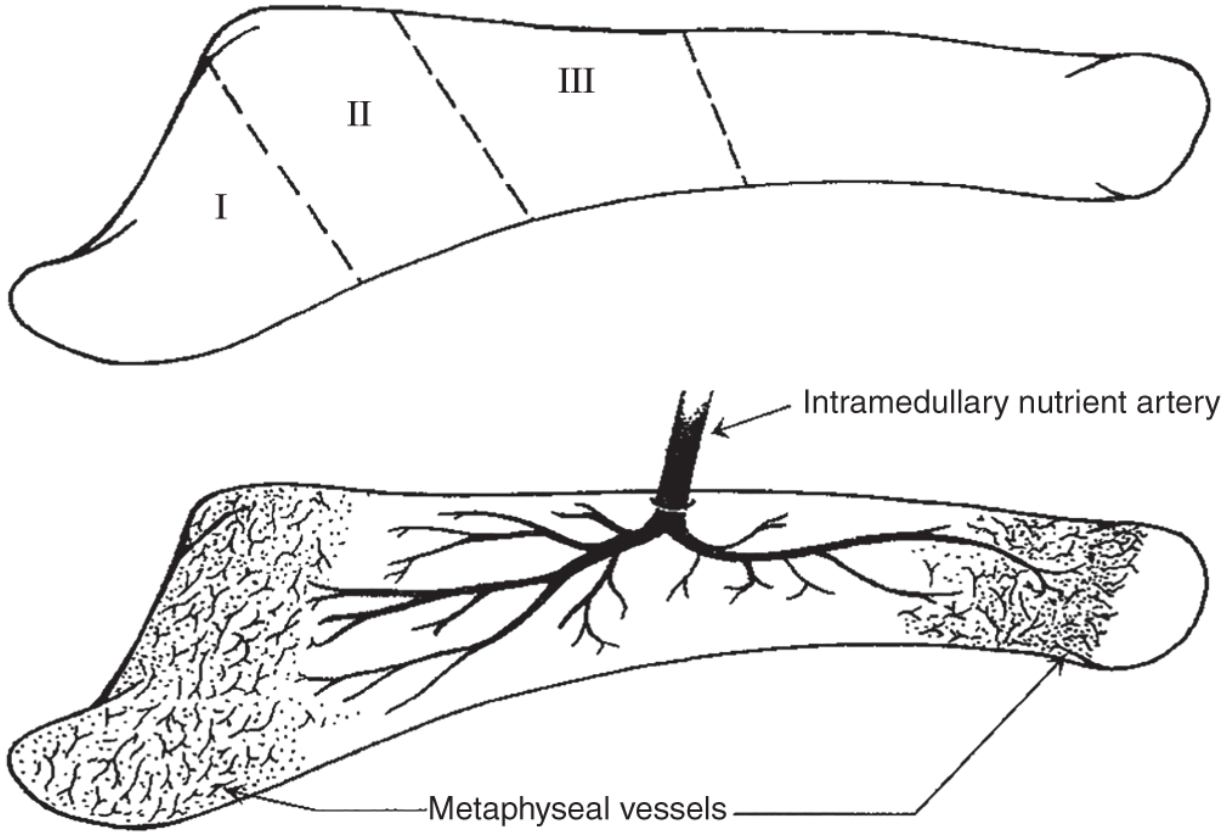

Figure 108.1 (Top) Dameron's three zones of the proximal fifth metatarsal. Zone 1 injuries are avulsion fractures of the tuberosity. Zone 2 injuries are fractures involving the intermetatarsal facet (as described by Jones). Zone 3 injuries are proximal diaphyseal fractures. (Bottom) Blood supply.9

Available literature and quality of the evidence

Level IV studies have further demonstrated the anatomical location affecting fracture location and union. Clapper et al. reviewed a series of 100 patients with fifth metatarsal fractures which were followed prospectively to determine outcomes of their injuries: three distinct subgroups were identified depending on fracture location.7 The study showed 68 zone 1 (avulsion), 25 zone 2 (Jones), and 7 zone 3 (diaphyseal stress) and provided a treatment algorithm, which yielded 100% union at 4.7 weeks for zone 1

(avulsion) injuries treated nonoperatively, and 100% union at 5.8 weeks for zone 3 (diaphyseal stress) injuries treated nonoperatively, and only 72% union at an average of 21.2 weeks for zone 2 (Jones) injuries treated nonoperatively.[7] A similar union rate was demonstrated by Kavanaugh et al., with a series of 22 zone 2 (Jones) fractures having delayed healing in two-thirds of those cases treated conservatively.[8]

Other level IV studies have reported on union rates in zone 1 (avulsion) fractures. Dameron reported a case series of 100 tuberosity fractures (zone 1) treated conservatively, all but one healed clinically within three weeks.[9] Vorlat et al. reported on a case series of 38 patients with zone 1 (tuberosity) fractures, and found the most significant predictor of poor functional outcome was prolonged nonweightbearing. Gender, age, and fracture type did not affect outcome.[10] A single level II study has also demonstrated 100% union rates in 60 patients with zone 1 (avulsion) fractures with nonoperative treatment.[11]

Lee et al. reviewed a cohort of 75 patients (level III), and introduced the concept of the plantar gap in the zone 3 (diaphyseal stress) injury; the distance between the fracture margins, measured on the lateral cortex of an oblique radiograph. The mean time for bone union in those patients with a plantar gap <1 mm was 71.21 ± 29.95 days compared to 126.4 ± 51.99 days in those with a plantar gap >1 mm ($p < 0.001$).[6]

Findings

Overall, there are many level IV studies that have been used to define proximal fifth metatarsal fractures, with Clapper et al. reporting on fracture pattern and union rates in 100 proximal fifth metatarsal fractures.[7] Torg et al. provided further understanding and classification with

description of the acuity of zone 3 injuries,[5] and Lee et al. introduced the concept of plantar gap distance having an effect on time to union.[6]

Multiple level IV studies[9,10] and a single level II[11] study have demonstrated excellent union rates in zone 1 (avulsion) fractures treated nonoperatively. Other level IV studies have shown that union rates in zone 2 (Jones) and zone 3 (diaphyseal stress) fractures are far less reliable with nonoperative treatment.[6–8] A retrospective study of 22 patients with zone 2 (Jones) fractures or zone 3 (diaphyseal stress) fractures treated surgically showed all fractures united (mean 6.25 weeks) with no to rare pain reported during athletic activity.[12]

Resolution of clinical scenario

- Zone 1 (avulsion) fractures should be treated nonoperatively, with symptomatic treatment being sufficient, with patients resuming normal activities as their symptoms permit irrespective of radiological appearance.
- Zone 2 fractures (Jones fracture) are slower to heal and more prone to re-fracture. A short leg cast or a functional brace may be used; however, surgical fixation should be considered, particularly in an athletic population.
- Zone 3 (diaphyseal stress) fractures are prone to nonunion and surgical fixation results in a quicker time to union and return to sport and this may be beneficial in selected patients.

Question 2: In patients with a proximal fifth metatarsal fracture, does operative fixation result in better outcomes than nonoperative management?

Rationale

The majority of proximal fifth metatarsal fractures heal with conservative management.[8,9] There is a small group which are prone to delayed healing and nonunion, which have been subclassified by Torg[5] and added to by Lee et al.[6] Identifying those patients which are best suited for operative management can be challenging. Return to a preinjury level of sporting activity can almost always be expected after a proximal fifth metatarsal injury.

Clinical comment

Zone 1 (avulsion) fractures and distal metatarsal fractures are commonly treated symptomatically, with evidence indicating weight bearing helps with fracture healing. Zone 2 (Jones) and 3 (diaphyseal stress) injuries, when treated conservatively, should be put in a CAM walker or plaster. Current recommendation in most patients would be to nonweightbear initially then consider changing at 4–6 weeks to weightbearing in a CAM walker until radiological union. In an athlete with an acute zone 2 (Jones) fracture or zone 3 (diaphyseal stress) fracture, most specialists would advise operative fixation to achieve a more rapid time to union and return to sport. Return to a preinjury level of sporting activity can almost always be expected after a fifth metatarsal injury.

Available literature and quality of the evidence

A randomized controlled trial (level I) compared cast treatment (n = 18) to screw fixation (n = 19) in acute zone 2 (Jones) fractures, which demonstrated 5/18 fractures treated with immobilization resulted in nonunion, 1/18 in delayed union (68 weeks), and 2/18 re-fracturing.[13] Time to union (7.5 weeks vs 22.1) was also significantly ($p < 0.01$) decreased in the surgical group.[13]

A recent systematic review (level II) of treatment of zone 2 (Jones) fractures found nonoperatively managed acute fractures had a union rate of 76% compared to 96% of those fractures treated with an intramedullary screw.[3] Most of the 26 studies were case series (level IV) with one randomized controlled trial (level I), and included 358 (of 630 patients, total) surgically treated fractures, but the authors concluded that union was quicker and more likely to be achieved in those treated operatively. The complication rate reported was 1.7% infection, 0.8% sural nerve damage, 1.4% intraoperative fracture, and 20 removal of screws.[3]

Multiple level four studies have assessed operative fixation in proximal fifth metatarsal fractures and time to union and return to sport. Japjec et al. series of 42 athletes with zone 2 and 3 fractures, supported operative fixation.[14] Porter et al. reported a case series of 23 athletes treated with internal fixation of the fifth metatarsal, all returned to sport (mean 7.5 weeks) (level IV).[15] A retrospective study of 22 patients with Jones fractures or proximal diaphyseal stress fractures treated surgically showed all fractures united (mean 6.25 weeks) with no to rare pain reported during athletic activity.[12] Another series reported union in 64% of patients at six weeks, with the remainder uniting by 12 weeks with one partial union. All patients returned to their previous levels of sporting activity.[16] De Lee et al. achieved union (mean 7.5 weeks) in all patients in their series (10 pts) with screw fixation.[17] Mindrebo reported

nine patients fixed surgically with mean time to return to running of 5.5 weeks, all fractures clinically and radiologically united.[18] Lareau et al. reviewed 25 professional NFL players with an operatively treated zone 2 (Jones) fracture and demonstrated 100% return to play, with an average time between 8 and 10 weeks.[19] O'Malley et al. demonstrated 100% return to play in 10 professional NBA athletes treated surgically with zone 2 (Jones) and zone 3 (diaphyseal stress) injuries at a mean time of 9.8 weeks.[20]

Level IV evidence has shown that of 38 patients with zone 1 (avulsion) fractures, the most significant predictor of poor functional outcome was prolonged nonweightbearing. Gender, age, and fracture type did not affect outcome.[10] Level II evidence has also demonstrated, with a review of 60 patients with zone 1 (avulsion) fractures, all fractures healed; however, those treated in a soft dressing returned to preinjury levels of activity faster (average 33 days vs 46 days).[11]

Findings

Level I evidence shows significantly faster time to union with operative fixation (7.5 weeks) compared to nonoperative treatment (22.1 weeks).[13] A systematic review (level II) found faster return to sport with fixation of Jones fractures, with slower time to union and function in those treated in a cast.[3] Furthermore, it was concluded that these fractures should be managed operatively and return to full function should be delayed until radiological union to reduce the risk of re-fracture.[3] There is increasing literature in support of operative management of zone 2 fractures, particularly amongst athletic individuals. The bulk of the supporting evidence is formed by retrospective case series (level IV), but shows faster rates of return to sport in the athlete in operatively treated zone 2 (Jones)

fractures,[12],[14]–[18] and an ability to reach preinjury activity levels.[19],[20]

In those patients with zone 1 (avulsion) fractures, more favorable outcomes were achieved with weightbearing (level IV),[20] and avoidance of cast immobilization (level II).[10]

Resolution of clinical scenario

- Patients with fifth metatarsal injuries can be reassured that they should be able to return to their preinjury sport.
- Athletes with zone 2 (Jones) and zone 3 (diaphyseal stress) fractures should have strong consideration for operative fixation.
- Zone 1 (tuberosity) fractures achieve union with nonoperative treatment, with faster union rates associated with weightbearing and avoidance of cast immobilization

Question 3: In patients with a proximal fifth metatarsal fracture, does intramedullary screw fixation lead to better biomechanical and clinical outcomes than other operative treatment options?

Rationale

Managing expectations is an important aspect of treating surgical patients and a thorough knowledge of prognosis helps in this respect. Most surgeons use an intramedullary screw to fix these fractures. However, the rate of nonunion

and re-fracture after this procedure remains a concern. Guidelines for treatment should be individualized depending upon type of fracture and sporting or functional demands.

Clinical comment

The optimal fixation method for proximal fifth metatarsal fractures has a bearing on radiological union rates, clinical outcomes, and potential complications.

Available literature and quality of the evidence

Level IV and V studies have utilized cadaver models to demonstrate the hardware failure and number of cycles to failure. Shah et al. used a cadaveric model to compare 4.5 mm and 5.5 mm screws to fix proximal fifth metatarsal fractures, with no difference in initial load to failure or ultimate load to failure.[21] Reese et al. cautioned against the use of screws of 4 mm and less due to the low number of cycles to failure in their cadaveric models fixed with these screws. They also found that solid screws displayed twice the number of cycles to failure when compared to cannulated screws.[22] Sides et al. compared bending stiffness and pull-out strength of tapered, variable pitch screws, and 6.5 mm cancellous screws in acute zone 2 (Jones) fractures using a cadaveric model. There was no demonstrable difference in bending stiffness between metatarsals fixed with the two types of screws ($p = 0.688$).[23] The 6.5 mm screw provided significantly higher resistance to pull-out ($p = 0.001$), a finding replicated in Kelly et al.'s cadaveric study.[24] The importance of torsional restraint was suggested by the findings of a cadaveric study by Vertullo et al.[25] Horst et al. tested torsional resistance of 5 mm and 6.5 mm screws used to fix simulated Jones fractures in cadaveric models. They found that both 5 mm or 6.5 mm screws provide equal torsional rigidity, but

5 mm screws needed to be longer to achieve stability and this could potentially cause problems in patients with curved metatarsals.[26] Moshirfar et al. studied strength of fixation comparing a bicortical lag screw with an intramedullary screw the lag screw technique resulted in a significantly greater mean (±SD) load to failure (150 ± 90 N) (level V).[27] Huh et al. compared biomechanical outcomes in eight cadavers which demonstrated intramedullary screw fixation had a greater bending stiffness and less fracture site angulation than plantar plate fixation during plantar-to-dorsal and lateral-to-medial bending, though this did not reach statistical significance.[28]

Level IV clinical studies have investigated optimal screw size and diameter. Porter al. compared the use of 4.5 mm and 5.5 mm screws to fix proximal fifth metatarsal fractures, which demonstrated no difference in union rates or return to sport in 20 athletes (mean 9.3 weeks), though there were three bent screws in the 4.5 mm group.[29]

Level IV studies have also investigated the outcomes of plantar plate internal fixation. Bernstein et al. demonstrated 100% union and return to play in eight elite athletes with acute metatarsal fracture (four patients) and acute re-fracture (four patients) treated with plantar plating and autologous bone grafting, with a mean time to union 6.5 weeks and return to sport at 12.3 weeks.[30] Sarimo et al. presents a series of zone 3 (diaphyseal stress) injuries treated successfully with a tension band wire construct. There were no re-fractures or hardware failures in their series of 27 patients, with a mean return to activity of 14.1 weeks.[31] Lee et al. retrospectively reviewed 168 patients with zone 3 (diaphyseal stress) fractures treated with tension band wiring, with mean 23.6-month follow-up, with 11 nonunion and 18 re-fracture, and found that surgical technique was reproducible, but a higher risk of

complications was present for patients with an increased body weight, wide fourth/fifth intermetatarsal angle, and curved metatarsal head.[32]

Findings

Overall, the evidence for fixation type is limited to level IV and V studies. There exist biomechanical studies which have shown no clear differences between 4.5 and 5.5 mm intramedullary screws,[21] and clinical studies with a similar outcome.[29] Other biomechanical evidence suggesting no difference between 5 and 6.5 mm screws, other than the 5 mm screw requiring a longer time period to achieve union.[26] Further biomechanical studies have shown no difference between intramedullary screw fixation and plantar plating.[28]

Clinical studies are restricted to case series (level IV), with Bernstein et al. showing successful union and return to sport in small numbers of patients treated with plantar plating,[30] and Sarimo et al. showing similar successful treatment outcomes with tension band construct.[31] Lee et al. reviewed 168 patients with zone 3 (stress) fracture with uncomplicated union in 82.7% of patients, and identified anatomic risk factors for poor union and patient factors including increased body weight.[32]

Resolution of clinical scenario

- A solid screw of adequate size such that the threads gain purchase in the cortical diaphyseal bone should be used.
- Cannulated screws and screws 4 mm and smaller risk failure; bending of the screw and re-fracture (Figure 108.2).

- Tension band wire and plantar plating remain options for fixation.
- No clear difference in biomechanical outcomes with 4.5 mm and 5.5 mm intramedullary screws.

Figure 108.2 4.5 mm screw fixation of proximal fifth metatarsal fracture.

Summary of answers

- It should be appreciated that there are three types of proximal fifth metatarsal fracture that may require different treatments and which have different prognoses.
- The prognosis of proximal fifth metatarsal fractures is good.
- When conservatively treating proximal fifth metatarsal fractures treat zone 1 injuries symptomatically and zone two-thirds of injuries in a plaster or boot: weightbearing should be encouraged as tolerated.
- Operative fixation of zone 2 and zone 3 proximal metatarsal injuries leads to a quicker time to union and return to sport and this may be beneficial in selected patients.
- Intramedullary screw fixation with a diameter of 4.5 mm and greater has good biomechanical and clinical evidence.
- There is no clear difference with the use of plantar plates, tension band constructs, or intramedullary screws.

V Spine

109
Mechanical Neck Pain

Kenneth Nwosu MD[1], and Thomas Cha MD MBA[2]
[1]NeoSpine, Puyallup, WA, USA
[2]Harvard Medical School, Massachusetts General Hospital, Boston, MA, USA

Clinical scenario

- A 50-year-old woman presents with acute neck pain, which she attributes to sleeping in an awkward position.
- The pain is sharp and tight, and located over the right posterolateral aspect of her neck, upper back, and shoulder.
- She denies radiating arm pain, impaired hand dexterity, or gait. She denies associated headaches. She denies antecedent trauma.

Top three questions

1. In adults with nonwhiplash-associated mechanical neck pain, do patient education strategies improve pain, function, and/or quality of life compared to no treatment?
2. Have nonsteroidal anti-inflammatory drugs (NSAIDs), muscle relaxants, or analgesics demonstrated efficacy compared to placebo or other treatments in treating patients with nonspecific neck pain?

3. In adults with nonwhiplash-associated mechanical neck pain, does the addition of exercise to mobilization/manipulation improve pain and function compared to mobilization/manipulation alone?

Question 1: In adults with nonwhiplash-associated mechanical neck pain, do patient education strategies improve pain, function, and/or quality of life compared to no treatment?

Rationale

Although the efficacy of patient education for mechanical low back pain is controversial, it is often recommended. Initially, a considerable amount of faith was placed in its potential benefits.[1] However, subsequent robust research has moderated these expectations.[2,3] However, a systematic review reported on the effectiveness of back schools, particularly in the occupational setting.[4]

Clinical comment

Because of reports recommending educational strategies for mechanical low back pain, providers often recommend such strategies for mechanical neck pain as well.

Available literature and quality of the evidence

- Level I: 6 randomized studies.[5–10]

Findings

Two trials compared advice focused on activation to no treatment and found no benefit for subacute and chronic mechanical neck disorders in pain at up to six months and immediately after completing treatment, respectively.[5,7] One study compared advice focused on activation to home exercise and found no difference in pain and self-reported ability to work at one year.[10] Two studies compared advice focused on activation to cognitive behavioral therapy (CBT) and found no difference in pain at one year; however, activation was inferior to CBT regarding functional disability and work-related outcomes at one year according to one study.[10] Kamwendo et al. found no difference in sick leave taken between both groups.[7] Two trials compared advice focused on activation to usual physiotherapy care and found activation was marginally inferior in pain relief; function, disability, or work-related outcomes; and quality of life at one year.[8,9]

One trial compared advice focused on pain and stress comping skills to no treatment and reported no benefit in pain or disability reduction.[6]

One trial compared neck school to no treatment and showed no benefit in pain, and function, disability, or work-related outcomes at six months.[7]

Resolution of clinical scenario

Patients with nonwhiplash-associated mechanical neck pain will likely not benefit from educational interventions, especially advice to activate, advice on pain and stress coping skills, and neck school.

Question 2: Have nonsteroidal anti-inflammatory drugs (NSAIDs), muscle relaxants, or analgesics demonstrated efficacy compared to placebo or other treatments in treating patients with nonspecific neck pain?

Rationale

Conservative treatments, specifically oral pharmacological agents, are often considered first-line treatments for most musculoskeletal conditions. To justify their use, these modalities should allow patients to maintain activities related to work and daily living, and a good quality of life.

Clinical comment

NSAIDs, muscle relaxants, and analgesics are often recommended and widely prescribed for nonspecific neck pain. These recommendations were extrapolated from literature addressing other musculoskeletal conditions, including low back pain.

Available literature and quality of the evidence

- Level I: 1 systematic review.[11]
- Level I: 1 best-evidence synthesis.[12]
- Level I: 1 randomized trial.[13]

Findings

A Cochrane review concluded that muscle relaxants, opioid analgesics, and NSAIDs have limited evidence and unclear

benefits for nonspecific neck pain.[11] The Task Force on Neck Pain found no evidence to suggest that one medication is superior to any other medication or nonmedication intervention.[12] Based on six clinical trials considered scientifically admissible, the Task Force on Neck Pain concluded that the short-term management of symptoms with nonnarcotic analgesics may be helpful for grade II neck pain.[14]

A subsequent trial found that oxycodone was effective for recurrent episodes of neck pain.[13] However, the use of oxycodone for noncancerous pain is controversial due to limited evidence for long-term efficacy, poor side-effect profile, and a potential for abuse and addiction.[15]

Resolution of clinical scenario

A short course of nonopioid analgesics or NSAIDs may be helpful for the short-term management of grade II neck pain symptoms.

Question 3: In adults with nonwhiplash-associated mechanical neck pain, does the addition of exercise to mobilization/manipulation improve pain and function compared to mobilization/manipulation alone?

Rationale

Chiropractors, often considered the gatekeepers between patients with musculoskeletal conditions and clinicians, including surgeons, have repeatedly demonstrated high value in the services they provide.[16–19]

Clinical comment

There is a general consensus that spinal manipulation and mobilization is highly cost-effective for spinal pathologies. However, one recent high-quality UK systematic review reported inconclusive evidence for cervical manipulation alone.[20] In addition, reports of increased incidence of stroke following cervical manipulation were concerning,[21],[22] although these reports were subsequently refuted by a systematic review in 2012.[23]

Available literature and quality of the evidence

- Level I: 2 systematic reviews.[24],[25]
- Level I: 1 clinical guideline.[26]

Findings

Gross et al., in a Cochrane review, reported on 33 randomized trials, of which 42% were considered high quality. They found no benefit of manipulation or mobilization to alleviate mechanical neck pain with or without headaches, compared to control groups, placebo, or other treatment modalities. However, they reported strong evidence supporting manipulation and/or mobilization combined with exercise toward improving pain, disability, and global perceived effects.[25]

The aforementioned study was fortified by a subsequent systematic review that reported on 88 randomized trials, of which 59% were considered high quality.[24] It reported strong evidence of maintained benefit for pain reduction, functional improvement, and global health improvement in patients that received manipulation and/or mobilization, and exercise compared to a control cohort of patients with mechanical neck pain

A *Clinical Practice Guidelines* regarding assessment and management of neck pain was subsequently published, concisely synthesizing the results from the above studies and others. They endorsed that clinicians should consider cervical manipulation and/or mobilization. Furthermore, it reported that exercise and manipulation and/or mobilization proved more effective for improving pain, disability, and global health.[26]

Resolution of clinical scenario

In patients with mechanical neck pain with or without headaches, manipulation and/or mobilization with exercise is likely to be beneficial and should be recommended.

Summary of answers

- Patients with nonwhiplash mechanical neck pain will likely not benefit from educational interventions such as neck school.
- A short course of nonopioid analgesics may be helpful for short-term symptomatic management.
- In patients with mechanical neck pain, manipulation and/or mobilization is likely to be beneficial.

110
Whiplash

Eren O. Kuris MD and Alan H. Daniels MD
Department of Orthopaedic Surgery, Brown University, Providence, RI, USA

Clinical scenario

- A 21-year-old college football players sustains a helmet-to-helmet collision and has immediate onset of neck pain.
- The patient previously had one episode of transient weakness in his right upper extremity after a football collision in high school, but he has never had symptoms like this.
- Initial evaluation reveals tenderness to palpation about the cervical spine, limited neck range of motion (ROM), and no neurological deficits.
- He is concerned about his ability to return to play this season and the effects of this injury on his long-term career prospects.

Top three questions

1. In athletes with whiplash and/or cervical spine injuries, what are the return-to-play criteria, and what injuries/conditions are contraindications to return to play?
2. In athletes who sustain a cervical disc herniation, do those who undergo surgery have higher return-to-play rates than individuals treated nonoperatively?

3. In athletes who sustain a burner/stinger injury, do preexisting factors contribute to an increased risk of this condition, and how do these factors impact resolution of symptoms and return to play?

Question 1: In athletes with whiplash and/or cervical spine injuries, what are the return-to-play criteria, and what injuries/conditions are contraindications to return to play?

Rationale

Sports-related cervical spine injuries are common and can range from minor cervical strains to catastrophic fractures/dislocations resulting in permanent neurological impairments and even death. Although severe neurological injuries are rare, many competitive athletes are quite motivated to return to sport. Therefore, the treatment for these injuries and criteria for return to play are important considerations for physicians.[1]

Clinical comment

Due to the risk of catastrophic spinal cord injury and persistent neurological dysfunction, certain criteria are absolute contraindications to return to play in intense athletic activity.

Available literature and quality of the evidence

There is a paucity of high-quality studies that guide return to play criteria, likely due to the relative rarity of these injuries. In addition, some athletes with certain spine injuries cannot justify returning to play due to the potential

for catastrophic spinal cord injury. The majority of guidelines that guide treatment decisions are based on retrospective evaluations and expert opinion.[2]

Table 110.1 Guidelines for return to collision/contact sports in patients with a cervical spine condition or injury. Asymptomatic patients are defined as athletes with no neurological deficits, neck pain, pain with ROM, or evidence of pseudarthrosis.[4]

Condition	**Return to Play**
Patients with healed, stable nondisplaced fractures without spinal malalignment	No Contraindication
Successful nonsurgical treatment of asymptomatic disc herniations	No Contraindication
Asymptomatic patients after a previous one-level cervical fusion	No Contraindication
Certain congenital conditions, such as Klippel-Feil type 2 anomoly	No Contraindication
	No Contraindication
Prior fracture of the upper cervical spine with evidence of union [nondisplaced Jefferson fracture, a dens fracture (type 1 or 2)]	Relative Contraindication (If Patient Asymptomatic)
A healed vertebral compression fracture without significant displacement or malalignment	Relative Contraindication (If Patient Asymptomatic)
A stable and healed fracture that involves the posterior elements (not including spinous process fractures)	Relative Contraindication (If Patient Asymptomatic)
Two-level cervical fusion	Relative Contraindication (If Patient Asymptomatic)

Condition	Return to Play
Odontoid abnormalities	Absolute Contraindication
Occipital-cervical arthrodesis	Absolute Contraindication
Atlantoaxial instability	Absolute Contraindication
Klippel-Feil typ 1 abnormalities	Absolute Contraindication
Spear Tackler's Spine	Absolute Contraindication
Subaxial cervical spine instability	Absolute Contraindication
Acute fracture of the body or posterior elements (both with and without instability)	Absolute Contraindication
United subaxial vertebral body fractures with persistent saggital malalignment	Absolute Contraindication
Retropulsed bone fragments	Absolute Contraindication
Continued pain, limited motion, or neurological deficits after a healed fracture	Absolute Contraindication
Acute or chronic disc herniation with associated pain, limited motion, or neurological deficts	Absolute Contraindication

Findings

Whiplash and cervical strains/sprains are common injuries encountered in most sports. Athletes may have localized cervical pain, tenderness to palpation, and decreased ROM *without* neurological deficits. An athlete with full, intact

ROM (including flexion, extension, lateral bending, and rotation) does not require further imaging and may resume activity. If physical examination reveals pain, diminished ROM, or sensorimotor deficits then imaging studies are required.[1]

Certain injuries and/or conditions are career ending, but many athletes can return to play after injuries that have been treated appropriately with minimal risk for significant recurrence or worsening of the injury.[3] Physicians often face extrinsic pressures, and the decision to allow return to competitive activity after cervical spine injuries can be challenging.[4] Table 110.1 summarizes return-to-play recommendations after certain injuries and conditions of the cervical spine.

Resolution of clinical scenario

- Athletes can generally return to contact/collision sports after a cervical spine injury if they have no pain, full ROM, and no neurological deficits.
- Certain injuries or congenital conditions preclude return to sports (Table 110.1). These are generally associated with an unacceptable level of risk for catastrophic spinal cord injury.

Question 2: In athletes who sustain a cervical disc herniation, do those who undergo surgery have higher return-to-play rates than individuals treated nonoperatively?

Rationale

Cervical disc herniations in athletes are relatively common, especially in contact sports, with a constellation of symptoms that can vary from neck pain to radiculopathy, myelopathy, and transient quadraparesis.[5]

Clinical comment

The treatment of cervical disc herniations in athletes is controversial, without a consensus on the optimal treatment approach for these injuries.

Available literature and quality of the evidence

Although neck injuries occur relatively frequently in athletes, these patients represent a small subset of the overall population, and it is difficult to design high-quality studies that can dictate management and return-to-play algorithms specifically for this group of patients. The majority of studies are based on retrospective analysis and expert opinion.[1,5]

Findings

Various studies have evaluated the effect of surgery on return-to-play rates in players who undergo surgery for cervical disc herniations. Hsu et al. retrospectively reviewed 99 National Football League players. Fifty-three of these 99 athletes underwent surgical treatment, and the athletes treated operatively were significantly more likely to return to professional football (72% vs 46%, $p = 0.04$). However, in the athletes that did return to play, there was no significant difference in number of games played and positional performance scores in the patients treated operatively and nonoperatively.[5,6]

Another study evaluated 15 athletes who underwent a single level anterior cervical discectomy and fusion (ACDF). Thirteen of these patients were able to return to

activity after demonstrating full, painless neck ROM, a solid radiographic fusion, and a normal neurological examination.[7] Several other studies validate these findings, although the data are somewhat limited due to the relative infrequency of this condition in athletic individuals.[5]

No studies have been able to effectively determine whether it is safe to return to play after multilevel cervical fusions. In general, a two-level ACDF is considered a relative contraindication and a 3+ level ACDF is considered an absolute contraindication to athletic activity.[5]

Resolution of clinical scenario

- In general, athletes with a cervical disc herniation can safely return to play after a one-level ACDF if they have evidence of a solid fusion, normal neurological examination, and normal neck ROM.
- Multilevel cervical fusions are considered contraindications to return to sport.
- Some literature suggests that athletes with symptomatic cervical disc herniations treated operatively have higher rates of return to athletic activity than patients treated nonoperatively.

Question 3: In athletes who sustain a burner/stinger injury, do preexisting factors contribute to an increased risk of this condition, and how do these factors impact resolution of symptoms and return to play?

Rationale

Stingers, also known as *burners*, are very common injuries, particularly in contact sports. One study found that they occur in approximately 65% of American college football players at least once during their four-year college football tenure.[5]

Clinical comment

Recognizing this injury is important, as the symptoms can coincide with more severe cervical spine injuries that require further workup and more stringent return-to-play criteria.[5] Although they are quite common, the mechanisms of injury associated with stingers can vary, which can influence the risk of recurrent injuries.

Available literature and quality of the evidence

Similar to other cervical spine injuries in athletes, the majority of evidence that guides treatment is based on retrospective evaluations and expert opinion.

Findings

Athletes who sustain a stinger injury typically experience pain, paresthesias, and occasionally weakness in a *single* extremity. The symptoms do not always follow a dermatomal pattern and often resolve after a short period of time.[1]

Several mechanisms responsible for the pathophysiology associated with stingers have been proposed. Some authors believe they are the result of foraminal compression of the exiting cervical nerve root as the neck is extended and bent laterally, causing an injury to the nerve root itself.[5] Several studies have popularized this proposed mechanism. For instance, Meyer et al. found that college football players with a Torg–Pavlov ratio less than 0.8 were over three times more likely to develop a stinger.[5,8] Another study

found that high school football players who had previously suffered from a stinger had significantly smaller Torg–Pavlov ratios relative to asymptomatic controls (0.88 vs 0.94; p = 0.02).[9]

Other authors believe that stingers are more commonly the result of traction injuries to the brachial plexus that occur when lateral impact to the head causes contralateral neck flexion and ipsilateral shoulder depression. Studies supporting this theory have described brachial plexus neuropraxia, such as axonotmesis, in the electromyograms of the majority of athletes who suffer from stingers. Both mechanisms likely contribute to these injuries, with nerve root compression more common in patients with chronic stingers and preexisting cervical spine spondylosis, and neuropraxia more common in acute stingers.[5]

These injuries often resolve quickly, sometimes after a few minutes, and most physicians allow return to play when the athlete has resolution of symptoms with full strength and full ROM of both the neck and the involved extremity. When symptoms persist, or an athlete has more than three episodes in less than one year, additional workup is required.[1]

Persistent symptoms or recurrent episodes (more than three stingers in less than a year) generally require further workup with an electromyograph (EMG) or magnetic resonance imaging (MRI) prior to return to play. Physicians must always differentiate stingers from transient neuropraxia, which involves more than one extremity and generally does not resolve quickly. These injuries require immediate workup and further treatment.[5]

Resolution of clinical scenario

- Stingers/burners are common conditions seen in contact athletes.

- When symptoms are localized to a single extremity and resolve after a short period (demonstrated by full strength and ROM of the neck and the involved extremity), the athlete may return to play.
- When symptoms persist, or an athlete has more than three episodes in less than one year, further workup is required.

Summary of answers

- Athletes can return to contact sports after cervical spine injury if they have full ROM, no pain, and no neurological deficits.
- Athletes with a cervical disc herniation can return to play after single-level ACDF if there is solid fusion, no neurological deficits, and normal neck ROM.
- Multilevel ACDF is a contraindication to return to contact sports.
- Stingers/burners are common, and when symptoms persist or recur, further workup is indicated.

Cervical Radiculopathy and Myelopathy

Michael Fehlings MD PhD FACS FRCSC, and Jetan Badhiwala MD
Division of Neurosurgery, Department of Surgery, University of Toronto, Toronto, ON, Canada

Clinical scenario

- A 53-year-old male presents to an ambulatory clinic with a history of bilateral hand numbness and clumsiness, leading to great difficulty with manual tasks, as well as gait difficulty.
- Examination reveals diminished power in bilateral hand grip and finger abductors, hyperreflexia, a positive Hoffmann's sign, upgoing plantar responses, and unsteadiness on tandem gait testing.
- Magnetic resonance imaging (MRI) of the cervical spine reveals multilevel cervical spondylosis with moderate central canal narrowing and spinal cord compression; there is T2 hyperintense signal within the cord at C4.

Top three questions

1. In patients with mild, moderate, or severe degenerative cervical myelopathy (DCM), does surgical decompression provide superior functional outcomes, as graded by the modified Japanese Orthopaedic

Association (mJOA) scale, compared to nonoperative management strategies?

2. In patients with asymptomatic cervical spinal cord compression (imaging evidence of cervical spinal cord compression without signs or symptoms of myelopathy or radiculopathy), what is the role of prophylactic surgery, and what are the frequency and timing of symptom development and clinical, radiological, and electrophysiological predictors of myelopathy development?
3. In patients with imaging evidence of cervical spinal cord compression and clinical and/or electrophysiological evidence of radiculopathy, but without myelopathy, what is the role of surgery, and what are the frequency and timing of symptom development and clinical, radiological, and electrophysiological predictors of myelopathy development?

Question 1: In patients with mild, moderate, or severe degenerative cervical myelopathy (DCM), does surgical decompression provide superior functional outcomes, as graded by the modified Japanese Orthopaedic Association (mJOA) scale, compared to nonoperative management strategies?

Rationale

DCM is a progressive degenerative spinal condition that results in chronic, nontraumatic compression of the cervical spinal cord and ensuing neurological deficits. The spectrum of disease severity is wide in DCM, and the severity of initial presentation dictates the optimal clinical management of affected patients. Classification of patients into severity groups is by the mJOA scale: mild (mJOA 15–17), moderate (mJOA 12–14), and severe (mJOA <12).[1]

Clinical comment

DCM represents the leading cause of spinal cord dysfunction globally.[2] DCM occurs when progressive age-related osteoarthritic changes (e.g. degenerative disk disease, spondylosis, ossification of the posterior longitudinal ligament) narrow the cervical spinal canal, leading to chronic spinal cord compression.[3] There is ischemia and breakdown of the blood–spinal cord barrier, ultimately resulting in neuronal and glial death and a pathological picture consistent with chronic spinal cord injury.[4] The natural history of DCM is thought to involve progressive, stepwise decline, with 20–62% of patients deteriorating at 3–6 years of follow-up, as assessed by the mJOA scale.[5,6] Given the limited potential for repair and recovery of the spinal cord, many of the pathological and clinical changes induced by this process are irreversible. With the aging population, DCM will portend a greater burden of disability on our population. Over 70% of individuals over 60–65 years old demonstrate pathological or radiological evidence of cervical degeneration, and approximately one-quarter of these people become clinically symptomatic from mechanical neural compression.[7–9] The proportion of the United States population 65 years or older is expected to nearly double from 13% in 2010 to 22% in 2050.[10] Orthopedic and neurosurgeons alike therefore should become comfortable

in making decisions related to the management of patients with this clinicopathological entity.

Available literature and quality of the evidence

Clinical practice guidelines for the management of patients with DCM were published in 2017.[11] The evidence for management of DCM is derived primarily from prospective (level II evidence) and retrospective (level III evidence) observational studies. There have been select randomized controlled trials (RCTs); however, these have had several methodological flaws. There have also been several systematic reviews.

Findings

There is a single RCT comparing the clinical outcomes of operative and nonoperative management for DCM. In 2000, Kadanka et al. published the results of a small RCT of 48 patients with mild or moderate DCM (mJOA ≥12) randomized to conservative or operative treatment.[12–16] Surgery consisted of anterior decompression in 22 patients, corpectomy in six patients, and laminoplasty in five patients. Conservative strategies included cervical collar, anti-inflammatory medications, and intermittent bedrest for patients with pain, discouragement from participation in high-risk activities, and avoidance of risky environments (e.g. physical overloading, movement on slippery surfaces, manipulation therapies, or prolonged flexion of the head). No significant difference was observed in mean mJOA score within or between the conservative and surgical cohorts over a 36-month period. At the three-year mark, 24.1% of the surgical cohort had improved two or more points on the mJOA scale, not significantly different from the corresponding proportion in the conservative cohort (23.3%).[13] At the 10-year mark, mean mJOA score was 15.0 in conservatively and 14.0 in surgically treated

patients.[15] However, several criticisms have been levied against this trial, most notably that it was underpowered and lacked a sample size calculation.[17] A recent sample size estimate for an RCT sponsored by the Patient-Centered Outcomes Research Institute (PCORI) indicates 159 patients would be needed to demonstrate a difference using the SF-36 Physical Component Summary (PCS) as the outcome instrument.[18] Hence, based on this study and one retrospective cohort study of 91 Chinese DCM patients,[19] there is low-level evidence that nonoperative treatment results in similar outcomes as surgery for patients with *milder* (mJOA ≥13), single-level DCM and intramedullary signal change on T2 MRI.[20,21]

In another prospective comparative study also published in 2000, Sampath et al. enrolled patients with subacute DCM, defined by at least eight weeks of symptoms. Patients were seen by a Cervical Spine Research Society (CSRS) surgeon and prescribed either medical or surgical therapy.[22] A total of 23 patients received conservative treatment, including a combination of pharmacotherapy, home exercise, physical therapy, bedrest, cervical traction, and neck bracing. By contrast, 20 patients underwent surgery. At a mean follow-up of 29.8 months, the surgical group demonstrated significant improvements in overall functional status as well as work and social activities. Conservatively treated patients, too, exhibited functional improvements, but this did not reach statistical significance. Additionally, surgical patients experienced no change in the number of activities that worsened their symptoms from before to after treatment, whereas the number of activities that exacerbated symptoms in the medical cohort increased from baseline to follow-up (+0.63).

Since then, there have been several contemporary prospective studies to support the safety and efficacy of

operative treatment in patients with DCM with regard to functional status, disability, pain, and complications. A 2017 systematic review of the literature identified 32 prospective investigations.[23] Pooled standard mean differences showed a large effect for improvement in mJOA score from baseline at short-, medium-, and long-term follow-up: 6–12 months (1.92; 95% confidence interval [CI]: 1.41–2.43); 13–36 months (1.40; 95% CI: 1.12–1.67); and >36 months (1.92; 95% CI: 1.14–2.69) (moderate-level evidence). There was also low-level evidence that surgery resulted in significant improvements in Nurick grade, Neck Disability Index (NDI), and Visual Analog Scale (VAS) scores. The cumulative incidence of complications was low (14.1%; 95% CI: 10.1–18.2%). The AOSpine CSM-NA and CSM-I trials represent two of the largest multicenter, prospective studies of surgical decompression for DCM.[24,25] An extensive battery of outcome metrics were evaluated, including functional status (mJOA, Nurick, 30-meter walk test [30MWT]), disability (NDI), and quality of life (SF-36). The CSM-NA study recruited 278 patients with symptomatic DCM and MRI evidence of spinal cord compression from 12 North American centers over a two-year period.[25] At enrollment, patients were classified into mild (mJOA ≥15), moderate (mJOA 12–14), or severe (mJOA < 2) groups based on disease severity. All patients underwent surgical decompression. There was significant improvement in mJOA score, Nurick grade, NDI, and all SF-36 dimensions, except *general health*, from baseline to one-year follow-up ($p < 0.05$). With the exception of mJOA, which exhibited a ceiling effect in patients with mild DCM, the degree of improvement did not depend on the severity of disease. The CSM-I trial enrolled 479 patients with symptomatic DCM with imaging evidence of compression from 16 global sites from 2007 to 2011.[24] At two-year follow-up, there was significant improvement in mJOA (12.5

to 14.9), NDI (36.4 to 23.2), and SF-36 PCS (34.3 to 40.8) and MCS (39.5 to 46.2) scores. The rate of neurological complications was 3.1%.

The primary limitation of the above studies was the absence of a control nonoperative group. However, in considering studies that evaluated structured nonoperative treatment, including therapeutic exercise, manual therapy, cervical bracing, and/or traction, a recent systematic review found very low-level evidence to suggest structured nonoperative treatment results in either a positive or negative change in function, as evaluated by the mJOA scale.[26] A majority of nonoperatively managed patients reported in the literature did not experience significant gains in function with structured nonoperative treatment. Moreover, a substantial proportion (23–54%) eventually underwent surgical treatment.

Distilling the above information, there is moderate-quality evidence to support the recommendation of surgical intervention in patients with moderate or severe DCM.[27] Current guidelines recommend surgical intervention or a supervised trial of rehabilitation in patients with mild DCM; if the latter is pursued, surgery is recommended if there is neurological deterioration or if the patient fails to improve.[27]

Question 2: In patients with asymptomatic cervical spinal cord compression (imaging evidence of cervical spinal cord compression without signs or symptoms of myelopathy or radiculopathy), what is the role of prophylactic surgery, and what are the frequency and timing of symptom development and clinical, radiological, and electrophysiological predictors of myelopathy development?

Rationale

Many patients present with imaging evidence of cervical spinal cord compression, but without clinical signs or symptoms of DCM or radiculopathy.

Clinical comment

In nonmyelopathic patients with imaging evidence of cervical spinal cord compression, it is important to consider the natural history of the disease, rates of disease progression, and myelopathy development, and risks of operative intervention.

Available literature and quality of the evidence

The clinical management of patients with asymptomatic cervical spinal cord compression is guided by prospective (level II evidence) and retrospective (level III)

observational studies. There are no RCTs (level I evidence) to guide decision-making in these patients.

Findings

Wilson et al. conducted a systematic review of the literature to assess the frequency, timing, and predictors of symptom development in patients with radiographic evidence of cervical spinal cord compression, spinal canal narrowing, and/or ossification of the posterior longitudinal ligament (OPLL), but without symptoms of myelopathy.[28] The authors identified five longitudinal cohort studies meeting eligibility criteria. The frequency of myelopathy development was reported to be 8% at one year and 22.6% at a median follow-up of 44 months in patients with cervical spondylosis. This was based on a prospective cohort study by Bednarik et al.[29,30] In this study, the presence of symptomatic radiculopathy (risk ratio [RR] = 3.0; 95% CI: 2.0–4.4), cervical cord hyperintensity on MRI (RR = 1.7; 95% CI: 1.0–2.7), and prolonged somatosensory- (SSEPs) (RR = 2.9; 95% CI: 1.7–5.1) and motor-evoked potentials (MEPs) (RR = 3.2; 95% CI: 1.9–5.6) were found to be significant independent predictors of myelopathy development. Traumatic events were not significantly associated with myelopathy development (RR = 0.9; 95% CI: 0.3–3.2).[30] In patients with OPLL, the rate of myelopathy development reported in three prospective cohort studies ranged from 0 to 61.5%.[31–33] One of these studies reported central canal stenosis ≥60% (RR N/A), lateral deviated OPLL (RR = 2.1; 85% CI 1.4–3.1), and increased cervical range of motion (RR N/A) to be significant predictors of myelopathy development.[32]

There are no studies that directly compare the efficacy of operative nonoperative management in nonmyelopathic patients with cord compression without signs or symptoms of radiculopathy. However, based on expert

recommendation and indirect lines of evidence surrounding rates of myelopathy development (derived from the studies discussed above), current guidelines provide a weak recommendation that prophylactic surgery not be offered to patients with evidence of cervical cord compression without signs or symptoms of radiculopathy.[27] These patients should be counseled about the risks of progression, educated about relevant signs and symptoms of myelopathy, and be followed clinically. If myelopathy were to develop, recommendations would follow that discussed in Question 1.

Question 3: In patients with imaging evidence of cervical spinal cord compression and clinical and/or electrophysiological evidence of radiculopathy, but without myelopathy, what is the role of surgery, and what are the frequency and timing of symptom development and clinical, radiological, and electrophysiological predictors of myelopathy development?

Rationale

Many patients present with clinical and/or electrophysiological evidence of radiculopathy and imaging evidence of cord compression, but without clinical signs or symptoms of myelopathy.

Clinical comment

Similar to Question 2, in nonmyelopathic patients with imaging evidence of cervical spinal cord compression and clinical and/or electrophysiological evidence of radiculopathy, it is important to consider the natural history of the disease, rates of disease progression, and myelopathy development, and risks of operative intervention.

Available literature and quality of the evidence

The clinical management of patients with cervical spinal cord compression and radiculopathy, but without myelopathy, is guided by prospective (level II evidence) and retrospective (level III) observational studies. There are no RCTs (level I evidence) to guide decision-making in these patients.

Findings

The findings presented for Question 2 are relevant to this important and practical question as well. As summarized in the systematic review by Wilson et al.,[28] the prospective study published by Bednarik and colleagues found symptomatic (clinical) radiculopathy (RR = 3.0; 95% CI: 2.0–4.4), prolonged SSEPs (RR = 2.9; 95% CI: 1.7–5.1), prolonged MEPs (RR = 3.2; 95% CI: 1.9–5.6), and EMG signs of anterior horn cell lesion (RR = 2.4; 95% CI: 1.5–3.9) to be significant predictors of myelopathy development on univariate analysis in nonmyelopathic patients with imaging evidence of cervical spinal cord compression.[29,30] Furthermore, a multivariate Cox proportional regression model revealed prolonged SSEPs and MEPs, clinically symptomatic radiculopathy, and lack of MRI hyperintensity to be associated with early (≤12 months) development of DCM.[28] More specifically, 62.5% of patients with clinical radiculopathy developed myelopathy by 12 months,

compared to 26.3% of patients without symptomatic radiculopathy.

Again, there are no studies that directly compare the efficacy of operative versus nonoperative management in nonmyelopathic patients with cord compression and signs or symptoms of radiculopathy. Based on expert opinion and the indirect lines of evidence discussed above, current guidelines offer a weak recommendation that nonmyelopathic patients with cord compression and clinical evidence of radiculopathy with or without electrophysiological confirmation be offered surgical intervention or nonoperative treatment.[27] The latter consists of close serial follow-up or a supervised trial of structured rehabilitation. These patients are at higher risk of developing myelopathy and should be counseled accordingly. If myelopathy were to develop, recommendations would follow that discussed in Question 1.

Resolution of clinical scenario

This patient presents with the signs and symptoms of DCM (i.e. symptomatic myelopathy). From the description, the patient has an mJOA score of 14 at the most; therefore, this patient falls into the *moderate* myelopathy group. Based on best available evidence and guideline recommendations, this patient should be managed with surgical intervention. The goal of surgery is to provide decompression of the cervical spinal cord, which can be achieved through an anterior, posterior, or combined approach, followed by reconstruction and stabilization of the spinal column to address any element of instability, whether degenerative or iatrogenic.

Summary of answers

- There is moderate evidence to support the recommendation of surgical decompression in patients with moderate or severe DCM, considering improvement in functional status. There is very low to low evidence to suggest patients with mild DCM should be offered surgical intervention or a supervised trial of structured rehabilitation. If the latter is opted, operative intervention is recommended if the patient fails to improve or deteriorates neurologically.
- There is low evidence that 22.6% of patients with asymptomatic cervical spinal cord compression will develop myelopathy at a median follow-up of 44 months. There is insufficient evidence to suggest 0–61.5% of patients with OPLL without myelopathy will develop symptomatic myelopathy. Current guidelines recommend against prophylactic surgery in nonmyelopathic patients with imaging evidence of cervical spine cord compression without signs or symptoms of radiculopathy.
- There is moderate evidence that, in nonmyelopathic patients with imaging evidence of cervical spinal cord compression, presence of clinically symptomatic radiculopathy, prolonged SSEPs, and prolonged MEPs are significant predictors of early development of myelopathy (<12 months). Current guidelines offer a weak recommendation that these patients be offered surgical intervention or nonoperative treatment consisting of close serial follow-up or a supervised trial of structured rehabilitation. The patients should be counseled about the higher risk of developing myelopathy. In the event of development of myelopathy, these patients should be managed according to the answer to Question 1.

Mechanical Low Back Pain: Operative Management

Pranay Patel MD[1], Ian Buchanan MD[2], Zorica Buser PhD[1], and Jeffrey C. Wang MD[1]
[1]Department of Orthopaedic Surgery, Keck School of Medicine, University of Southern California, Los Angeles, CA, USA
[2]Department of Neurological Surgery, Keck School of Medicine, University of Southern California, Los Angeles, CA, USA

Clinical scenario

- A 60-year-old male presents with a two-year history of isolated low back pain with no lower extremity radicular component.
- Patient's symptoms are refractory to multiple conservative treatment modalities including oral analgesia, physical therapy, and epidural steroid injections.
- The anesthetic discogram is concordant with pain at the L5–S1 level with normal controls at L3–L4 and L4–L5.
- Physical examination shows diminished range of motion throughout the lumbar spine in terms of flexion and extension, normal gait, and a normal neurovascular exam.

Top three questions

1. In patients with isolated mechanical back pain, does fusion provide improved pain relief compared to nonoperative treatment?
2. In patients with chronic low back pain (LBP), do some diagnostic tests more accurately select the right patient for spine fusion than other tests?
3. In patients undergoing spine fusion, what risk factors are associated with poorer outcomes?

Question 1: In patients with isolated mechanical back pain, does fusion provide improved pain relief compared to nonoperative treatment?

Rationale

The presenting patient has clinical and radiographic findings consistent with degenerative disc disease (DDD). He has exhausted conservative measures and wishes to know if a fusion can reliably improve his low back pain.

Clinical comment

There is a great deal of controversy regarding the treatment of mechanical LBP among orthopedic surgeons. Whether the intervertebral disc is the actual pain generator and operative fusion for treating mechanical low back is warranted remains controversial in both the literature and in clinical practice.

Available literature and quality of the evidence

Multiple randomized controlled trials (RCTs) are detailed below.

Findings

The common measurement outcome employed by four randomized trials was the Oswestry Disability Index (ODI), a validated measure specific for lumbar degenerative disorders. This index is measured from 1 to 100 with higher scores indicating a higher level of disability. Developers of the ODI indicate that a clinically relevant change is 4 points, whereas other studies have suggested thresholds of up to 18 points are required for clinical relevance.[1]

All four of the randomized trials compared surgical treatment of mechanical LBP with nonoperative treatment. Of the four randomized trials reviewed, three of them had structured nonoperative regimens.[2–4] The Fritzell et al. 2002 study did not have a structured regimen of physical therapy. Instead it used any kind of physical therapy as the main component, which could be supplemented with "information and education, TENS (transcutaneous electrical nerve stimulation), acupuncture, injections, cognitive and functional training, and coping strategies."[5]

All four studies showed a similar improvement in the surgical arm of patients, with improvement from baseline ranging from 8.9 to 15.6 points (percent improvement 18.9 to 37.1%).[6] In the nonoperative arm, improvements ranged from 2.8 to 12.8 (percent improvements from baseline were 5.8 to 30.1%). Only in the Fritzell et al. study was the improvement in nonoperative treatment below the clinically relevant threshold of 4 points on the ODI,[5] whereas in the other three studies the improvement seen in the nonoperative patients was similar to that of the operative patients. These three studies used a structured

nonoperative treatment regimen incorporating cognitive behavioral therapy, whereas the Fritzell et al. study did not.

The greatest improvement in surgical patients, when compared to their nonsurgical counterparts, was seen in the Fritzell et al. study (ΔODI surgery group − ΔODI nonsurgical group) at 8.8.[5] The Fairbank et al. study showed improvement in the surgical group of patients as well, with a minor improvement at 4.1 (95% confidence interval [CI]: 0.1–8.1). This value was not considered statistically significant.[2] Neither Brox et al. study showed a statistically significant difference between surgical and nonsurgical intervention for the ODI. The first study, looking at patients without prior surgery, the improvement seen with surgery for this study was 2.3 (95% CI: −6.8 to 11.4).[3] In the second Brox et al. study, looking at patients with a prior discectomy, greater improvements in the ODI were seen with nonsurgical treatment. When adjusted for gender and treatment expectations, this value was −9.7 (95% CI: −21.7 to 1.7).[4] Mannion et al. in their study consisting of three multicenter RCTs of surgery versus multidisciplinary cognitive-behavioral and exercise rehabilitation found no difference in patient self- reported outcomes between fusion and multidisciplinary cognitive-behavioral and exercise rehabilitation for chronic LBP.[7]

Resolution of clinical scenario

- Compared with an unstructured nonoperative treatment regimen, lumbar fusion can be expected to reduce pain by about 63% and improve ODI by about 25% (overall quality: moderate).
- Structured nonoperative treatment regimens that incorporate cognitive behavioral therapy can provide pain relief and improvements in the ODI that are

comparable to, if not better than, lumbar fusion (overall quality: moderate).

- Nonoperative treatment for mechanical back pain should be strongly considered (overall quality: high).

Question 2: In patients with chronic low back pain (LBP), do some diagnostic tests more accurately select the right patient for spine fusion than other tests?

Rationale

Spine surgeons often use diagnostic tests such as discography, magnetic resonance imaging (MRI), facet joint blocks, and brace immobilization to determine patient selection for lumbar fusion for DDD and chronic LBP.

Clinical comment

Understanding the prognostic value of these diagnostic tests can help the surgeon better select patients who may have better outcomes from lumbar fusion for isolated DDD.

Available literature and quality of the evidence

Although this topic has been reported frequently in the literature, few quality studies have been produced to adequately address this question of which diagnostic tests provide prognostic value for patient selection for lumbar fusion. After a thorough review of the literature, systematic reviews prove to be the most reliable and valuable method of understanding these diagnostic tests. Due to the nature of these tests, high-level evidence is not readily available

and systemic reviews consisting of retrospective analysis of prospectively collected data were utilized.

Findings

Patient selection for lumbar fusion due to isolated DDD remains a challenging question but one that is important for clinical success. Several studies have looked at various diagnostics tests to determine if they have validity in providing prognostic value. Diagnostic tests reviewed for prognostic accuracy include MRI, discography, facet joint blocks, pantaloon cast test (PCT), immobilization by orthosis, Modic changes, and a summary of physical symptoms termed *loading factor*.[8,9] Willems et al. compared the results of MRI, provocative discography, facet joint blocks, orthosis immobilization, and temporary external fixation with the clinical outcome of patients who underwent spinal fusion for chronic LBP.[8] The outcome measure was to determine the prognostic accuracy of diagnostic tests in predicting clinical efficacy of spinal fusion in regards to sensitivity, specificity, and likelihood ratios (LRs). In their review, immobilization by an orthosis (median [range] positive LR, 1.10 [0.94–1.13] and negative LR, 0.92 [0.39–1.12]), provocative discography (median [range] positive LR, 1.18 [0.70–1.71] and negative LR, 0.74 [0.24–1.40]), and temporary external fixation (median [range] positive LR, 1.22 [1.02–1.74] and negative LR, 0.58 [0.15–0.94]) did not have clinically relevant prognostic accuracy.[8] Overall, in this review, these tests could not identify a subset of patients with chronic LBP in which a fusion would have predictable and effective outcomes.

Staartjes et al. performed a systematic review investigating the value of prognostic tests following lumbar fusion surgery for DDD with a retrospective analysis of prospectively collected data.[9] The outcome measures were pre- and postoperative Visual Analog Scale (VAS) and ODI

scores. The review found discography, Modic changes, and loading factor were of no value for predicting outcome scores ($p > 0.05$).[9] However, in patients without prior surgery, a positive PCT did correlate with improved outcomes in back pain severity suggesting a possible promising prognostic tool. Furthermore, Willems et al. specifically examined the value of a PCT in surgical decision making with a systematic review supplemented with a prospective cohort study. They found patients with DDD without prior spine surgery and who had significant pain relief with the PCT, had a higher likelihood of a favorable outcome of lumbar fusion compared to conservative management.[10]

Resolution of clinical scenario

- Diagnostic tests such as MRI, discography, facet joint blocks, and immobilization by orthosis have very little prognostic value in terms of identifying the best candidates for lumbar fusion for DDD. However, a positive PCT has been correlated with improved outcomes, highlighting its promise as a prognostic tool.

Question 3: In patients undergoing spine fusion, what risk factors are associated with poorer outcomes?

Rationale

Lumbar fusion is a mainstay in the surgical management of degenerative spine pathologies. Awareness of modifiable risk factors that produce suboptimal outcomes is therefore imperative for any spine surgeon.

Clinical comment

The success of spine fusion depends on efficient bone remodeling and new bone formation. The literature on risk factors is extensive; however, it is somewhat unclear which risk factors are modifiable and are independently causing poor fusion outcomes.

Available literature and quality of the evidence

Multiple RCTs are detailed below.

Findings

Conditions such as osteoporosis, diabetes, smoking, and others can significantly impair bone formation and remodeling, resulting in poor bone quality and lower fusion rates. Patient demographics have also been implicated in fusion outcomes. In a study on twins, Suri et al. found that BMI ≥35, smoking, lack of physical activity and sleep, depression, and post-traumatic stress disorder were associated with LBP.[11] However, when genetic and familial factors were removed, obesity and the presence of mental disorders significantly correlated with LBP.[11]

In a systematic review, Choma et al. looked at the impact of patient risk factors on spine fusion or conservative management of chronic LBP.[12] Based on the few eligible studies in their review, fusion proved only slightly beneficial in patients without risk factors and nonsmokers. In an RCT by Hägg et al. patients were randomized in two groups, fusion or nonoperative, and radiological, personality disorders, sociodemographics, and clinical outcomes were compared.[13] Among the surgical patients with co-morbidities, 66% reported improvement versus 61% without co-morbidities. In the nonoperative group, those percentages were 40 versus 23%. Similar changes were seen with smoking: in the surgical group, improvement was observed in 58% of the patients who

were smokers and in 66% of nonsmokers. For the nonoperative groups, improvement was seen in 32 and 26% of smokers and nonsmokers, respectively. At the same time, the confidence intervals between the different groups were overlapping, suggesting no significant difference in treatment effects. In addition, the nonoperative treatment was not well defined. In another RCT, Fairbank et al. evaluated the effect of smoking on fusion or intensive rehabilitation outcomes at 24 months.[2] Among smokers, the ODI values changed from 47.8 ± 14.5 (baseline) to 40.6 ± 22.2 (24 months) for surgical patients, and from 46.9 ± 14.6 (baseline) to 38.4 ± 22.2 (24 months) for rehabilitation patients. In nonsmokers, the ODI values improved for both the surgical (from 45.5 to 29.5) and nonoperative (from 43.1 to 34.6) patients.[2] Based on the Forest plot analysis, Choma et al. found that nonsmokers in Fairbank's RCT had better fusion outcomes than patients who were smoking.[12]

The effect of mental disorders on the outcomes in patients with spine pathologies has been reported. Daubs et al. found that only one RCT compared the outcomes between surgical and nonoperative groups stratified by physiological condition in chronic LBP patients.[14] The improvements at two years postoperatively were 12% in patients with a personality disorder and 18% in patients without a personality disorder.[14] In the nonsurgical group, the improvement was seen in 27 and 9% of patients with and without personality disorders, respectively. The Zung Depression Scale (ZDS) scores were similar between surgical patients with or without any improvements at two years postoperatively. On the other hand, nonoperative patients who reported improvements had higher ZDS score than the patients without improvements (48 vs 40). Daubs et al. showed significant differences in the ZDS scores among surgical and nonoperative patients who improved at

two years postoperatively (39 vs 48, p <0.009).[14] Hägg and co-workers also reported significant changes in the personality traits scores for neuroticism among the surgical patients.[13] At two years postoperatively the score was 50.1 ± 8.3 in patients designated as *improved* versus 54.1 ± 9.8 in the *nonimproved* group (p = 0.006). An opposite trend was seen in nonoperative groups.

When it comes to sociodemographic factors Mroz and co-workers reported that patients with lighter jobs, pending litigation, and not being on sick leave responded better to fusion than nonoperative treatment.[15] In the RCTs done by Fritzell et al. surgical patients without litigation did better than patients under litigation or compensation at two-year follow-up (70% vs 58%);[5] however, it was not significant. In the nonoperative arm similar trends were seen (50% vs 18%, p = 0.043).[5] Fairbank and co-workers reported a reduction in the ODI values in both surgical and intensive rehabilitation groups.[2] In the surgical group, the ODI scores improved in both patient groups, with litigation (−17.9) and without litigation (−11.6) at two-year follow-up. Compared to the surgical group, the intensive rehabilitation patients had less improvement in the ODI scores −8.8 to −7.6, with or without litigation.[2] Due to the lack of statistical analysis between the treatments, it is unclear if there was a significant effect modification.

Resolution of clinical scenario

- Smoking is perhaps the most well-known risk factor that produces suboptimal outcomes in surgical fusion candidates.

Summary of answers

- Structured nonoperative treatment for LBP can provide pain relief and functional improvement.
- Diagnostic tests have little prognostic value, though a positive PCT has been correlated with improved outcomes.
- Smoking is a major risk factor for suboptimal outcomes in surgical fusion candidates.

113 Mechanical Low Back Pain: Nonoperative Management

Kirkham Wood MD[1], and Craig McMains MD[2]
[1] Stanford Health Care, Stanford University, Stanford, CA, USA
[2] Community Health Network, Indianapolis, IN, USA

Clinical scenario

- A 57-year-old male truck driver presents with low back pain (LBP) along the beltline after a recent long drive across the country.
- Symptoms have been present for the last three weeks.
- Pain is described as a dull ache that does not radiate anywhere else. He denies any numbness or tingling. He does note occasional shooting pain that radiates down the lateral right thigh and into the anterolateral lower leg. No reported weakness.
- He has treated himself so far with heating pads and occasional acetaminophen, which is minimally effective.

Top three questions

1. In patients presenting with acute or subacute LBP, does early advanced imaging, e.g. computed tomography (CT) and magnetic resonance imaging (MRI), lead to improved outcomes when compared to delayed imaging?
2. For patients undergoing initial treatment of mechanical LBP, does skeletal manipulation prevent the

progression of symptoms more effectively than medical care?

3. Is there a role for spinal injections in the treatment of patients with mechanical LBP instead of oral medications?

Question 1: In patients presenting with acute or subacute LBP, does early advanced imaging, e.g. computed tomography (CT) and magnetic resonance imaging (MRI), lead to improved outcomes when compared to delayed imaging?

Rationale

In the US, LBP is one of the most common issues leading to medical evaluation. Roughly 85% of the population will experience an episode of mechanical LBP at some point in their lives.[1,2] More than 85% of patients who present to primary care with this symptom will have LBP that cannot reliably be attributed to a specific disease or spinal abnormality.[3] This translates to a significant healthcare expense, with only cancer and heart disease having a larger financial impact.[4–8] A variety of advanced imaging studies can be used to evaluate LBP, but many have high associated costs. However, more expensive tests may be justified if there is a possibility to positively affect outcomes.[9]

Clinical comment

Physicians are burdened with appropriately and effectively treating a patient while also preventing financially wasteful testing. Expensive imaging is difficult to justify if the clinical outcomes are unaffected. In addition to the stress the physician feels to be fiscally responsible, the patient is taxed with potentially having to make another appointment to obtain the advanced imaging. This can lead to decreased patient satisfaction if the additional time within the healthcare system is not justified. Furthermore, unindicated imaging could lead to findings that trigger further intervention without benefit.

Available literature and quality of the evidence

The overwhelming consensus in the treatment of LBP is that advanced imaging is not indicated for acute and subacute symptoms. Multiple clinical guidelines and meta-analyses support this opinion in both the United States and the United Kingdom.[10]

Findings

A 2009 meta-analysis of randomized controlled trials (RCTs) showed that in the primary care setting there was no significant difference in outcomes between early imaging versus no immediate imaging for acute or subacute LBP.[11] This was true for both short-term (up to three months, standardized mean difference 0.19; 95% confidence interval [CI]: –0.01 to 0.39 for pain and 0.11, –0.29 to 0.50 for function; with negative values favor routine imaging) or long-term (6–12 months, –0.04, –0.15 to 0.07 for pain and 0.01, –0.17 to 0.19 for function) follow-up. Imaging in this study was defined as radiography, MRI, or CT.

The American College of Physicians and the American Pain Society released a series of clinical guidelines in 2007

regarding the diagnosis and management of LBP.[12] In their second recommendation, the guidelines state that "Clinicians should not routinely obtain imaging or other diagnostic tests in patients with nonspecific LBP." This was labeled a strong recommendation with moderate quality evidence. They further clarified indications for imaging by delineating neurologic deficits or underlying conditions that could support the administration of injections or surgery as a reason to obtain an MRI or CT.

Several studies have also documented both the overuse and underuse of advanced imaging in the treatment of LBP.[13] When being referred for lumbar spine imaging, 34.8% of referrals (95% CI: 27.1–43.3) were deemed inappropriate by the absence of red flags for serious pathology and 31.6% (95% CI: 28.3–35.1) were determined to be inappropriate by the criteria of no clinical suspicion of pathology. Subsequent research demonstrated how little the actual management of LBP is informed by lumbar MRI, with one study stating only 13% of said MRIs were actionable.[14]

Resolution of clinical scenario

- Immediate advanced imaging (CT, MRI, etc.) is not indicated for this patient who presents without a worsening neurologic deficit or significant underlying medical or traumatic condition relating to his LBP.
- Without any defined injury or trauma, immediate radiographs are also not indicated at the time of initial presentation.

Question 2: For patients undergoing initial treatment of mechanical LBP, does skeletal manipulation prevent the progression of symptoms more effectively than medical care?

Rationale

With most population centers supporting both medical and chiropractic practices, many patients often ask about skeletal manipulations as a form of treatment for LBP. Many physicians do not have any direct experience with or in-depth knowledge of these treatments in order to inform their patients regarding use.

Clinical comment

Once diagnosed with acute or subacute LBP, most patients are typically encouraged to undergo a variety of both pharmacological and nonpharmacological conservative treatments. Commonly used medications include nonsteroidal anti-inflammatories (NSAIDs), acetaminophen, and muscle relaxants. Opioids are typically avoided in these scenarios. Nonpharmacological therapies include a variety of modalities: exercise and physical therapy, spinal manipulation, acupuncture, yoga, and psychological therapies. Chiropractic care is often a popular option among patients with acute or subacute LBP. However, is this extra method of treatment more beneficial than standard medical care?

Available literature and quality of the evidence

Several well-powered meta-analyses and RCTs exist regarding the question proposed previously. Furthermore,

these form the basis for several practice guidelines from the American College of Physicians.

Findings

The American College of Physicians has proposed several recommendations regarding the use of skeletal manipulations in the treatment of LBP. It found that skeletal manipulation was as effective as other active interventions with a moderate strength of evidence. This was comparable to the moderate recommendation endorsing multidisciplinary rehabilitation and exercise.[15,16]

In a 2016 randomized clinical trial, Schneider et al. reported that manual thrust manipulation (MTM) was superior to usual medical care (UMC) in providing greater short-term reduction in self-reported disability and pain scores.[17] In the study's responder analysis, defined as 30 and 50% reductions in Oswestry scores, the authors revealed a significantly greater proportion of responders at four weeks in MTM (76%, 50%) compared to UMC (48%, 39%). These differences were only present in the short-term, however. There were no statistically significant differences between groups at three or six months.

A 2017 meta-analysis also reported that spinal manipulation provided modest improvements in pain and self-reported function for up to six weeks.[18] Fifteen randomized clinical trials (encompassing 1699 patients) provided moderate-quality evidence that spinal manipulation has a statistically significant association with improvements in pain (pooled mean improvement in the 100 mm Visual Analog Scale (VAS), −9.95 (95% CI: −15.6 to −4.3), while 12 randomized clinical trials (1381 patients) produced moderate-quality evidence that manipulation has a significant association with improvements in function (pooled mean effect size, −0.39 (95% CI: −0.71 to −0.07).

Shekelle et al. echoed this finding, demonstrating that in patients presenting with uncomplicated, acute low back pain, the difference in probability of recovery at three weeks in the context of treatment with spinal manipulation was 0.17 (95% probability limits of estimate, 0.07–0.28).[19]

While this evidence suggests that spinal manipulation is effective in alleviating acute LBP, there are relatively few high-quality studies comparing this method of treatment directly to other standard approaches. Assendelft et al. performed a meta-analysis and found no evidence that spinal manipulative treatment was superior to other modalities of conservative treatment for acute or chronic LBP.[20] They defined standard methods of treatment as general medical care, analgesics, physical therapy, exercises, or back school.

To determine who would benefit from spinal manipulation, Flynn et al. proposed a prediction rule that classified patients according to who would demonstrate short-term improvement.[21] They first identified five variables (symptom duration, fear-avoidance beliefs, lumbar hypomobility, hip internal rotation range of motion, and no symptoms distal to the knee) as correlating to an increasing probability of success. The presence of four of five of these variables (positive likelihood ratio = 24.38) increased the probability of success with manipulation from 45 to 95%. This rule was then subjected to a validation study and found to show that a patient who was positive on the rule and received manipulation enjoyed a 92% chance of a successful outcome.[22]

Resolution of clinical scenario

- Spinal manipulation is an effective tool in providing short-term relief for acute LBP.

- There is little evidence to suggest that spinal manipulation is superior to standard medical treatments, however.
- Patient and physician preference should dictate which initial method of treatment is attempted, as both appear to be cost effective.[23]

Question 3: Is there a role for spinal injections in the treatment of patients with mechanical LBP instead of oral medications?

Rationale

Many patients presenting with LBP are very limited in their daily activities while symptoms are present. Patients often ask about and actively seek an immediate and tangible intervention, such as an injection instead of an oral medication.

Clinical comment

Injection therapy has been shown to be moderately effective when treating compressive nerve-related pathology such as that from herniated discs or spinal stenosis, but not so much for nonspecific LBP. While not a surgical procedure in terms of invasiveness, an injection still involves a foreign material entering the body. While this method of treatment is often considered conservative by patient and physicians, there remains the potential for complications to develop. Also, the cost of such a procedure must be weighed against the clinical efficacy it provides over less expensive and more readily accessible alternatives.

Available literature and quality of the evidence

There is little evidence at all, let alone high-level evidence, to suggest that injection therapies should be favored over oral medications for acute LBP.

Findings

While there are a variety of treatment options available in terms of injection therapies, there is simply too much heterogeneity to support the use of such methods as standard treatment of subacute LBP.[24] Some conditions responded equally well to either local anesthetic injections with or without steroids, while nonspecific LBP failed to demonstrate a clinically effective response to facet joint injections.[25],[26]

Oral medications present a readily accessible method for treatment of acute LBP. The literature supports the use of NSAID medications, with multiple studies documenting their efficacy. In a systemic review, four trials found a greater mean improvement for NSAID medications over placebo: (weighted mean difference, 8.39 points on a 0 to 100-point scale [CI: 12.68–4.10 points]; chi-square test, 3.47 points; $p > 0.10$).[27] Surprisingly, the role of acetaminophen is limited.[28] Muscle relaxants can be effective secondary means of treating these acute symptoms as well.[29] With the increasing scrutiny that opioids have developed, the literature now supports only a very limited role for their use in the treatment of LBP.[30],[31]

Resolution of clinical scenario

- First-line treatment should consist of oral medications such as NSAIDs and muscle relaxants.

- Opioids should have an exceedingly limited role, if any, in the management of acute and subacute LBP.
- Injections are likely ineffective for acute and subacute pain if there is no specific radiographic pathology or well-characterized etiology for the pain.

Summary of answers

- Immediate advanced imaging is not indicated for patients without significant trauma or neurologic deficit.
- Spinal manipulation can provide short-term pain relief, but it is unclear whether it is superior to standard medical treatments.
- First-line treatment for LBP should consist of NSAIDs and muscle relaxants, with opioids used very rarely.

114 Neurogenic Claudication

Gregor Lønne MD PhD, and Øystein Nygaard MD
Norwegian University of Science and Technology, Trondheim, Norway

Clinical scenario

- A 68-year-old woman presents with leg and buttock pain after walking less than 250 meters, accompanied by lower extremity numbness.
- No severe back pain. Symptoms relieved when bending forward or sitting down. The symptoms have gradually been more intense in the last 2–3 years.
- Clinical examination normal: no sign of muscle weakness in the lower extremity, no sign of numbness or reduced sensibility, normal tendon reflexes.
- Magnetic resonance imaging (MRI) of the lumbar spine reveals severe spinal stenosis at L4/L5, with homogeneous gray signal in the spinal canal with no cerebrospinal fluid signal visible between the rootlets. An anterolisthesis of 4 mm is seen in the sagittal view. X-ray is not revealing any instability on flexion/extension view.

Top three questions

1. In elderly patients with lumbar spinal stenosis, does decompressive surgery result in better patient-reported outcomes compared to nonoperative treatment?
2. In elderly patients with lumbar spinal stenosis, does minimally invasive (midline-sparing) decompression

result in better patient-reported outcomes compared to laminectomy?

3. In elderly patients with lumbar spinal stenosis and concomitant spondylolisthesis, does surgical treatment with decompression and fusion result in better patient-reported outcomes compared to decompression alone?

Question 1: In elderly patients with lumbar spinal stenosis, does decompressive surgery result in better patient-reported outcomes compared to nonoperative treatment?

Rationale

Lumbar spinal stenosis (LSS) is the most common indication for spinal surgery among the elderly. The prevalence of symptomatic LSS is approximately 10%.[1],[2] Classical symptoms are neurogenic claudication accompanied by pain and paresthesia in the back, buttocks, and lower limbs, typically, but not always, relieved by flexion of the spine. The condition represents a significant negative impact on quality of life.[3] The goal of the treatment is pain relief and improved function, and decompressive surgery is a frequently used operative strategy. Nonoperative treatments vary from simple pain medication and physiotherapy to epidural steroid injections. There is no international consensus on when to operate, and studies evaluating the clinical benefit of surgery over conservative treatment are few in number.

Clinical comment

The indication for surgery is relative but remains an option for patients with persistent and severe symptoms that include both back and leg pain. Due to higher age and frequent presence of co-morbidities the risk has to be weighed against benefit. In many patients radiographic findings are consistent with LSS, but the clinical signs and symptoms are not. The clinical history is a prerequisite to conclude whether to operate or not.

Available literature and quality of the evidence

There are four level I evidence studies examining this question, comparing decompressive surgery to physiotherapy and/or to epidural steroid injections. Small size and high crossover rate make the quality of these studies low.

Findings

In a Finnish study from 2007, 94 patients were randomized into decompressive surgery (n = 50) or nonoperative treatment (n = 44). Surgery consisted of laminectomy, in 10 patients combined with fusion.[4] The nonoperative treatment was individually adjusted physiotherapy treatment, with nonsteroidal anti-inflammatory drugs when indicated. The primary outcome was Oswestry Disability Index (ODI) and the follow-up period was two years. In this small study with fewer patients than the a priori power calculation (total participants were 94 vs 104 in the power calculation), and with a crossover of 10% in each group, the results must be interpreted with caution. Mean difference in ODI (95% confidence interval [CI]) after two years was 7.8 (0.8–14.9) in favor of surgery but with improvement in both groups.

In the Spine Patient Outcomes Research Trial (SPORT) Weinstein et al. reported two-year outcomes in patients

with LSS without degenerative spondylolisthesis, randomized to surgical or nonsurgical treatment.[5] A total of 289 patients were enrolled in a randomized cohort and 365 in an observational cohort. In the randomized cohorts, 67% of patients in the surgery group had undergone surgery, whereas 43% in the nonsurgical group also had undergone surgery at two years. Surgery was decompressive laminectomy without fusion. In the intention-to-treat analysis, treatment effects of surgery compared to nonsurgery (95% CI) were 7.8 (1.5–14.1) for Short-Form General Health Survey 36 (SF-36) bodily pain, 0.1 (–6.4 to 6.5) for physical function, and –3.5 (–8.7 to 0.1.7) for ODI. For the as-treated analysis the corresponding numbers were 11.7 (6.2–17.2), 8.1 (2.8–13.5) and –8.7 (–13.3 to –4.0).

A parallel study was done on LSS-patients *with degenerative spondylolisthesis*.[6] Here 304 patients were included in the randomized cohort and 303 in the observational cohort. The surgery group received decompressive laminectomy with or without fusion. The nonsurgical group was given *usual care*. Primary outcomes were SF-36 on pain and physical function and ODI. In the intention-to-treat analysis treatment effects (95% CI) were 1.5 (−4.2 to 7.3) for SF-36 bodily pain, 1.9 (−3.7 to 7.5) for physical function, and 2.2 (−2.3 to 6.8) for the ODI at two years. For the as-treated analysis the corresponding numbers were 18.1 (14.5–21.7), 18.3 (13.4–23.6), and –16.7 (–19.9 to –13.9).

A high rate of crossover was also seen in the study of Delitto et al. randomizing patient to either surgical decompression or physiotherapy treatment.[7] Eligible patients were already assigned for surgery. The physiotherapy treatment program emphasized lumbar flexion exercises, general conditioning exercises, and

patient education. Out of 169 eligible patients, 87 were allocated to surgery and 82 to physical therapy. In the conservative group 57% crossed over to surgery, while two crossed over from surgery to physical therapy. The primary outcome for the study was the physical function score on SF 36 at the two-year endpoint. The mean difference in effect was (95% CI) 1.9 (−7.3 to 11.2).

In conclusion, surgery had a favorable effect on overall disability in three out of the four studies. Improvement also occurred in the nonoperative treatment group. Surgical decompression should be suggested with caution and only after due conservative treatment of the patient. Due to high rate of crossovers and loss to follow-up >20%, the certainty based on these studies is low.

Resolution of clinical scenario

Decompressive surgery is indicated if conservative treatment has been tried and have had no or limited effect.

Question 2: In elderly patients with lumbar spinal stenosis, does minimally invasive (midline-sparing) decompression result in better patient-reported outcomes compared to laminectomy?

Rationale

In the 1950s the pathophysiology of this condition was understood, and laminectomy became the gold standard for surgical treatment of LSS.[8] A new approach was developed in the mid-1990s, and minimally invasive decompression became an alternative procedure. The essence of this

procedure was to spare the midline structures. Theoretically, this will reduce the risk of postoperative instability, and hence improve the results compare to laminectomy. On the other hand, there is a possibility that minimally invasive decompression does not result in sufficient decompression of the nerve roots. A Norwegian cohort study comparing minimally invasive decompression to laminectomy found no difference in outcome in unmatched cohort or propensity matched cohort.[9]

Clinical comment

Minimally invasive decompression can be done in several ways, and has different names, sometimes with confusing overlap. Expressions as bilateral laminotomy, microdecompression, foraminotomy, unilateral approach with crossover technique, and *over the top decompression* are commonly used. Endoscopic technique for minimally invasive decompression is also described. There is, however, little evidence for advocating one surgical technique over another.[10],[11]

The narrowing of the spinal canal is a slow degenerative process and the symptoms usually appear gradually. Patients with persistent severe pain seem to benefit from surgery. On the other hand, some patients with degenerative LSS expose challenging clinical decisions due to high age and co-morbidities. MRI may also show narrowing of the spinal canal in more than one level. This makes the decision on which level to operate more difficult. The main surgical approach is decompression, either by minimally invasive technique or laminectomy. The aim is to remove bone, like the medial aspect of the medial facet and ligamentum flavum, to relieve compression on the spinal nerves.

Available literature and quality of the evidence

There are five randomized prospective studies addressing this question. The timespan is large and the sizes of the studies vary, as do the conclusions.

Findings

In a study from 2010, Celik et al. randomized 71 patients to laminectomy (n = 34) or bilateral *microdecompressive laminotomy* (n = 37).[12] Mean follow-up was five years and primary outcome was Visual Analog Scale (VAS) for back and leg pain in addition to the ODI as a measure of physical disability. A statistically significant reduction in the severity of pain and increased physical function was observed in both groups postoperatively ($p < 0.05$). Although there was less postoperative pain in the microdecompressive laminotomy group, no statistically significant between-group difference was found regarding postoperative pain reduction and physical disability improvement ($p > 0.05$).

Fu et al. compared in a study from 2008 minimally invasive decompression (*windows technique*) to laminectomy in 152 patients.[13] Primary outcome included VAS for back and leg pain, and ODI. All though both groups had significant improvement of pain and disability, the results were significantly better in the minimally invasive group compared to laminectomy at follow-up. After 40 months VAS for back pain was 0.05 compared to 0.63 ($p < 0.001$), VAS for leg pain was 0.01 compared to 0.36 ($p = 0.001$), and ODI was 0.37 compare to 3.37 ($p = 0.003$). A good to excellent result was described for 89% in the minimally invasive group and 63% in the laminectomy group ($p < 0.001$).

In a study published in 2005, Thomé et al. randomized 120 patients to three groups, operated with bilateral laminotomy, unilateral laminotomy with bilateral decompression, or laminectomy.[14] Bilateral laminotomy

and unilateral laminotomy with crossover technique are both midline-sparing techniques and should be considered as minimally invasive decompression as compared to laminectomy. Pain in VAS was primary outcome and follow-up was 12 months. The surgery resulted in a reduction of overall pain in all three groups ($p < 0.001$). There was significantly more residual pain in the unilateral laminotomy group (3.6) and laminectomy group (4.0) compared with patients operated with bilateral laminotomy (2.3) ($p < 0.05$). Neurogenic claudication (leg pain during walking) improved in 92% of patients in the bilateral laminotomy group compared with 74 and 68% in unilateral laminotomy and laminectomy group ($p < 0.05$), respectively.

Postacchini et al. compared in 1993 multiple laminotomy with laminectomy including 67 patients with LSS at two or three levels.[15] The protocol, however, allowed multiple laminotomy to be changed to total laminectomy if preoperatively assumed as necessary to achieve adequate decompression. There were therefore three treatment groups: 26 patients submitted to multiple laminotomy, 9 patients scheduled for laminotomy but submitted to laminectomy, and 32 patients scheduled for, and submitted to, laminectomy. The primary clinical outcome score was the mean of two scores, from the patient and from the clinical examination rated as excellent, good, fair, or poor. The mean follow-up was 3.7 years. There were no significant differences in the mean objective improvement scores for each group.

In conclusion, minimally invasive decompression had favorable effect on pain and overall disability in one out of the four studies. Improvement occurred after both minimally invasive decompression and laminectomy. The choice of technique should mainly be based on the surgeon's preference. Due to concerns with inadequate

allocation concealment and small numbers per group, the certainty based on these studies is low.

Resolution of clinical scenario

- Decompression surgery can be performed as minimally invasive decompression or laminectomy.
- Minimally invasive decompression has shown shorter operation time and shorter length of hospital stay.

Question 3: In elderly patients with lumbar spinal stenosis and concomitant spondylolisthesis, does surgical treatment with decompression and fusion result in better patient-reported outcomes compared to decompression alone?

Rationale

Spinal stenosis is the result of a degenerative process narrowing the spinal canal. Often, there is coexisting degenerative spondylolisthesis, a radiological finding often regarded as a sign of segmental instability. Concomitant arthrodesis has been used in addition with nerve decompression to provide spinal stability and prevent progressive deformity.

Clinical comment

Although it has been disputed, adding surgical fusion in addition to decompression has been recommended to prevent persistent back pain. There is a large and possibly unwarranted practice variation in the use of additional

arthrodesis, implicating higher cost and possible higher complication rate compared to decompression alone.

Available literature and quality of the evidence

There are two randomized controlled studies addressing this issue, both published in 2016.

Findings

In a Swedish randomized controlled study, Försth et al. compared the efficacy of fusion surgery in addition to decompression alone in LSS with or without degenerative spondylolisthesis.[16] In this study 247 patients, aged 50 to 80, were enrolled and primary outcome was the difference in ODI two years after surgery. There were no significant differences from baseline between decompression and fusion (ODI = 27) compared with decompression alone (ODI = 24; p = 0.72).

In a study from the US, Ghogawala et al. compared the effectiveness of instrumented fusion in addition to decompressive laminectomy to decompression alone in patients with symptomatic grade I degenerative spondylolisthesis.[17] There were 66 patients, between 50 and 80 years of age. The primary outcome measure was the change in the physical-component summary score of the SF-36 two years after surgery. In this study the ODI score was planned as the primary outcome, but presented as a secondary outcome. In the primary outcome there was significantly greater increase in the SF-36 physical-component summary score in the fusion group (15.2 vs 9.5, p = 0.046). Reduction in disability measured by ODI was also greater in the fusion group, but did not differ significantly (−26.3 vs −17.9, p = 0.06). The cumulative reoperation rate was lower in the fusion group (14% vs 34%, p = 0.05).

In conclusion, decompression surgery alone is effective in improving symptoms in patients with lumbar spinal stenosis and concomitant spondylolisthesis. Due to some degree of high rate of loss to follow-up and a small number of events, the certainty based on these studies is moderate.

Resolution of clinical scenario

Decompression surgery alone can be performed in LSS in most cases, also when there are concomitant mild spondylolisthesis, as in this case.

Summary of answers

- Decompressive surgery is indicated for lumbar spinal stenosis if conservative treatment has been tried and have had no or limited effect.
- Decompression surgery can be performed as minimally invasive decompression or laminectomy.
- Minimally invasive decompression has shown shorter operation time and shorter length of hospital stay.
- Decompression surgery alone can be performed in lumbar spinal stenosis in most cases, also when there are concomitant mild spondylolisthesis, as in this case.

115 Lumbar Radiculopathy

Daniel G. Tobert MD[1] and James D. Kang MD[2]
[1] Harvard Medical School, Massachusetts General Hospital, Boston, MA, USA
[2] Brigham and Women's Hospital, Boston, MA, USA

Clinical scenario

- A 48-year-old woman is referred to clinic with pain on the outside of her thigh radiating down her leg for the past nine weeks.
- The symptoms began atraumatically and has been steady in its intensity and location since its onset.
- She reports no problems with leg strength, or bowel or bladder control.

Top three questions

1. In adult patients with lumbar radiculopathy, what work-up is needed to establish a diagnosis?
2. In adult patients with lumbar radiculopathy, do injections alter the natural history of the symptoms compared to noninvasive or surgical treatments?
3. In adult patients with lumbar radiculopathy, does surgical treatment result in superior sustained symptom relief compared to nonsurgical treatment?

Question 1: In adult patients with lumbar radiculopathy, what work-up is needed to establish a diagnosis?

Rationale

A patient's complaint of *sciatica* can originate from myriad pathologies in the lumbar spine and distal to the spine. The clinician must understand the common and rare etiologies of lumbar radiculopathy and the appropriate work-up.

Clinical comment

Radiating leg pain is a common complaint in the outpatient and Emergency Department setting. It is important to understand which exam maneuvers are more sensitive than others in narrowing the differential diagnosis. Additionally, an awareness of the role of advanced imaging avoids unnecessary tests.

Available literature and quality of the evidence

There is level III evidence available regarding the ability of history-taking to establish a diagnosis in patients with lumbar radiculopathy. Level I evidence from multiple prospective studies and subsequent meta-analyses has been published to better understand the diagnostic role of physical exam maneuvers in lumbar radiculopathy. There is level I evidence supporting the use of MRI (magnetic resonance imaging), CT (computed tomography) and CT-myelogram in the work-up of lumbar radiculopathy.

Findings

The history and physical exam steer the clinician toward a diagnosis of lumbosacral pathology if radiculopathy is present, and primary clinicians are trained to search for

red flag symptoms that would prompt a referral to a specialist. However, the diagnostic accuracy of history-taking is low. Verwoerd et al. performed a cross-sectional study investigating the ability of individual questions and a six-question model to predict lumbosacral nerve root compression confirmed by MRI.[1] Questions pertaining to sensory loss were effective, with odds ratios of 2.31 (95% confidence interval [CI]: 1.10–4.85) for nerve root compression and 3.54 (1.64–7.64) for disc herniation. However, the six-question model as a whole was poorly predictive of lumbosacral nerve root compression with an area under the receiver operator characteristic curve (AUC) of 0.65 (0.58–0.71) and 0.66 (0.58–0.74).

Earlier prospective studies argued that physical exam maneuvers and testing could sufficiently diagnose lumbar radiculopathy and even localize the vertebral level of pathology.[2] However, a subsequent Cochrane review concluded the role of diagnostic physical exam tests in lumbosacral radiculopathy was poorly substantiated after reviewing 18 studies on the subject.[3] Iversen et al. performed a prospective study on the accuracy of the physical exam maneuvers recommended by the American Spinal Injury Association (ASIA) to predict nerve root impingement.[4] They reported that no individual test was reliable at predicting the laterality or level of impingement, with low sensitivities and specificities and wide confidence intervals.

A systematic review by Wassenaar provided level I evidence on the role of MRI in diagnosing lumbosacral pathology.[5] The pooled data calculated a sensitivity of 75% (95% CI: 65–83%) and specificity of 77% (95% CI: 61–88%) for diagnosing herniated nucleus pulposus (HNP). Likewise, for nerve root compression, two studies showed sensitivities of 81 and 92% with specificities of 52 and

100%. Importantly, clinicians must be aware that there is poor interrater agreement on MRI findings in degenerative lumbar conditions.[6] A systematic review of the use of CT for diagnosing lumbosacral pathology concluded CT was useful for HNP but not other causes of lumbosacral radiculopathy.[7]

Resolution of clinical scenario

- History is useful to ascertain the presence of radiculopathy as a symptom.
- Both history and physical exam poorly correlate with lumbosacral pathology and localizing the etiology of radiculopathy.
- MRI is a useful tool to diagnose lumbosacral pathology but can be misleading due to the level of detail it provides.
- CT or CT-myelogram is capable of detecting certain lumbosacral pathologies if MRI is unavailable to a patient, but its limitations prevent it from a being a first-line imaging modality.

Question 2: In adult patients with lumbar radiculopathy, do injections alter the natural history of the symptoms compared to noninvasive or surgical treatments?

Rationale

The use of injections for treating pathology causing lumbar radiculopathy is a middle ground between physical therapy modalities and surgical treatment. Although desirable for

its relative minimal morbidity, clinicians must understand the impact of injections on the long-term outcomes of lumbar radiculopathy.

Clinical comment

Patients are commonly referred to clinic and enquire as to the likelihood of injections alleviating lumbar radiculopathy.

Available literature and quality of the evidence

There is level I evidence that evaluates the short- and long-term efficacy of lumbar injections when used for radiculopathy caused by HNP. There is level I evidence comparing the approach and type of injection used to alleviate lumbar radiculopathy from HNP.

Findings

The majority of the evidence addressing injections for lumbar radiculopathy involves HNP as the etiology of radiculopathy. Therefore, we cannot recommend extrapolation of these data to lumbar etiologies of radiculopathy other than HNP. Ackerman et al. performed a randomized controlled trial (RCT) comparing transforaminal, caudal, and interlaminar epidural steroid injections (ESI) in patients with radiculopathy from a HNP.[8] This study demonstrated superior relief from transforaminal injections than the other routes, which was sustained at 12 and 24 weeks. Ghahreman et al. performed a prospective trial of 150 patients who were randomized into five groups: transforaminal with normal saline, transforaminal with local anesthetic, transforaminal with corticosteroid, intramuscular with normal saline, and intramuscular with corticosteroid.[9] Of the transforaminal group that received corticosteroid, 54% of patients

reported >50% improvement in leg pain after one month (95% CI: 0.36–0.72). This was statistically significant compared to the other routes at one month but not sustained at 12 months and therefore the authors advocated short-term use.

The finding of short-term relief was echoed in a study by Nandi et al., who reported the results of a prospective comparative study between caudal ESI with corticosteroid versus saline for HNP.[10] At four weeks there was a significant difference based on a four-part descriptive scale with 17% of the saline group reporting improvement compared to 68% in the corticosteroid group. This difference was not significant at three months. Chou et al. performed a systematic review incorporating nine high-quality studies and concluded that injections provided a moderate short-term benefit for radiculopathy.[11]

Resolution of clinical scenario

- There is high-quality evidence that a transforaminal ESI will provide moderate short-term relief for the patient in the above clinical scenario if HNP is the etiology of her radiculopathy.
- There are published studies of long-term pain relief from ESI but that finding has not been reproducible in larger systematic reviews.

Question 3: In adult patients with lumbar radiculopathy, does surgical treatment result in superior sustained symptom relief compared to nonsurgical treatment?

Rationale

This question addresses the most pressing concern of the patient and the surgeon when making a shared clinical treatment plan. The clinician must be aware of the nuanced data available to help patients make informed decisions.

Clinical comment

The patient must be appropriately counseled about expectations regarding the outcomes of surgery. It is the surgeon's responsibility to adequately translate the scientific evidence to allow the patient to make an informed decision.

Available literature and quality of the evidence

There is level I evidence comparing the outcomes of surgical and nonsurgical treatment for radiculopathy secondary to HNP. There is level IV evidence evaluating the timing of surgery in patient outcomes.

Findings

Buttermann published the results of a prospective RCT evaluating discectomy versus interlaminar epidural steroid injection.[12] The outcomes were leg and back pain measured by Visual Analog Scale (VAS) and function measured by the Oswestry Disability Index (ODI). He reported an improvement in leg pain and ODI scores in both groups but a greater improvement in leg pain and function at the 1–3 month and 4–6 month follow-up time periods ($p < 0.0001$ and $p = 0.03$, respectively).

The Spine Patient Outcomes Research Trial (SPORT) provides prospective, randomized data comparing nonoperative and operative treatment of radiculopathy for HNP.[13] There has been much debate on the results of

intent-to-treat analyses versus as-treated analyses. From a surgical perspective, the as-treated analysis shows long-term statistically significant improvement with surgical treatment. At one year, the Short Form 36 (SF-36) bodily pain score improved by 15.0 points (95% CI: 10.9–19.2) and physical function improved by 17.5 points (95% CI: 13.6–21.5). The ODI scores of the surgical group decreased by 15.0 points (95% CI: 11.7–18.3).

Atlas et al. published the results of the Maine Lumbar Spine Study group at 10-year follow-up, which compared surgical and nonsurgical treatment of HNP.[14] This study found a significant improvement in leg pain and function but similar rates of work status and disability in both groups. Finally, Ng et al. prospectively collected data on a series of patients who underwent discectomy for radiculopathy and concluded that patients who undergo discectomy more than one year after the onset of symptoms have less improvement on the ODI.[15]

Resolution of clinical scenario

- For patients with radiculopathy from HNP who have undergone nonoperative therapy for six weeks without improvement, surgical treatment is a reasonable alternative that can provide reliable pain relief.
- In this clinical scenario, if the patient has an HNP confirmed by MRI and is having radiculopathy affecting her function, discectomy can be offered as treatment if there are no contraindications.

Summary of answers

- Patients that present with radiating lower extremity pain suggestive of lumbar radiculopathy should

undergo a comprehensive history and physical exam to rule out extraspinal etiologies.

- MRI is the modality of choice for investigating lumbar radiculopathy symptoms.
- HNP is the most common cause of lumbar radiculopathy, and transforaminal epidural steroid injections are capable of provided short-term pain relief.
- Surgical discectomy is an option after six weeks of pursuing nonoperative treatment for radiculopathy, and is most effective if done within one year of symptom onset.

116 Adolescent and Adult Spinal Deformity: Nonoperative Management

Patrick Thornley MD[1] and Colby Oitment MD FRCSC[2]
[1] Division of Orthopaedic Surgery, McMaster University, Hamilton, ON, Canada
[2] Division of Orthopaedic Surgery, University of Toronto, Toronto, ON, Canada

Clinical scenario

- You see an asymptomatic 13-year-old Risser 0 female patient in your orthopedic clinic with a first-time presentation of a right thoracic curve with associated 30° Cobb angle from T7 to L1. She presents with a normal examination and an unremarkable past medical and developmental history.
- The patient, along with her mother and father, wishes to avoid surgical intervention but worries about the effectiveness of bracing therapy and has read about the negative psychosocial effects of bracing.
- The patient's mother is concerned about her daughter becoming short of breath with any type of exertional activity, like her aunt who had untreated scoliosis.
- The patient's father asks how you can be certain her current curve will not progress when she is done growing and cause her “problems” as an adult.

Top three questions

1. In patients with adolescent idiopathic scoliosis (AIS), how does bracing influence health-related quality of life (HRQoL)?
2. In patients with AIS, does nonoperative management result in pulmonary compromise in adulthood?
3. Which risk factors predict patients with adult scoliosis curves will progress and cause low back pain (LBP)?

Question 1: In patients with adolescent idiopathic scoliosis (AIS), how does bracing influence health-related quality of life (HRQoL)?

Rationale

Older reports suggest a negative impact of bracing on psychosocial development and HRQoL. It is important to understand whether bracing therapy for AIS continues to cause negative HRQoL.

Clinical comment

The Bracing in Adolescent Idiopathic Scoliosis Trial (BrAIST) is a landmark multicenter randomized cohort trial demonstrating efficacy of brace treatment in preventing curve progression to surgical thresholds among adolescents with remaining growth and curve magnitudes under 40°.[1] Importantly, brace treatment has traditionally been associated with poor body image, decreased psychosocial wellbeing, and self-esteem when compared to healthy peers.[2] Brace treatment has also been associated with poor psychosocial health due to body image disturbance.[3] Furthermore, Danielsson et al. showed that after brace treatment patients report greater subjective

body distortion than nonbranched peers with similar truncal rotation and curve magnitude.[4]

Available literature and quality of the evidence

BrAIST provides level II evidence on HRQoL among those patients undergoing bracing treatment compared to nonbraced controls.[1] Further available evidence to inform HRQoL predictors related to bracing therapy for AIS comes from level II studies spun off of the BrAIST trial. Schwieger et al. provided two level II prospective cohort studies based on BrAIST analyzing the HRQoL of braced patients at baseline and up to two-year follow-up post initiation of bracing therapy.[5,6] Importantly, Schwieger et al. examined whether HRQoL and body image affected compliance to brace therapy.[6] The largest cohort of braced AIS patients comes from Cheung et al. (level III).[7] Cheung et al. analyzed 652 patients with scoliosis using the refined Scoliosis Research Society 22-item (SRS-22r) and 5-level EQ-5D (EQ-5D-5L) questionnaires. They compared patients undergoing clinical observation to a group of patients in thoracolumbar orthosis and patients who were previously braced.

Findings

In Cheung et al. HRQoL scores were initially higher when bracing was initiated; however, there was a time-dependent deterioration associated with duration of brace treatment.[7] The respective SRS-22r scores were higher for the observation than bracing and previously braced groups ($p < 0.001$). Curves greater than 40° had worse HRQoL ($p < 0.001$). Additionally, previously braced patients had better HRQoL than currently braced patients, with 0.23 higher SRS-22r scores ($p < 0.001$), thus supporting a transient effect to bracing therapy in AIS.

Interestingly, the BrAIST trial found no differences in pediatric quality of life scores between the bracing control group at baseline or follow-up (mean scores in primary analysis 82.9 and 81.9, respectively p = 0.97).[1] Schwieger et al. found no significant differences within or between study arms of observation or braced AIS patients; however, patients with Cobb angles >40° had significantly poorer body self-image.[5] In Schwieger et al., 167 patients undergoing brace treatment were found to have no statistically significant correlation to compliance with brace wear; however, there was a trend toward improved satisfaction with treatment when these patients were involved in their treatment decisions.[6] Therefore, while initial reports suggested that bracing may be associated with poorer psychosocial development, poor body-image, and reduced HRQoL, newer evidence suggested this to not be the case.

Resolution of clinical scenario

- Level II evidence supports that bracing is a safe and effective method of treating scoliosis in patients with growth remaining and curves ranging from 20 to 40° in their coronal cobb angle.
- While initial reports suggested that bracing in scoliosis was associated with a negative effect on self-image and psychosocial health, newer level II reports suggest that HRQoL may not be significantly different between patients receiving brace treatment and those not receiving brace treatment.
- Level II evidence supports improved treatment satisfaction in patients taking on an active role in making decisions regarding their own bracing treatment.

Question 2: In patients with AIS, does nonoperative management result in pulmonary compromise in adulthood?

Rationale

Thoracic curves in AIS can affect respiratory function, leading to restrictive respiratory abnormalities based on alterations to the anatomy of the thorax. It is important to identify nonoperatively treated AIS patients at an early age to best understand who is at greatest risk in adulthood of pulmonary compromise.

Clinical comment

While the causal relationship between spinal deformity and pulmonary function has yet to be fully elicited, there is a known negative correlation between curve magnitude and pulmonary function.[8] Forced vital capacity (FVC) and forced expiratory volume in one second (FEV_1), both measures of pulmonary function, are most significantly reduced with greater thoracic curves and higher apical vertebral levels.[9] Long-term follow-up of patients with AIS has demonstrated clinically relevant pulmonary compromise affecting mortality only in thoracic curves which progress over 100°.[8–10] Importantly, almost two-thirds of AIS patients commonly complain of decreased cardiovascular ability and exercise capacity with increasing significance based on thoracic curve magnitude.[10–14] In patients who undergo nonoperative AIS treatment, it is important to understand the degree of expected pulmonary dysfunction that may occur in adulthood.

Available literature and quality of the evidence

The highest available quality of evidence to inform expected pulmonary capacity in adulthood among nonoperatively managed AIS patients is derived from level III cohort studies. There has been little new long-term longitudinal analyses on the effects of nonoperative AIS management and adult pulmonary compromise. Pehrsson et al. compared a consecutive group of 251 patients with posterior fusion (141) or brace (110) treatment at a mean of 25-year follow-up with a group of 100 age- and sex-matched controls (level III).[15] Similarly, Weinstein et al. provided a 50-year follow-up of an AIS patient cohort treated nonoperatively and followed prospectively, compared to age- and sex-matched controls (level III).[10] In an effort to establish the effects of thoracic curve on cardiopulmonary exercise tolerance, Shen et al. recently analyzed a cohort of 40 AIS patients (level III).[6] All patients had a full radiographic, pulmonary function, and cardiopulmonary bicycle ergometer assessment to maximal exertion. Among included patients, an average 49° coronal thoracic curve was present at analysis among patients ranging from 11 to 35 years at analysis.

Findings

In Pehrsson et al. among brace-treated AIS patients, vital capacity (VC) calculated as a percentage of expected VC based on height and age corrected for height loss related to curve increased from 77% predicted pretreatment to 89% ($p < 0.0001$) 25 years after initiation of treatment, for a mean change of 12.3% (95% confidence interval [CI]: 10.5–14.1).[15] There was no significant difference among all groups in reported dyspnea or wheezing rates.[10],[15] Weinstein et al. demonstrated that patients with thoracic curves >80° or lumbar curves >50° had greater odds of shortness of breath (SOB) than lesser lumbar curves (odds ratio [OR] = 9.75; 95% CI: 1.15–82.98).[10] Of 79 available

patients at all three points of analysis in the study, those with Cobb angles >50° at skeletal maturity were at significantly increased odds of SOB at all time points (OR = 3.67, latest follow-up; 95% CI: 1.12–12.12). Shen et al. found no correlation between kyphosis and exercise tolerance; however, a correlation between kyphosis and pulmonary function was reported, with FVC ($r = 0.366$, $p = 0.043$) and FEV_1 ($r = 0.456$, $p = 0.001$), consistent with previous reports.[16] Patients performing regular aerobic exercise had better physical exertion responses with peak oxygen intake normalized by predicted value ($p = 0.003$), maximum heart rate ($p = 0.020$), and heart rate reserve at maximal exercise ($p = 0.013$). However, there were no differences in pulmonary function results or in parameters related to ventilation and pulmonary gas exchange. These results support the importance of early and consistent aerobic exercise programs for AIS patients regardless of age of diagnosis or degree of curvature at time of diagnosis.

Resolution of clinical scenario

- Level III evidence supports improved pulmonary function in AIS patients treated nonoperatively when compared to prebracing measurements at long-term follow-up.
- Level III evidence provides supportive evidence to emphasize the importance of early intervention of aerobic exercise regimens for all AIS patients, regardless of how minimal a curve is at initial diagnosis.

Question 3: Which risk factors predict patients with adult scoliosis curves will progress and cause low back pain (LBP)?

Rationale

For patients with nonoperatively managed adult idiopathic scoliosis (AIS) it is important for physicians to understand future risks of LBP and curve progression to better inform clinical decision-making and appropriate follow-up of this patient population.

Clinical comment

The most compelling indication for intervention in AIS is curve progression and the effort to prevent such a phenomenon in adulthood.[17] Thus, surgical intervention is often pursued in patients with curves approaching or exceeding 50°. While it is known that as skeletal maturity occurs peak curve progression slows dramatically, the challenge to clinical practice for adult patients with scoliosis is predicting far into the future which patients treated nonoperatively will see progression to their curves and predict those patients who may become symptomatic in the future.[17]

Available literature and quality of the evidence

There is limited literature on the natural history of nonoperative management of AIS. As such, the bulk of the evidence available to practitioners is in the form of longitudinal level III and IV retrospective follow-up studies. The so-called Iowa studies have largely shaped our understanding of the natural history of AIS in nonoperatively managed patients.[10,17–19] Compiled

evidence from the ensuing long-term follow-ups of the Iowa studies demonstrate curves >30° at adulthood progress at a rate of <1° per year, with rates of progression up to curves of ~80° increasing at slightly greater rates annually.[10,17–19] Similarly, quantification of the rates of the prevalence of LBP among AIS patients comes from level III retrospective cohort studies. Mayo et al. assessed the prevalence of LBP among 1476 AIS subjects compared to 1755 age-, sex-, and regional-matched controls in a retrospective cohort (level III).[20] Mayo et al. assessed the prevalence of LBP among this cohort via mailed questionnaires of both the McGill Pain Questionnaire and the Oswestry Disability Index (ODI). In a retrospective level III cohort study Danielsson et al. reported on 142 surgically treated and 110 braced patients at a mean of 23- and 22-year follow-up, respectively, compared to 100 age- and sex-matched control group participants (level III).[21] Recently, Ohashi et al. reported on 56 nonoperatively treated AIS patients with an average follow-up of 25 years ± 7 years in a retrospective case series (level III).[22] Ohashi et al. performed both a Visual Analog Scale (VAS) for LBP as well as the ODI and magnetic resonance imaging (MRI) among included patients.

Findings

Danielsson et al. reported a curve progression of 7.9° in nonoperatively treated patients at last follow-up compared to 3.5° for surgically treated patients ($p < 0.001$).[21] Both surgically treated and braced patients were more likely than control group patients to experience degenerative disc changes ($p < 0.001$). Ohashi et al. reported that patients with a Cobb angle of 37.3° ±7.5° progressed to 47.8° ±12.6° (0.41° per year) at 25-year follow-up.[22] Multivariate analysis demonstrated L3 tilt at skeletal maturity to predict curve progression >0.5° per year (OR = 1.17), while L4 tilt

at skeletal maturity predicted a VAS >3 (OR = 1.20) and an ODI >21% (OR = 1.25) in adulthood. Furthermore, lumbar disc degeneration on MRI was associated with L4 tilt at skeletal maturity and associated LBP in adulthood.

Mayo et al. demonstrated significantly more persons with AIS compared to control subjects reported LBP in the preceding year (73% vs 56%; sex-adjusted risk ratio = 1.28; 95% CI: 1.21–1.35).[20] This relative prevalence was equivalent to a sex-adjusted OR of 2.00 (95% CI: 1.72–2.32). Furthermore, for patients currently experiencing LBP, the association to AIS presence was even stronger with 44% of AIS subjects reporting current LBP compared to 24% of controls (RP = 1.80; 95% CI: 1.63–2.00), in addition to an elevated rate of radicular leg pain (RP = 1.30; 95% CI: 1.13–1.49).

Resolution of clinical scenario

- Level III evidence at long-term follow-up supports the finding that most nonoperatively treated AIS curves do not significantly increase in adulthood.
- Level III evidence supports increased rates of LBP in AIS patients compared to control subjects.
- Degenerative disc changes are more common in patients with AIS than non-AIS patient controls, with significant L3 and L4 tilt at adulthood potentially warranting closer follow-up for further degeneration.

Summary of answers

- Bracing is a safe and effective method of treating AIS in patients with growth remaining and curves ranging from 20–40°.

- HRQoL is not significantly different between patients receiving brace treatment and those who do not receive brace treatment.
- Pulmonary function has been shown to improve in patients receiving bracing treatment, with evidence to support early incorporation of aerobic exercise activities into daily life of all patients with AIS regardless of curve severity to mitigate adulthood pulmonary compromise.
- At long-term follow-up measures, most AIS patients treated nonoperatively do not see significant curve progression in adulthood, though significant L3 and L4 tilt at skeletal maturity may predict increased rates of curve progression.
- Degenerative disc changes and slight increased rates of LBP are expected in AIS patients compared to controls.

NYU Langone Health, New York University, New York City, NY, USA

Clinical scenarios

- A 16-year-old girl previously diagnosed and braced for adolescent idiopathic scoliosis (AIS) presents with chronic radiating midback pain. Examination reveals a significant left thoracic prominence and abnormal gait. Radiographs show a 67° primary thoracic Cobb angle and 61° lumbar secondary Cobb angle, an increase from the previous visit. Patient reports bracing noncompliance. Patient is one-year postmenarchal.
- A 57-year-old male presents with progressive spinal deformity (ASD). Patient reports acute lower back and leg pain and difficulty ambulating and sleeping for longer than four hours. Patient has exhausted all conservative treatment options, without any pain or discomfort improvements. Radiographs reveal moderate stenosis at L2/3 and L3/4.

Top three questions

1. Have current classification systems improved preoperative planning and fusion level determination for AIS and ASD patients?

2. For AIS and ASD patients, do minimally invasive surgical techniques have better operative and radiographic outcomes compared to traditional open techniques?
3. For AIS and ASD patients, does operative management achieve better correction and quality of life outcomes compared to patients treated otherwise?

Question 1: Have current classification systems improved preoperative planning and fusion level determination for AIS and ASD patients?

Rationale

Operative management of scoliosis patients begins with clinical and radiographic deformity assessment. Classification systems for AIS and ASD have been developed to reduce treatment inconsistency, guide decision-making, and improve outcomes. While the development of consistent and reliable classification systems has gone through several iterations and arguably progressed, controversy regarding the proper course of action in optimal preoperative planning has persisted.

Clinical comment

Classification system limitations and inconsistencies could result in improper surgical indications, preoperative planning, and execution, namely improper fusion level selection and realignment resulting in several clinical consequences. For instance, suboptimal postural realignment or further coronal or sagittal decompensation

may occur, resulting in issues related to pelvic obliquity, shoulder imbalance, junctional kyphosis, or suboptimal functional outcomes during inappropriate exclusion of curvature segments. Contrarily, unnecessary functional loss of motion, additive surgical duration and risk, and increased adjacent segment pathology may occur for excessive levels fused.

Available literature and quality of the evidence

Level II–IV.

Findings

Regarding AIS, the Lenke classification remains the standard.[1] Comparative studies determined the Lenke classification to have good–excellent (kappa >0.75) interobserver and intraobserver reliability for curve type (kappa 0.92–0.83), lumbar modifiers (kappa 0.80–0.84), and sagittal thoracic modifiers (kappa 0.94–0.97), respectively, revealing significant improvements from the previously universally accepted King–Moe classification.[2–4] Further, a retrospective study investigating 606 AIS patients determined that 90% of operative cases had surgically recognized structural regions of the spine predicted by the Lenke curve type.[5] While the Lenke classification offers comprehensive radiographic evaluation, improved decision-making, and good-excellent reliability, retrospective and comparative studies have suggested that its complexity (42 curvature types) and inability to define end construct levels hinder feasibility for surgical planning.[6,7]

Despite controversy over operative decision-making (31% prevalence),[8] variations in operative management have reduced (18% vs 12%, p = 0.001) since the Lenke classifications implementation.[9] According to the Lenke

classification, major curves should be included in the fusion construct, along with the structural minor curves, leaving nonstructural minor curves to spontaneously correct.[10] Selective fusion involves fusing one of two curves that crosses the midline, and the lower instrumented vertebra (LIV) extending no lower than L2. A meta-analysis determined that for Lenke 1C curves, selective thoracic fusions decreased postoperative main thoracic Cobb angle (mean difference [MD]: −27.78° [−30.71° to −24.85°]; p <0.01), postoperative thoracolumbar/lumbar Cobb angle (MD: −16.24° [−17.99° to −14.48°]; p <0.01), and improved coronal balance (MD: 0.47 cm [0.07–0.87]; p = 0.02).[11] While selective fusion maximizes postoperative mobility, corona -decompensation is a concern. Nonselective thoracic fusion, where LIV may extend past L2, sacrifices mobility to more definitively prevent coronal decompensation. Regarding upper instrumented vertebra (UIV) determination, the primary objective is to minimize shoulder imbalance and prevent proximal junctional kyphosis (PJK) development. UIV caudal to proximal upper-end vertebra (Lenke 1; odds ratio [OR] = 15.91 [2.18–115.95]; p = 0.0063) and cephalad to upper end vertebra (Lenke 5, OR = 9.07 [1.77–46.45]; p = 0.0081) were significant PJK risk factors.[12]

After wide adaptation of the Lenke classification, the Scoliosis Research Society (SRS) classification was established to guide categorization and management of ASD. A comparative study determined the SRS classification to have moderate interobserver (kappa: 0.64), regional sagittal modifier (kappa: 0.73), and degenerative lumbar modifier (kappa: 0.65) classification reliability. Interobserver reliability for determining UIV (kappa: 0.56) and LIV (kappa: 0.77) was substantial.[13] While this system describes structural curvature, it overlooks other important clinical factors relevant to ASD decision-making (e.g. age,

BMI, disability). Building off of the SRS classification, Schwab and colleagues created a system which guides operative decision-making by identifying clinically significant radiographic parameters associated with patient-reported outcome measures (PROMs).[14] Comparative studies have determined the SRS Schwab classification to have good–excellent interobserver (kappa: 0.73–0.87) and intraobserver (kappa: 0.83–0.94) reliability.[15,16] The most clinically significant SRS Schwab radiographic parameters are pelvic incidence minus lumbar lordosis (PI-LL), pelvic tilt (PT), sagittal vertical axis (SVA), and T1 pelvic angle (TPA).[17,18] A prospective comparative study determined PT, SVA, and PI-LL to correlate most strongly with disability in operative and nonoperative cohorts, with PT ≥22° (r = 0.38), SVA ≥47 mm (r = 0.47), or PI-LL ≥11° (r = 0.45) most strongly predictive of ODI >40 (indicative of severe disability).[19] Correlations between age and PROMs also exist (r >0.510, p <0.001), with younger patients requiring more rigorous alignment objectives.[20] Prospective studies have validated the use of SRS Schwab modifiers. Patients with improved PT, PI-LL, SVA, and TPA were associated with improved SRS 22 (total, pain, activity, appearance), ODI, and physical component scale (PCS) (p <0.05).[21,22] SRS Schwab modifiers also correlated with operative decision-making. A prospective study of 527 consecutive patients determined patients with abnormal sagittal spinopelvic modifiers required major osteotomies, iliac fixation, interbody fusions, and/or decompression procedures (p <0.001).[23]

Resolution of clinical scenario

- The Lenke classification offers substantial intra- and interobserver reliability, and comprehensive operative guidelines for multiple AIS curve types. Selective

fusions for Lenke C curves correct deformity and improve coronal balance. Depending on Lenke curve type, UIV placement has been associated with certain complications (PJK, proximal curve progression, shoulder imbalance).

- The SRS Schwab classification offers substantial intra- and interobserver reliability for determining ASD curve types, radiographic sagittal modifiers, degenerative lumbar modifiers, and UIV + LIV placement. Operative decision-making should account for patient age. Sagittal spinopelvic modifiers can guide decision-making regarding instrumentation extending to the ilium, osteotomies, and interbody fusions.

Question 2: For AIS and ASD patients, do minimally invasive surgical techniques have better operative and radiographic outcomes compared to traditional open techniques?

Rationale

Open fusions using hook and/or pedicle screw instrumentation are associated with significant blood loss, soft tissue damage, prolonged rehabilitation, and morbidity. Recent technological advances have increased utilization of minimally invasive surgical (MIS) techniques for both AIS and ASD patients. Emerging evidence gives insight into how MIS techniques compare to open surgical techniques, regarding intraoperative and postoperative outcomes.

Clinical comment

MIS techniques may provide adequate deformity correction, disability improvement, and pain alleviation while minimizing blood loss, hospital length of stay, and complication risks.

Available literature and quality of the evidence

Level I–IV.

Findings

Profound morbidity associated with operative intervention, specifically in elderly ASD patients, and technological advances have driven the development of MIS techniques. A retrospective review utilizing propensity-matched MIS, hybrid, and open operative cohorts observed MIS patients to have less blood loss (669 vs 2322 mL, p = 0.001), intraoperative complications (0.0% vs 25%; p <0.03), PI-LL correction (−3° vs −14°; p = 0.04), similar overall complications (p >0.05), operative time (p >0.05), more fused interbody levels (4.5 vs 1.6, p <0.001), and insignificant improvement to Visual Analog Scale (VAS) leg pain compared to open surgeries.[24] A meta-analysis found no difference in overall complication rates between MIS extreme lateral interbody fusions (XLIF), MIS decompressions, and open surgeries with or without osteotomy.[25] MIS and hybrid operative patients undergoing similar levels of posterior fusion were shown to have similar PJK (48.1% vs 53.8%; p = 0.68) and reoperation rates (11.1% vs 19.2%, p = 0.41).[26] A systematic review found MIS patients to have a 46% complication rate, and postoperatively improved VAS leg pain (avg 18.9; p = 0.009), ODI (9.3–33%), coronal Cobb angle (11–28.5°), coronal balance (avg 14.5 cm; p <0.001), SVA (2.1–14.9 cm; p <0.05), PT (11.4°; p = 0.009), and lumbar lordosis (5–25.1°; p <0.05).[27] A retrospective review of prospective,

consecutively enrolled patients observed MIS patients to have a ceiling effect of 34° curve correction, significantly less than the ceiling effect of 55° curvature correction observed in hybrid patients.[28]

Regarding MIS in AIS, a meta-analysis found that, of 272 patients, the percentage of curvature correction was 62.05% for MIS and 70.0% for open surgeries ($p < 0.001$).[29] A retrospective comparative study found that compared to patients (Lenke Type 5C) undergoing open procedures, patients who underwent MIS with O-arm navigation had less blood loss ($p < 0.001$), longer operation times ($p = 0.002$), better SRS pain and self-image scores ($p = 0.013$, 0.046, respectively), a higher pedicle placement accuracy, and no complications compared to open procedures.[30] A retrospective comparative study of 131 Lenke I and Lenke V curves reported MIS anterior thoracoscopic procedures without thoracoplasty had less decreases to forced expiratory volume in 1 second (FEV_1: −4.40% vs −10.97%), forced vital capacity (FVC; −4.73% vs −12.97%), and greater total lung capacity increases (TLC; 3.19% vs −8.00%) compared to anterior open procedures without thoracoplasty (all $p < 0.05$). Patients undergoing thoracoplasty were associated with worse FEV_1 and FVC.[31]

Resolution of clinical scenario

- Evidence points to less blood loss and less intraoperative complications as benefits from MIS. Open/hybrid techniques appear to have similar overall complication rates, greater correction potential, and VAS leg pain improvement. Elderly ASD patients and those at higher risk of intraoperative complications or of mild deformity may benefit from MIS techniques.

- AIS patients undergoing open procedures have a greater potential for curvature correction. Utilization of MIS techniques with O-arm navigation may reduce intraoperative blood loss and complications, and improve postoperative patient pain and self-image. Optimal pulmonary function may be obtained by implementing MIS thoracoscopic procedures during anterior approach.

Question 3: For AIS and ASD patients, does operative management achieve better correction and quality of life outcomes compared to patients treated otherwise?

Rationale

Surgical intervention for AIS and ASD remains a contentious topic. Advocates of operative intervention emphasize the benefits of deformity correction, which include prevention of curve progression, restoration of balance, improvements to disability, pain, and quality of life. Those opposing operative intervention often highlight complication potential and lack of evidence proving long-term medical benefit.

Clinical comment

Operative treatment, a potentially life-altering intervention, should not be recommended without proper evidence and indication. Undergoing operative management subjects patients to the possibility of neurologic deficit, infection, decreased pulmonary function, sexual dysfunction, and mortality. Is operative intervention an effective and reasonable treatment for AIS and ASD patients?

Available literature and quality of the evidence

Level I–IV.

Findings

Regarding operative intervention for ASD patients, a systematic review reported an average ODI postoperative improvement of −23.3 ± 11.3, reduction in coronal Cobb angle of 48.5% ± 210%, and a 49% complication incidence.[32] A meta-analysis reported postoperative improvements to coronal Cobb angle (−11.1° [−13.85° to −8.40°]), coronal balance (7.674 mm [−10.5 to −4.9°]), VAS pain (−3.24 [−4.5 to −1.98), and ODI score (−27.18 [−34 to −20]). A systematic review showed operative intervention to have a large positive effect on ≥2-year follow-up scores for the SRS questionnaire (Cohens d = 1.35 [0.93–1.76]) and ODI (Cohens d = 0.88 [0.36–1.41]).[33] When compared to conservative management, a systematic review found operative patients had improved ODI (−19.1), back pain (−4.14), leg pain (−3.36), SF36-PCS (11.2), SF36-MCS (9.93), and a 48% complication rate; while nonoperative treatment exerted no effects on pain, disability, complications or quality of life.[34] A prospective comparative study found patients reporting SRS-22 “worst” or “severe” baseline disability were more likely to perceive greater disability improvements at 2-year follow-up, compared to patients reporting less disability.[35]

For AIS, prognostic studies have shown curvature >50° left untreated will progress at least 1° per year after skeletal maturity. Untreated patients with curves >50° are likely to experience chronic or acute back pain, dissatisfaction with self-image, while patients with curves ≥80° main Cobb or ≥50° lumbar curve have significantly increased instances of shortness of breath (OR = 9.75 [1.15–82.98]).[36,37] Cardiorespiratory failure is a possibility in curves ≥110°.[38]

Prospective controlled trials with propensity-matched operative, nonoperative, and control cohorts have demonstrated operative and braced patients to have similar long-term follow-up (>20 years), main Cobb curves (28°–38°, p >0.05), prevention of significant curvature progression, improvements to pulmonary function vital capacity (p <0.001), and reoperation rate of 5.1%.[39–41] Operative patients had less curvature deterioration (3.5° vs 7.9°, p <0.001) and lumbar lordosis (33° vs 45°) compared to braced patients.[41] A retrospective study of 6334 operatively treated patients reported a 5.7% overall complication rate and a 0.03% overall complication-related mortality rate.[42] Operative AIS patients have also exhibited improved postoperative SRS pain, self-image, function, and level of activity scores (p <0.001).[43,44]

Resolution of clinical scenarios

- ASD patients with progressive or severe deformity/disability benefit most from operative intervention. Operative intervention offers correction of deformity, improved balance, quality of life, and reduced pain and disability. Complication occurrence is a significant risk with operative treatment.
- Operative intervention is an effective treatment for skeletally mature AIS patients at risk for curvature progression. Advantages include prevention of curvature progression with associated morbidities, improvements to pulmonary function and quality of life (pain, self-image, disability), and low complication and reoperation rates.

Summary of answers

- The Lenke and SRS Schwab classification systems are beneficial guides to operative decision-making in adolescent and adult scoliosis.
- Higher-risk patients and those of mild deformity reap the greatest benefits from MIS procedures.
- While operative intervention for AIS patients is an effective treatment for advanced curvatures, and has a minimal associated risk of complication or mortality, operative correction of ASD is associated with both significant quality-of-life improvements and high complication rates. Physicians and patients alike should be aware of the highest levels of evidence for appropriate treatment decision-making and proper risk stratification.

118 Metastatic/Myeloma Disease

Marco Ferrone MD[1] and Justin Bulcher MSc[2]
[1] Dana-Farber Cancer Institute, Boston, MA, USA
[2] Rutgers University, New Brunswick, NJ, USA

Clinical scenario

- A 78-year-old man with a known history of widely metastatic nonsmall cell lung cancer presents to the Emergency Department with atraumatic back pain and is found to have metastatic spinal cord compression.
- He remains ambulatory with preserved bowel and bladder function, but he is objectively weak on examination.

Top three questions

1. In patients with metastatic carcinoma or myeloma disease resulting in metastatic epidural spinal cord compression, does radiation combined with direct decompressive surgery result in improved functional status for patients compared to radiation alone?
2. In patients with metastatic carcinoma or myeloma disease affecting the spine, does assessment of spinal stability by a scoring algorithm provide reliable and useful prognostic information compared to opinion alone?
3. In patients with metastatic carcinoma or myeloma disease affecting the spine, do simple prognostication algorithms that take patient-specific and tumor-specific

factors into account better predict outcomes than those that do not?

Question 1: In patients with metastatic carcinoma or myeloma disease resulting in metastatic epidural spinal cord compression, does radiation combined with direct decompressive surgery result in improved functional status for patients compared to radiation alone?

Rationale

There are two treatment modalities available for metastatic spinal cord compression: radiation and decompressive surgery. Decompressive surgery for metastatic spinal cord compression is an invasive and risky intervention relative to radiation alone, thus operative intervention may be justified only if the functional outcomes for the patient are improved when decompressive surgery is combined with radiation. This question of whether to offer surgery is pondered over daily by all physicians who regularly care for patients with metastatic spinal cord compression.

Clinical comment

For the patient in this scenario, making a shared, informed decision with his healthcare team of whether to undergo the risks of decompressive surgery versus pursuing radiation treatment alone is a critical branch point in his treatment course and can only be made once he

understands what the benefits might be of taking on the risk of surgical decompression.

Available literature and quality of the evidence

There is one level I randomized controlled trial that addresses the question at hand published by Patchell et al. in 2005 comparing ambulatory function, urinary continence, muscle strength, functional status, corticosteroid and opioid analgesic use, and short-term (30-day) survival between patients undergoing radiotherapy alone and direct decompressive surgery followed by radiotherapy for metastatic extradural spinal cord compression.[1] The study enrolled only adult patients with tissue-proven noncentral nervous system (CNS) origin metastatic spinal cord compression affecting only a single area of the spine with at least one neurological sign or symptom (inclusive of pain) and who had not been paraplegic for greater than 48 hours prior to study enrollment and who did not have a particularly radiosensitive tumor (lymphoma, leukemia, multiple myeloma, germ cell tumor). This is the only level I evidence available.

Findings

The primary outcome from Patchell's study is ambulatory function post treatment.[1] In the radiotherapy alone group, post-treatment ambulatory rate was 57% (29/51) versus 84% (42/50) in the surgery followed by radiotherapy group. The odds ratio (OR) for post-treatment ambulatory function with surgery followed by radiotherapy was 6.2 (95% confidence interval [CI]: 2.0–19.8) with $p = 0.001$. This fell below the predetermined criteria for early termination, so the trial was stopped early. Patients who underwent surgery plus radiation also retained the ability to ambulate

for a longer period of time (median 122 days vs 13 days; p = 0.003).

In terms of secondary outcomes, patients who underwent surgery plus radiation maintained urinary continence for longer (156 days vs 17 days) with relative risk (RR) of 0.47 (95% CI: 0.25–0.87). Surgical patients also maintained their functional status for longer, as measured by the ASIA score (566 days vs 72 days) with RR = 0.28 (95% CI: 0.13–0.61). Survival time was longer in patients undergoing surgery of 126 days vs 100 days with RR = 0.60 (95% CI: 0.38 – 0.96). All differences were statistically significant at $p < 0.05$.

Resolution of clinical scenario

- In patients with metastatic carcinoma resulting in spinal cord compression at a single level who have not been paraplegic for greater than 48 hours, direct decompressive surgery followed by radiation results in an increased rate of ambulation, increased rate of retaining the ability to ambulate (if relevant), decreased rate of urinary incontinence, increased rate of preservation of neurologic functional status, and increased survival time relative to radiation alone.
- Patients who meet these criteria should be offered direct decompressive surgery followed by radiation.
- This recommendation cannot necessarily be made for patients who are deemed to be poor candidates for surgery, have myelomatous disease (or other highly radiosensitive tumors), do not have any neurologic compromise, have had a more extended period of paraplegia, or who have multiple sites of spinal cord compression.

Question 2: In patients with metastatic carcinoma or myeloma disease affecting the spine, does assessment of spinal stability by a scoring algorithm provide reliable and useful prognostic information compared to opinion alone?

Rationale

The local tumor burden within the spine from metastatic disease occupies space within the spinal elements and can thus be a destructive presence that compromises the stability of the spine itself, but determining when spinal stability has been compromised by metastatic disease to the point of potentially benefiting from surgical stabilization is difficult to ascertain.

Clinical comment

For the patient in this scenario, to ascertain whether he has impending spinal instability influences whether surgical intervention is recommended. Assessing impending instability is notoriously difficult for all clinicians, thus having a validated clinical prediction algorithm may prove helpful.

Available literature and quality of the evidence

The Spinal Instability Neoplastic Score (SINS) was developed by the Spine Oncology Study Group (SOSG) and was initially published in 2010.[2] Three subsequent studies have been carried out to assess reliability and validity of SINS: one from members of the SOSG who initially developed SINS,[3] another from a single independent

multispecialty group,[4] and the third from an international group of radiation oncologists.[5] No level I evidence exists evaluating SINS compared to any other method of judging neoplastic spinal instability. Two level II prospective cohort studies have been published evaluating the ability of SINS for predicting symptomatic improvement with radiotherapy and/or surgical stabilization based on the SINS assessment of instability.[6],[7]

Findings

In terms of validating SINS from a reliability perspective, the SOSG found its inter- and intraobserver reliability of total SINS score measured by the kappa statistic to be 0.846 (95% CI: 0.773–0.911) and 0.886 (95% CI: 0.868–0.902), respectively.[3] Assessed by an independent group of clinicians, inter- and intraobserver reliability of total SINS score by kappa was 0.79 (95% CI: 0.69–0.88) and 0.96, respectively.[4] Assessed by an international group of 33 international oncologists, inter- and intraobserver reliability of SINS on a binary scale (“stable” vs “current or possible instability”) by kappa was 0.76 (95% CI: 0.56–0.88) and 0.80 (95% CI: 0.74–0.86), respectively.[5]

In terms of prospective validation, Hussain et al. reported on a prospective cohort of 131 patients who underwent instrumented fusion for metastatic spinal cord compression over a two-year period at a single institution for whom preoperative patient-reported outcomes assessed by the Brief Pain Inventory (BPI) and MD Anderson Symptom Inventory (MDASI) were available, in addition to SINS scores.[6] When patients were stratified by SINS score into three categories (stable, indeterminate, and unstable), there was a statistically significant difference among these three groups in the degree to which pain improved after surgery, as assessed by both the BPI and the MDASI. In the

stable group, the BPI score increased by 1.5 and the MDASI by 2.5. In the indeterminate group, the BPI score decreased by 2.3 and the MDASI by 2.2. In the unstable group, the BPI score decreased by 3.0 and the MDASI by 2.8. The p values were 0.04 for both the BPI and the MDASI.

Van der Velden et al. reported on a prospective cohort of 124 patients from two institutions who underwent palliative radiotherapy for spinal metastases (exclusive of multiple myeloma) for whom pre- and postradiation pain scores were assessed.[7] Patients were defined as having a complete pain response after radiotherapy if the pain score was reported as 0 and the oral morphine equivalent dose was stable or reduced. When SINS was analyzed as a binary variable (stable: 0–6; unstable: 7–18), adjusted OR for complete response with an unstable SINS was 0.21 (95% CI: 0.06–0.67) with p = 0.009. The adjusted OR of any response after radiotherapy with unstable SINS was 0.88 (95% CI: 0.36–2.15) with p = 0.782.

Resolution of clinical scenario

- In patients with metastatic carcinoma or myeloma disease affecting the spine, assessment of spinal stability by the spinal instability neoplastic score (SINS) is a reliable method for assessment of spinal instability among physicians (surgeons and nonsurgeons).
- In patients with metastatic carcinoma or myeloma disease affecting the spine who are assessed to have a SINS >6 may benefit from decreased pain with surgical stabilization and may be less likely to benefit from palliative radiotherapy than patients with lower SINS.

Question 3: In patients with metastatic carcinoma or myeloma disease affecting the spine, do simple prognostication algorithms that take patient-specific and tumor-specific factors into account better predict outcomes than those that do not?

Rationale

In deciding whether surgical intervention for metastatic spine disease is indicated, each patient's overall prognosis must be taken into consideration. Several prognostic scoring systems for spinal metastasis have been developed and reached varying states of validation. Those that take into account both patient-specific and tumor-specific factors may best prognosticate outcomes and determine which patients are best suited to derive benefit from surgery.

Clinical comment

For the patient in this scenario, knowledge of his overall prognosis is an important component in deciding whether to proceed with surgical decompression and stabilization. A patient with very limited life expectancy and poor preoperative assessment of prognosis may be deemed a poor surgical candidate, even if the data presented earlier in the chapter suggest an unstable spine and improved neurologic outcome with surgery.

Available literature and quality of the evidence

No level I evidence exists prospectively validating any prognostic scoring algorithm for patient outcomes with

operative and nonoperative treatment of metastatic spinal cord compression.

Two level III studies published in 2015 retrospectively validated a set of prognostic factors, now known as the New England Spinal Metastasis Score (NESMS), associated with short-term (30- and 90-day) and longer-term (one-year) survival in patients with metastatic spine disease.[8,9]

Two level II studies were subsequently published in 2016 demonstrating the validity of NESMS when applied to a large population dataset – the National Surgical Quality Improvement Program (NSQIP) – and to an independent cohort of patients from a separate center from which NESMS was originally described.[10,11] No validation studies have been published employing cohorts which included patients managed nonoperatively, a significant limitation of the current evidence base given the potential selection bias of patients deemed fit for surgery.

Findings

In terms of retrospective validation of NESMS for one-year survival, 318 patients were included in the cohort with 48% survival rate.[8] Independent predictors of survival were preoperative modified Bauer score with OR = 3.00 (95% CI: 1.90–5.01), ambulatory status with OR = 2.47 (95% CI: 1.48–4.14), and serum albumin with OR = 2.80 (95% CI: 1.66–4.72). The modified Bauer score considers the presence of visceral metastases and lung cancer, the primary tumor histology, and the number of skeletal metastases. The predictive score combining the modified Bauer score with serum albumin and ambulatory status was able to explain 74% of the variation in one-year survival, while the modified Bauer score alone explained 64% of said variation.

A separate study using the same patient cohort evaluated 30- and 90-day mortality, which was 9 and 27%, respectively.[9] In a multivariate logistic regression model of 30-day survival, serum albumin >3.5 g/dL was the strongest predictor of survival with OR = 9.0 (95% CI: 3.1–26.6), followed by ambulatory status with OR = 6.8 (95% CI: 1.5–30.7). At 90 days, replete serum albumin and intact ambulatory status were similarly strong predictors of survival, while lung cancer metastases predicted negative outcome with OR = 0.36 (95% CI: 0.18–0.72) and lymphoma/myeloma portended a more favorable prognosis with OR = 4.5 (95% CI: 1.4–14.5). The final predictive model explained 76% of variation in 90-day survival.

The authors of NESMS applied the model to a cohort of 776 patients undergoing surgery for spinal metastasis from the NSQIP.[10] OR for 30-day mortality for NESMS score 1 patients was 0.46 (95% CI: 0.24–0.87), for NESMS score 2 patients was 0.19 (95% CI: 0.10–0.38), and for NESMS score 3 patients was 0.11 (95% CI: 0.04–0.31) with all ORs being statistically significant at $p < 0.05$. The model explained 71% of variation in 30-day mortality within the NSQIP population.

Independent validation of NESMS by a separate center was reported on a cohort of 161 patients with one-year survival of 45%. In the adjusted, multivariable logistic regression model, 80% of the variation in one-year survival was explained by NESMS.[11]

Briefly, several other prognostic scoring systems in metastatic spine disease exist. The Tokuhashi score is reportedly the most widely used and also takes into account patient- and tumor-specific factors, in addition to numerous other variables which increases its complexity and thus compromises its utility and reliability. The Tomita score is also well known but has not been independently verified as

predictive of patient outcome. The modified Bauer score is improved upon by adding the aforementioned variables to form the NESMS.

Resolution of clinical scenario

- In patients with metastatic carcinoma or myeloma disease affecting the spine, the NESMS is the most simple and well-validated prognostication algorithm and may explain up to 80% of variation in one-year survival by accounting for patient- and tumor-specific factors.
- In patients with metastatic carcinoma or myeloma disease affecting the spine who are otherwise deemed to potentially benefit from surgical decompression and stabilization, accurate assessment of overall prognosis is a vital component of surgical decision-making.

Summary of answers

- In patients with metastatic carcinoma (not myeloma) resulting in spinal cord compression at a single level who have not been paraplegic for longer than 48 hours, direct decompressive surgery followed by radiation results in an improved functional status relative to radiation alone.
- In patients with metastatic carcinoma or myeloma disease affecting the spine, the SINS provides reliable information regarding spinal stability and may provide useful prognostic information with regards to which patients may benefit most from surgical stabilization in terms of pain control.
- In patients with metastatic carcinoma or myeloma disease affecting the spine, the NESMS provides the

simplest and most validated prognostic assessment of patient survival to be used by clinicians and patients when deciding on whether to proceed with surgery.

119 Spinal Infections

Stuart D. Kinsella MD MTR, Lauren B. Barton BS, and Andrew J. Schoenfeld MD MSc
Department of Orthopaedic Surgery, Brigham and Women's Hospital, Harvard Medical School, Boston, MA, USA

Clinical scenario

- A 40-year-old man with a history of chronic liver disease and intravenous drug use (IVDU) presents to the Emergency Department with neck pain, midthoracic back pain, and fevers.
- He denies radiating pain, numbness, or weakness.

Importance of the problem

The incidence of vertebral osteomyelitis (VO) and spinal epidural abscess (SEA) are presently on the rise. An aging population with associated co-morbidities, increased IVDU, and the prevalence of spinal instrumentation are among the reasons thought to explain the elevated rates of these spinal infections.[1–5] The incidence of VO has been reported to be 2.2–7.4 per 100 000 population per year,[6–8] and the incidence of SEA has been reported to be 0.2–2.8 per 10 000 hospital admissions per year,[9,10] or 1.8 per 100 000 persons per year.[11]

Top three questions

1. What are the typical presentation, examination findings, and imaging characteristics of patients with VO/epidural abscess?

2. What is the evidence for operative compared to nonoperative management for patients with VO/epidural abscess?
3. What is the prognosis for patients with VO and epidural abscess, including post-treatment morbidity?

Question 1: What are the typical presentation, examination findings, and imaging characteristics of patients with VO/epidural abscess?

Rationale

In order to assess treatment options and prognosis, one must first have the correct index of suspicion for VO and epidural abscess. Understanding the characteristic presentation of the problem permits accurate diagnosis.

Clinical comment

VO and SEA are serious conditions with significant morbidity and mortality. Unfortunately, the diagnosis is often difficult, and as a result delayed, which only increases morbidity and mortality.[12–14] It is essential to understand typical presentation, examination findings, and imaging characteristics in order to correctly diagnose the condition when present and provide efficient management.

Available literature and quality of the evidence

- Level I: 0 studies identified.
- Level II: 0 studies identified.
- Level III: 3 systematic reviews of retrospective observational studies, 1 retrospective case series study.

Findings

A systematic review and meta-analysis of 12 retrospective studies considering the medical and surgical management of SEA found IVDU to be the most frequently reported risk factor (22%), and diabetes (27%) and hepatic disease to be the most commonly reported co-morbidities. The most common symptoms were back pain (67%), motor weakness (52%), and fever (44%). There were significantly more patients with back pain, fever, and motor weakness compared to historical data.[15] The grade of recommendation from this systematic review is low given the retrospective nature of the studies reviewed.

A systematic review of 14 retrospective studies found that back pain was the most common presenting symptom (85% of patients), followed by fever (60%), and neurologic deficit (34%). In the five studies that included duration of symptoms, the mean time from onset of symptoms to diagnosis ranged from 11 to 59 days. Paraspinal or epidural abscesses were found in 44% of cases of VO.[16] A recent retrospective observational study over a 12-year period found local tenderness in <20% of cases of VO.[17,18] Magnetic resonance imaging (MRI) is considered the gold standard for diagnosis of VO, with sensitivity/specificity >90%.[1,3,4,18] The systematic review found MRI to have a sensitivity and specificity of 94% but also noted that plain radiography revealed abnormalities in 89% of cases, though other reviews note its limited utility in early disease.[1,11] Notably, 6% of patients demonstrated continuous lesions spanning multiple levels, and 3% had skip lesions.[16] The grade of recommendation from this review is low based on the low levels of evidence of the included studies.

A retrospective case-control study of 233 adult patients with SEAs who underwent entire spinal imaging over an

18-year period at a tertiary referral healthcare system found 22 patients with skip lesions. Three risk factors were identified: delay in presentation (>7 days), concomitant area of infection outside the spine, and an erythrocyte sedimentation rate (ESR) >95 mm/h at presentation. The predicted probability for the presence of skip lesions was 73, 13, 2, and 0% with the identification of 3, 2, 1, and 0 risk factors, respectively.[19] The grade of recommendation from this single retrospective study is low based on the retrospective nature of the study.

Resolution of clinical scenario

- Axial pain, fever, and neurologic findings are the most common presenting symptoms, but they are not specific, and often not all found at the same time (grade of recommendation: low).
- MRI is the most useful diagnostic imaging modality. Consideration should be given to imaging the entire spine in cases of VO/SEA (grade of recommendation: low).
- Patients with delay in presentation, concomitant area of infection outside the spine, and ESR >95 are at high risk of having skip lesions (grade of recommendation: low).

Question 2: What is the evidence for operative compared to nonoperative management for patients with VO/epidural abscess?

Case clarification

MRI of the cervical spine reveals a large, loculated SEA from C4 to T1 (Figure 119.1) with VO at C5 and C6. The patient expresses a desire to avoid any surgery.

Figure 119.1 Sagittal T-2 weighted MRI image of a patient with a spinal epidural abscess at C4–T1 and vertebral discitis/osteomyelitis at C5 and C6. The patient was treated with a C6 corpectomy, abscess evacuation and C5–7 reconstruction with instrumentation and a titanium cage.

Rationale

Both nonoperative and operative management options exist for the treatment of patients with VO and SEA. Operative management is not without inherent risk and potential complications.

Clinical comment

Historically, SEA has been thought of as a surgical emergency due to the risk of precipitous neurologic decline.[10,13,20,21] More recently, success has been reported with medical management of SEAs.[22,23] Traditionally, medical management has been the mainstay of treatment for VO, with surgery more generally playing a role in diagnosis through biopsy,[1] unless medical treatment fails or fracture/instability is impending.[2,24,25] It is generally accepted that urgent surgical management is necessary in cases of acute or progressive neurological deficit, but it is unclear how best to manage patients without neurologic symptoms.[5,15] Which patients might be successfully treated medically, and in what fashion, remains a subject of great controversy.

Available literature and quality of the evidence

- Level I: 1 randomized controlled trial (RCT).
- Level II: 0 studies identified.
- Level III: 3 systematic reviews of retrospective studies.

Findings

No studies that prospectively compared operative management and nonoperative management for the treatment of SEA were found. A systematic review of 10 retrospective studies found that overall outcomes among

patients treated with operative and nonoperative management were not different, though there was significant allocation bias based on pretreatment neurologic function. In addition, there was significant crossover among the studies. The odds ratio for improvement or stability of neurologic status for operative and nonoperative management was 0.653 ($p = 0.11$), and of good outcome was 1.11 ($p = 0.69$).[26] The grade of recommendation from this review is low based on the retrospective nature of the included studies.

A systematic review of 12 retrospective studies directly comparing surgical to nonsurgical management of SEA found no statistically significant difference between treatment modalities, though it did find a significant increase in the proportion of patients medically managed compared to historical controls. It also found that patients with no neurological deficits were significantly more likely to be treated medically than surgically.[15] The grade of recommendation from this systematic review is low given the retrospective nature of the studies reviewed.

No studies that prospectively compared operative management and nonoperative management for the treatment of VO were found. In a systematic review of 14 retrospective studies of VO management, all patients received antibiotic treatment. Indications for surgery included spinal stabilization, abscess drainage, and decompression for the management of neurologic symptoms.[16] Given the heterogeneity of decisions for surgical intervention, and the retrospective nature of studies, the grade of recommendation is low.

An RCT comparing antibiotic treatment for six weeks versus 12 weeks in patients with pyogenic VO found that six weeks of antibiotic treatment was not inferior to 12 weeks of antibiotic treatment with respect to the

proportion of patients with pyogenic VO cured at one year.[27] Although the RCT was well powered, the lack of additional studies makes the grade of recommendation moderate.

Resolution of clinical scenario

- Nonoperative management may be as effective as operative management of SEA in patients without neurologic symptoms (grade of recommendation: low).
- Nonoperative management is the main treatment modality for VO, unless stabilization or decompression in the setting of neurologic symptoms is necessary (grade of recommendation: low).
- Necessary antibiotic treatment duration for VO may be shorter than that historically employed with six weeks of antibiotics demonstrating similar efficacy to 12 weeks of antibiotics (grade of recommendation: moderate).

Question 3: What is the prognosis for patients with VO and epidural abscess, including post-treatment morbidity?

Clinical clarification

The patient agrees to proceed with surgery after his symptoms fail to improve with a trial of antibiotics and the abscess is found to enlarge on repeat imaging. He undergoes a C6 corpectomy with reconstruction using plate instrumentation and a spanning titanium cage. He is concerned about postoperative complications and the likelihood of full recovery.

Rationale

Both operative and nonoperative management of VO and SEA are not without complications. The prognosis of patients with either condition depends on the timing of diagnosis, clinical presentation, and treatment modality.

Clinical comment

Operative management imparts inherent perioperative risk. Long-term antibiotic use can increase the likelihood of antibiotic resistance and healthcare-related infections.[28–30] Both operative and nonoperative management can fail, or be complicated by a recurrence of disease. Furthermore, patients who receive surgery have additional risks of construct failure, pseudarthrosis, and the need for revision surgery (Figure 119.2). Those who fail medical management, and ultimately require surgical intervention may carry a worse prognosis.[5,31] In the case of VO and SEA, successful management is often assessed through the proxies of mortality and recovery from neurologic deficits.[4] The potential for these events is highly predicated on the location of the spinal infection, its size, duration of symptoms prior to presentation, the patient's nutritional and immunologic status, as well as the presence of other medical co-morbidities.

Figure 119.2 Sagittal computed tomography (CT) image of the same patient in Figure 119.1, six months following surgical management. In the intervening period, the patient had developed pseudarthrosis, subsidence of the titanium cage and inferior screw cut-out from the C7 vertebral body.

Available literature and quality of the evidence

- Level I: 0 studies identified.
- Level II: 0 studies identified.
- Level III: 1 meta-analysis of retrospective studies and 4 systematic reviews of retrospective studies.

Findings

A systematic review and meta-analysis of 12 retrospective observational studies of the medical management of SEA – which defined *failed medical management* as persistent severe neurologic deficit, poor clinical outcome, death, or need for surgery – found the overall pooled risk of failed medical management to be 29.3% (95% confidence interval [CI]: 21.4–37.2%). Considering only the six studies which provided data for analysis by intention to treat, the pooled risk of failed medical management was 35.1% (95% CI: 15.7–54.4%).[5] The grade of the recommendation from this systematic review and meta-analysis is low due to the retrospective, observational nature of the included studies, as well as the heterogeneity in reported outcomes.

A systematic review of 10 retrospective studies comparing surgical and medical management found that failure rates after medical management ranged from 10 to 50%, with three studies reporting large effect sizes for neurologic outcome if early surgery was performed.[26] The review found that gender was not significantly associated with patient outcome but that younger age correlated with

better neurologic outcomes, while diabetes mellitus correlated with worse neurologic outcomes. Overall, pretreatment neurologic status correlated strongly with neurologic outcome.[26] The grade of recommendation from this review is low based on the low level of the included studies.

A systematic review of 18 retrospective studies found that cases with a delay in diagnosis had an increased risk of residual weakness versus those with no delay, and that duration and severity of neurological symptoms correlated with ultimate outcome. Mortality rates were found to range from 2 to 20%, and were higher in patients with multiple co-morbidities.[3] The grade of recommendation from this review is low based on the low level of evidence among the included studies.

A systematic review of 14 retrospective studies investigating VO found a mortality rate of 6%, with relapses in 32% of cases. That being said, 27% of patients had complications that seriously affected their quality of life. The six studies that detailed the complications found 28% of patients have persistent pain, 16% have weakness, and 7% have bowel or bladder dysfunction. In the one study that compared the functional outcome of nonoperatively and operatively managed patients, 64% of nonoperatively managed patients experienced disabling pain or relapse, while only 26% of the operatively managed patients did.[16] Given the heterogeneity of outcomes and complications reporting, as well as the retrospective nature of the studies, the grade of recommendation is low.

Resolution of clinical scenario

- Medical management alone of SEA fails approximately one-third of the time (grade of recommendation: low).

- Pretreatment neurologic status in cases of SEA correlates with neurologic prognosis (grade of recommendation: low).
- Approximately one-third of cases of VO recur, and one-third of patients with VO have complications (grade of recommendation: low).

Summary of answers

- The body of evidence that can be used to support evidence-based decision-making in the treatment of VO and SEA is fairly low in both grade and quality.
- Axial pain, fever, and neurologic impairment are the most common presenting symptoms, but they are not specific, and may not be present in all cases.
- MRI is the most useful imaging modality for the diagnosis of VO and SEA.
- Nonoperative management is the usual treatment for VO, unless stabilization is required or neurologic deficits are present.
- Nonoperative treatment may be as effective as surgical intervention for patients with SEA who do not manifest neurologic impairment. In appropriate patients, nonoperative management may still fail 33% of the time.
- There is a single RCT that maintains six weeks of antibiotic therapy for VO is as effective as 12 weeks of antibiotics.
- In the setting of SEA, neurologic status at the time of presentation is one of the most important prognostic factors for post-treatment outcome.

VI Sports Medicine

120 Ergogenic Aids

Michael J. O'Brien MD
Harvard Medical School, Division of Sports Medicine, Department of Orthopedics, Children's Hospital Boston, Boston, MA, USA

Clinical scenario

- You are performing preseason physicals for a youth hockey team.
- One of the players, a 16-year-old male, asks you about creatine supplementation.
- He states that he has been told he is too small and needs to put on mass to have a chance at a future professional career.
- He wants to know if creatine supplementation will enhance his performance on the ice and in the gym.

Top three questions

1. Do young adults using creatine supplementation experience an enhancement in performance compared to nonsupplemented young adults?
2. In young adults supplementing with creatine, is there resultant physiological change associated with supplementation as compared to nonsupplemented young adults?
3. Do young adults using creatine supplementation experience adverse side effects compared to nonsupplemented young adults?

Question 1: Do young adults using creatine supplementation experience an enhancement in performance compared to nonsupplemented young adults?

Rationale

Dietary nutritional supplements are a multibillion-dollar industry worldwide. The most common legal performance enhancing supplements used by athletes are creatine, protein powders, and caffeine. Creatine, however, is the most popular nutritional supplement used as an ergogenic aid at all levels of competition.[1–3]

Clinical comment

Creatine is predominately stored in skeletal muscle (fast twitch, type II fibers) where it serves as the energy substrate for muscle contraction.[3] In its phosphorylated form, creatine contributes to the re-synthesis of adenosine triphosphate (ATP) from adenosine diphosphate (ADP) which occurs during short-duration and high-intensity exercises.[4] This suggests and therefore serves as the rationale for creatine supplementation as an ergogenic aid.[5]

Available literature and quality of the evidence

A number of randomized controlled trials (RCTs) exist to answer this question.

Findings

A double-blind study tested 12 adult male cyclists pre- and post- a 28-day creatine supplementation regimen. The

changes in plasma volume from pre- to post-supplementation were significantly greater in the creatine group (14.0 ± 6.3%) than the placebo group (−10.4 ± 4.4%; $p < 0.05$) at 90 minutes of exercise.[6]

In short-interval exercise it was concluded that creatine supplementation increases short-terms bursts, such as dribble and power tests (vertical jumping) with young soccer players.[7]

In a double-blinded, placebo-controlled RCT, 14 men ingested 25 g/day of creatine monohydrate for seven days. Subjects performed five sets of bench press to failure and a jump squat (five sets of 10 repetitions using 30% of each subject's one repetition max [RM]). It was concluded that one week of creatine supplementation (25 g/day) enhances muscular performance during repeated sets of bench press and jump squat exercises.[8]

A study on cyclists for five days of 20 g creatine supplementation testing maximal power output to exhaustion found oxygen consumption larger after creatine supplementation (10.40 ± 0.65 L) to (11.82 ± 0.34 L).[9]

Reardon et al. looked at the potential effect of creatine supplementation on aerobic long durance exercise. Subjects completed 45-minute cycling sessions. It was concluded that the ergogenic potential of creatine supplementation in endurance performance does not produce significant results.[10]

A test on 12 regional class triathletes for five days on a 6 g/day creatine dosing and cycling 30 minutes to exhaustion found endurance performance was not influenced as interval power was only increased by 18%.[11]

Fourteen female and eight male collegiate athletes supplemented with seven days of 25 g/day creatine were subjected to three timed 60 m sprints trials. Results showed

creatine supplementation did not enhance speed during 60 m sprints.[12]

Recent literature has illuminated the anabolic/performance-enhancing mechanisms of creatine,[13] suggesting that these effects may be due to satellite cell proliferation, myogenic transcription factors, and insulin-like growth factor-1 signaling.[14] Changes in myogenic transcription factors occur when creatine supplementation and resistance training are combined in young healthy males. It was observed that serum levels of myostatin, a muscle growth inhibitor, were decreased in the creatine group.[15]

Resolution of clinical scenario

The suggestion from various sports and training regimens is that creatine supplementation may be effective as an ergogenic aid in short bursts of intense exercise, but that it does not seem to be beneficial in aerobic, endurance exercises.

Creatine has been demonstrated to be of performance benefit in modes of exercise such as high-intensity sprints or endurance training. The evidence also demonstrates that it appears that the effects of creatine diminish as the length of time spent exercising increases.

Question 2: In young adults supplementing with creatine, is there resultant physiological change associated with supplementation as compared to nonsupplemented young adults?

Rationale

Supplementation with creatine is widely used to increase strength, fat-free mass, and muscle morphology.

Clinical comment

Studies show that creatine supplementation increases intramuscular creatine concentrations, which may help explain the observed improvements during high-intensity exercise.[16]

Available literature and quality of the evidence

A number of RCTs exist to answer this question.

Findings

Twelve weeks of training with creatine supplementation demonstrated increases in heavy resistance exercise in a double-blind, placebo-controlled RCT.[8] Treated subjects improved bench press and squat exercises by 24 and 32%, respectively, versus the placebo group (16 and 24%, respectively) who had training but no supplementation.[8] The gains in mass appeared to be due to an improvement in the ability to recover faster from heavy load workouts and high-intensity training, thereby resulting in greater muscle hypertrophy.

A double-blinded, placebo-controlled RCT, observed the effect of creatine supplementation on anaerobic performance and body composition of American football players evaluating one repetition maximum (1RM) parallel squat, 1RM bench press, dynamic explosive strength test of vertical jump, and high-intensity endurance test of 15 five-second cycling rides with a one-minute rest period between rides. Results showed an 11.6% increase in squat, 10% increase in bench press, and 1.5% increase in vertical

jump. Both hydrostatic (7%) and skin-fold method (2.6%) indicated a substantial gain in lean body mass, and an increase in body mass of 1.4 % over five weeks.[17]

A double-blind RCT studied 24 male resistance trainers taking 20 g/day of creatine for five days followed by 5 g/day for the remaining 23 days and then completed a resistance-training program with four supervised workouts per week which targeted the major muscle groups. It was found that ingestion of creatine promotes increases in lean mass, body composition, and 1RM bench press and leg press.[18]

In a double-blind, placebo-controlled trial, similar results were found in the Birch et al. study utilizing the *Wingate tests* (30 seconds of maximal cycling effort).[19] In the creatine group, the total power output increased by 7.6%.[19]

Multiple studies including double-blind studies demonstrated physiological changes post creatine supplementation regimen.[8],[18] These physiological changes include enhanced muscular performance, increases in lean mass and body composition, as well as increased oxygen consumption.

Resolution of clinical scenario

Enhanced muscular performance, increase in lean body mass and composition, and increased oxygen consumption were the resultant physiological effects during and following creatine supplementation.

Question 3: Do young adults using creatine supplementation experience adverse side effects compared to nonsupplemented young adults?

Rationale

While creatine supplementation has been suggested to be effective in enhancing performance in short, high-intensity athletic-related situations, it is paramount to evaluate whether this supplement has any adverse effects or safety concerns. Creatine is a legal supplement that is readily available over the counter. It is not a banned or regulated substance in any amateur or professional sport.

Clinical comment

Short-term use of creatine has generally been considered safe but can still have potential side effects, which are usually mild.[20],[21] The most common side effects are bloating, cramping, and diarrhea.[22] These effects may be minimized by forgoing the loading dose and staying well hydrated. Creatine does not seem to adversely affect kidney function, but special consideration should be taken for athletes with pre-existing kidney disease. It has not been tested thoroughly for patients under the age of 18; however, for adults it seems to be safe and possibly effective.[16],[23]

Available literature and quality of the evidence

A number of retrospective and cross-sectional studies are available to answer this question.

Findings

Liver changes were studied during medium-term (four weeks) creatine supplementation in young athletes. No evidence of dysfunction based on serum enzymes and urea production was found. There was an increase in body mass during short-term creatine supplementation likely due to

water retention, with a 0.6 L decline in urinary volume after ingestion of creatine 20 g/day for 6 days.[24]

A review on various studies undertaken on the long-term effects of creatine supplementation noted an increased muscle mass which may result because of fluid retention and not increased protein synthesis. An increase of 0.7 to 3 kg in one month has been reported. Weight gain can be maintained on 5 g per day of creatine during a 10-week period of detraining and maintained four weeks after it is stopped. Other adverse effects that are often cited but not proven include anecdotal reports of muscle cramps, strains, dehydration in hot humid weather, diarrhea, migraines, and nausea.[3]

A retrospective study utilized questionnaires and blood samples on 26 athletes from various sports who had used creatine supplementation for 0.8–4 years. All groups fell within normal clinical ranges, and no significant adverse health effects were found with long-term creatine supplementation. Some subjects reported short-terms side effects of gastrointestinal distress, but in this study evidence was anecdotal and relied on athlete recollection.[25]

A study of Egyptians aged 13–18 found that a child's ability to regenerate high-energy phosphates during high-intensity exercise is less than that of an adult. Therefore, creatine supplementation may benefit the rate and use of creatine phosphate and ATP re-phosphorylation. However, performance in short-duration high-intensity exercise can be improved through training; therefore, supplementation may not be necessary.[26]

A survey of 1103 middle and high school athletes aged 10–18 found 62 (5.6%) admitting to creatine use. The main reasons for taking creatine were cited as: performance (74.2%) and improved appearance (61.3%). The most

common reason cited for not taking creatine was safety (45.7%).[27]

Creatine supplementation does not appear to have significant adverse side effects from either short- or long-term use in most young adult athletes. Shortcomings in the current studies available for review include a lack of high-quality, well-designed RCTs. There is also a paucity of data for creatine use in athletes younger than 18 years old.

Resolution of clinical scenario

The current consensus is to recommend against creatine use in athletes with existing renal disease. The current position of the International Society of Sports Nutrition is that, under proper supervision, creatine monohydrate supplementation in children and adolescent athletes is acceptable and may provide a safer alternative to potentially dangerous anabolic androgenic drugs.[16] It is also recommended that creatine supplementation only be considered for use by younger athletes who (i) are involved in competitive supervised training, (ii) are consuming a well-balanced diet, (iii) are educated about the appropriate use of creatine, and (iv) follow recommended dosages.[16]

Summary of answers

- Creatine supplementation may be effective as an ergogenic aid in short bouts of intense exercise.
- Creatine supplementation does not appear to be beneficial in aerobic, endurance exercise.
- Enhanced muscular performance, increased lean body mass, and increased oxygen consumption are the physiological effects of creatine supplementation.

- Current statement is that creatine supplementation should be avoided in those with existing renal disease and supervised in children and adolescents.

121 First Time Shoulder Dislocation

Dane Swinehart MD, Jordan Meiss MD, and Charles Cox MD
Vanderbilt University Medical Center, Vanderbilt Orthopaedic Institute, Nashville, TN, USA

Clinical scenario

- A 20-year-old collegiate football lineman sustains an injury to his dominant shoulder while blocking that involves a sudden posteriorly directed force on his forearm while his arm was in a position of abduction and external rotation.
- On examination, he holds his arm at his side and refuses any attempts at range of motion assessment.
- He is neurovascularly intact distally.
- This is the first episode of anterior shoulder instability sustained by the athlete.

Top three questions

1. In patients undergoing reduction of primary glenohumeral dislocations, does intravenous (IV) sedation for closed reduction present a greater chance for successful reduction and fewer complications than other methods of premedication for reduction?
2. In a patient undergoing a primary glenohumeral dislocation reduction, is there an ideal reduction and immobilization method that results in fewer complications and reduced recurrence rates?
3. What is the long-term prognosis for a patient who sustains a primary anterior glenohumeral dislocation?

Question 1: In patients undergoing reduction of primary glenohumeral dislocations, does intravenous (IV) sedation for closed reduction present a greater chance for successful reduction and fewer complications than other methods of premedication for reduction?

Rationale

An athlete with a primary dislocation of the glenohumeral joint will be in obvious discomfort and resistant of closed reduction attempts secondary to pain. In the current medical care setting, there are several options for premedicating patients that range from IV sedation to intra-articular anesthetic to regional nerve block. The treating clinician must decide on the best method of anesthesia delivery (IV sedation vs intra-articular injection) to maximize patient safety while achieving successful reduction and minimizing complications.

Clinical comment

Premedication is an important aspect of reduction as it can allow for a better outcome in regards to patient safety and satisfaction, in addition to aiding the clinician in a more facile reduction.

Available literature and quality of the evidence

- Level I: 4 systematic reviews/meta-analysis[1–4] and 7 randomized trials.[5–11]

Findings

The included trials compared various outcome measures among techniques for premedication that included IV sedation, intra-articular lidocaine injection, and suprascapular nerve block. Outcomes that were compared included reduction success, complications, pain level, time to reduction, and overall time spent in the Emergency Department. In the included studies, no difference was seen in rates of reduction among the different techniques used for sedation. Furthermore, patient pain and satisfaction between the various techniques showed no significant differences.

There were differences found in complication rates between intra-articular lidocaine injection and IV sedation. The most common complication involved respiratory depression in the setting of IV sedation. One meta-analysis found statistically significant increases in rates of respiratory depression, vomiting, and thrombophlebitis in the IV sedation group when compared to the intra-articular lidocaine group. There were no significant differences found in regards to nausea, hypotension, drowsiness, or headache.[4]

Time to reduction and overall time spent in the Emergency Department has also been evaluated by the included studies. In general, studies comparing time to reduction favor IV sedation as the quicker method, while intra-articular lidocaine results in the least overall time spent in the Emergency Department. One systematic review found that mean time spent in the Emergency Department was 109.46 minutes less with intra-articular lidocaine as compared to IV sedation (95% confidence interval [CI]: 84.60–134.32). In terms of time to reduction, IV sedation was favorable with a time of 105 seconds to reduction (95% CI: 84.0–126.1), while intra-articular lidocaine had an average time of 284.6 seconds to reduction (95% CI: 185.3–383.9).[3]

Resolution of clinical scenario

- No significant difference exists among premedication techniques for glenohumeral reduction in regards to success rate for reduction and patient pain level.
- Intra-articular lidocaine significantly reduces the risk of complications, mainly in the form of respiratory depression associated with IV sedation.
- Time to reduction and overall time spent in the Emergency Department were variable with studies favoring IV sedation in time to reduction and intra-articular lidocaine with overall time spent in the Emergency Department.

Question 2: In a patient undergoing a primary glenohumeral dislocation reduction, is there an ideal reduction and immobilization method that results in fewer complications and reduced recurrence rates?

Rationale

The standard of care for the athlete with a dislocated glenohumeral joint is expeditious reduction and immobilization. It is important to select a technique to best achieve reduction and then to place the arm in a position of relative stability. There are numerus techniques for achieving reduction and immobilization of the glenohumeral joint. Each technique utilizes different strategies to overcome muscular forces and allow the humeral head to reduce back into congruent anatomic alignment with the glenoid. Furthermore, immobilization methods are aimed at maximal stability and preventing recurrent dislocation.

Clinical comment

It is important to achieve safe, expeditious reduction in a manner that avoids iatrogenic injury to the anatomic structures of the shoulder. Furthermore, choice of immobilization may be important for postreduction stability and prevention of recurrent dislocations.

Available literature and quality of the evidence

- Level I: 3 systematic reviews/meta-analysis[12–14] and 8 randomized trials.[15–22]
- Level II: 1 observational cohort study[23] and 2 randomized trials.[24,25]

Findings

There are numerous techniques for glenohumeral reduction. Some of these include: Milch technique, Kocher technique, Hippocratic method, FARES (Fast, Reliable, and Safe), Traction–Countertraction, and the Scapular Manipulation technique. The above studies looked at several variables when comparing the techniques with regards to rate of successful reduction, patient pain according to visual analog pain ratings, and reduction time.

Scapular Manipulation was the most successful (97%), fastest (1.75 minutes), and least painful (Visual Analog Scale [VAS] 1.47). FARES was also successful (92%), fast (2.24 minutes), and relatively painless without analgesia (VAS 1.59). Traction–Countertraction showed high rates of success (95%) but was more painful (VAS 4.75). Table 121.1 gives details for each method.[13]

Table 121.1 Techniques for glenohumeral reduction. Source: Modified from Alkaduhimi et al.[13].

Technique	Total Patients (N)	Reduction Success (%)	Reduction Time (min)	Reduction Pain (VAS 1–10)
Hippocratic	51	73	5.55 (SD 0.395)	4.88 (SD 0.54)
Milch	148	80	4.29 (SD 0.14)	5.28 (SD 0.54)
Kocher	317	85	4.19 (SD 1.25)	4.68 (SD 2.00)
FARES	133	92	2.24 (SD 0.27)	1.59 (SD 0.46)
Traction–Countertraction	278	95	6.05 (SD 2.49)	4.75 (SD 0.55)
Scapular Manipulation	78	97	1.75 (SD 0.38)	1.47 (SD 0.44)

SD: standard deviation.

Classically, immobilization in a position of internal rotation has been employed. However, some advocate for immobilization in external rotation to place tension along the anterior capsulolabral structures to improve restoration of preinjury anatomy and decrease likelihood of recurrence. One systematic review found that there was no evidence to show a difference in re-dislocation rates between internal and external rotation immobilization at two years or greater follow-up (relative risk [RR] = 1.06 favoring internal rotation; 95% CI: 0.73–1.54, p = 0.77, 252 participants over three trials). There was also no evidence found to show a difference between the two groups in return to preinjury levels of activity (RR = 1.25 favoring external rotation; 95% CI: 0.71 to 2.2; p = 0.43; 278 participants over two trials).[14]

In regards to length of immobilization, Hovelius et al. followed a cohort of patients for over 25 years comparing time of immobilization in internal rotation. They found that length of time immobilized had no difference in rate of recurrent dislocation. Overall, recurrence rate of dislocation progressively increases over time but plateaus at about five years after the initial injury (29% at 2 years, 45% at 5 years, 48% at 10 years).[18]

Resolution of clinical scenario

- There are several techniques for shoulder reduction that are relatively quick and have a high success rate (FARES, Scapular Manipulation, Traction–Countertraction). These can be employed safely with either IV sedation or intra-articular lidocaine use.
- The FARES and Scapular Manipulation techniques can be used with minimal to no pre-sedation medication and have a high success rate while also producing little pain during the reduction.
- There is no significant difference in recurrent dislocation rate between immobilization for several weeks in internal rotation versus early motion.
- There is no high-level evidence to suggest a difference in immobilization in internal rotation versus external rotation in regards to recurrent dislocation.

Question 3: What is the long-term prognosis for a patient who sustains a primary anterior glenohumeral dislocation?

Rationale

Once a primary anterior glenohumeral dislocation in an athlete has been successfully reduced and immobilized, they will likely enquire about future ramifications for shoulder function later in life. It is important to guide patients on expectations for the short term in regards to immobilization, rehabilitation, and recurrent dislocation risk. However, it is equally important to educate them on the possible long-term sequela of a first-time dislocation.

Clinical comment

The short-term risk of recurrent dislocation is important; however, the long-term sequela of glenohumeral arthritis can be impactful in terms of resultant shoulder dysfunction for the patient.

Available literature and quality of the evidence

- Level I: 1 randomized trial.[26]
- Level II: 1 cross-sectional study.[27]

Findings

One of the biggest concerns is the threat of post-traumatic osteoarthritis and how one dislocation event versus recurrent dislocations impacts this outcome. Ogawa et al. found a high incidence of osteoarthritis in patients with traumatic anterior instability for whom surgery was planned. Incidence of osteoarthritis on plain x-ray was 11%, while incidence was 31% on computed tomography (CT) analysis. The total number of dislocation/subluxation events and frequency of those events in osteoarthritic shoulders were significantly larger and higher than in nonosteoarthritic shoulders.[27]

Hovelius et al. followed 227 patients for 25 years after an initial glenohumeral dislocation event treated no-operatively. He used Disabilities of the Arm, Shoulder, and Hand (DASH) scores to evaluate patients. He found that shoulders

classified as nonrecurrent, stable over time, or surgically stabilized had similar DASH scores and fared better than shoulders classified as persistent, recurrent dislocations.[26]

Resolution of clinical scenario

- DASH scores are comparable amongst groups regardless of treatment, as long as stability is achieved and displayed over time.
- Patients with persistent, recurrent dislocation events have an increased incidence of osteoarthritis and lower DASH scores long term.

Summary of answers

- No difference exists between premedication techniques for glenohumeral reduction regarding success rate for reduction and patient pain level.
- Intra-articular lidocaine significantly reduces the risk of complications, mainly in the form of respiratory depression associated with IV sedation.
- There are several techniques for shoulder reduction that are relatively quick and have a high success rate (FARES, Scapular Manipulation, Traction–Countertraction). These can be employed safely with either IV sedation or intra-articular lidocaine use.
- There is no significant difference in recurrent dislocation rate between immobilization for several weeks in internal rotation versus early motion.
- There is no high-level evidence to suggest a difference in immobilization in internal rotation versus external rotation in regards to recurrent dislocation.
- Patients with persistent, recurrent dislocation events have an increased incidence of osteoarthritis and lower

DASH scores long term.

122 Recurrent Shoulder Instability

Joost I. P. Willems MD[1], Amber von Gerhardt MD[1], W. Jaap Willems MD[2] and Arthur van Noort MD PhD[1]
[1] Department of Orthopaedic Surgery, Spaarne Gasthuis, Hoofddorp, The Netherlands
[2] Lairesse Kliniek, Amsterdam, The Netherlands

Clinical scenario

- A 28-year-old soccer keeper had a traumatic anterior dislocation of the right shoulder at the age of 24. He was treated conservatively and has had five recurrences afterwards.
- At physical examination there is no hyperlaxity. The apprehension, relocation, and release tests are positive.
- A computed tomography (CT) scan shows a small defect of the anterior glenoid (Figure 122.1) and a large Hill–Sachs lesion in the posterolateral part of the humeral head (Figure 122.2).

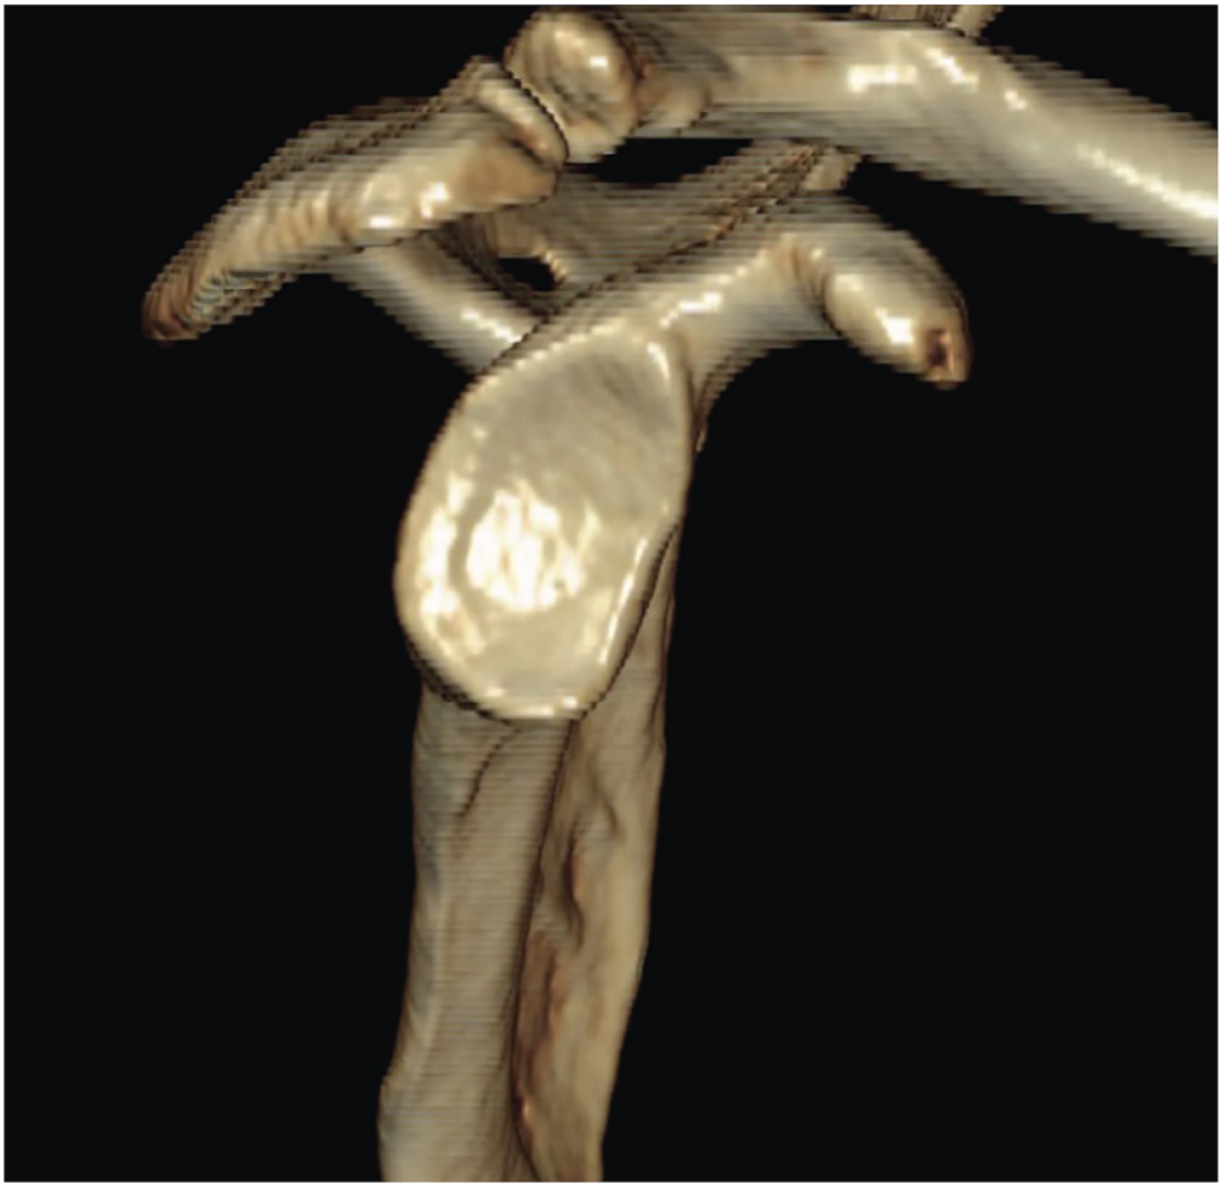

Figure 122.1 CT scan of the right shoulder, with erosion of the anterior glenoid. Source: Joost I. P. Williams, Amber von Gerhardt, W. Jaap Willems, Arthur van Noort.

Figure 122.2 CT scan of the humeral head, showing a Hill–Sachs defect on the posterolateral part of the humeral head. Source: Joost I. P. Williams, Amber von Gerhardt, W. Jaap Willems, Arthur van Noort.

Top three questions

1. In patients with recurrent post-traumatic anterior shoulder instability with a bony defect, does a bony

procedure lead to less recurrent instability in comparison to a labrum repair alone?

2. In patients undergoing a bony procedure in shoulder instability, does the original Latarjet procedure (onlay) show superiority to other bony procedures in the prevention of recurrent instability?
3. In recurrent post-traumatic anterior shoulder instability with a large Hill–Sachs lesion without considerable glenoid bone loss, is a remplissage combined with a labrum repair superior to a labrum repair alone?

Question 1: In patients with recurrent post-traumatic anterior shoulder instability with a bony defect, does a bony procedure lead to less recurrent instability in comparison to a labrum repair alone?

Rationale

Historically, an open or arthroscopic labrum repair is the gold standard for treating recurrent anterior instability, but long-term follow-up studies have shown that the rate of recurrence is rather high. Bony procedures seem to show better long-term results with lower recurrence rates, but at the expense of greater number of complications.[1]

Clinical comment

Labrum repair is nowadays mostly performed arthroscopically and is a procedure with low morbidity but high recurrence in cases with considerable bone loss. The bony procedures, of which the Latarjet is the most popular,

are a more difficult operation with potentially less recurrence, but with a higher complication rate.

Available literature and quality of the evidence

In a recent systematic review, including seven studies of level III and one study of level II, 795 patients were evaluated of which 416 underwent an open or arthroscopic Bankart repair and 397 an open Latarjet procedure with a mean range of follow-up of 4.9 to 17.5 years. None of these studies reported on the preoperative bone loss. Latarjet procedure leads to less recurrence and less revision surgery, with no higher complication rate leading to reoperation.[2]

In another recent systematic review with a minimum follow-up of five years, arthroscopic (n = 336) and open Bankart (n = 632), as well as open Latarjet repairs (n = 684), were evaluated. Recurrence rates were respectively 15.1, 7.7, and 2.7%. Only the difference between arthroscopic Bankart repair and Latarjet was statistically significant.

Complication rates were higher in Latarjet repair (9.4% vs 0%) in the arthroscopic Bankart repair (p = 0.002).[1]

One level III study,[3] comparing arthroscopic Bankart versus open Latarjet with a minimum follow-up of six years, showed superior results for the Latarjet procedure regarding any type of recurrent instability (positive apprehension, subluxation, dislocation) (41% vs 11% respectively, p = 0.0001). Small bone lesions were operated by Bankart repair, larger bone defects with a Latarjet. Revision surgery was more frequent in the Bankart repair group (21% vs 5.3%, p = 0.0001).

In two studies, Bankart repair combined with remplissage was compared with Latarjet procedure in patients with

considerable Hill–Sachs lesions.[4,5] Both were retrospective level III studies. With a follow-up of both studies varying between two and four years, the recurrence rate was not significantly different. In one study the rate of complications was higher in the Latarjet group; in the other study, the patients with Bankart plus remplissage showed more pain and loss of external rotation.

Apart from the bony lesions, other clinical factors play a significant role in predicting the chance of recurrence after arthroscopic Bankart repair, especially for those aged <22, male, with a number of preoperative dislocations who participate in competitive sports.[6]

Findings

There is moderate evidence, that labrum repair alone (Bankart repair) is inferior to the Latarjet procedure in recurrent instability.

No high-level evidence data are available if, in minor bony erosions of the glenoid, the labrum repair alone is as effective in preventing recurrence compared to the Latarjet procedure. A randomized controlled trial would be helpful. Following the data at present, with a higher recurrence after labral repair in undefined bone lesions, it is probable, that the Latarjet procedure is superior whenever there is a bone lesion.

Resolution of clinical scenario

- Level III evidence demonstrates that the Latarjet procedure is superior to open or arthroscopic labrum repair regarding re-dislocation and recurrence of instability.
- There is no evidence for a higher complication rate after Latarjet procedure compared to open or

arthroscopic labrum repair.

- Level III evidence demonstrates no difference in recurrence between labrum repair combined with remplissage versus Latarjet procedure.

Question 2: In patients undergoing a bony procedure in shoulder instability, does the original Latarjet procedure (onlay) show superiority to other bony procedures in the prevention of recurrent instability?

Rationale

With many different bony procedures described in literature, the question remains: which technique is the most suitable for shoulders with considerable glenoid bone loss?

Clinical comment

Recurrent shoulder instability is commonly associated with glenoid bone loss.[7] In cases with significant glenoid bone loss, often a soft tissue procedure alone is not sufficient.[8] In the last decade there has been an increasing tendency to perform bony procedures to augment the anterior glenoid. Although some techniques are used more frequently, there is still debate as to which procedure is the best regarding postoperative stability, function, return to activity level, and patient satisfaction.

Multiple types of glenoid augmentation procedures have been described in the literature. The first description of bone augmentation was by Eden, who used an autograft

from the tibia.[9] Hybinette adapted the technique by using an autograft from the iliac crest.[10] In 1954, Latarjet was the first to publish on a technique which describes a transfer of the coracoid with the attached conjoined tendon to the anterior part of the glenoid with mostly two screws, through a split of the subscapularis muscle. It increases the glenoid surface and creates a dynamic sling which prevents dislocation in abduction and external rotation.[11]

The classic onlay technique describes a transfer of the coracoid with the inferior part of the coracoid transferred to the anterior glenoid. A subsequent adaptation of this technique is the congruent arch technique, which describes a transfer of the concave inferior side of the coracoid in the same direction as the articular side of the glenoid.[12]

The classic technique allows the use of a portion of the cut coracoacromial ligament for re-attachment of the articular capsule for increased anterior stability. The congruent arch technique aims to create a better match to the concavity of the glenoid and, because of the flat shape of the coracoid, creates a larger articular surface for the glenoid in comparison to the classic technique.

Although the Latarjet procedure has proven to be a successful procedure in the short and long term,[1] there are some risks involved in this technique, such as bone graft resorption, inadequate placement of the bone block creating increased rates of osteoarthritis, failure of fixation, nonunion, or screw loosening, most of these requiring re-operation.

A variation of the coracoid transfer was developed by Bristow, where the tip of the coracoid is fixed to the glenoid rim with one screw.[13] Other types of bone grafts that have been used for glenoid reconstruction are distal tibia osteochondral allograft[14] and lateral clavicle autograft.[15]

More recent techniques of iliac crest bone graft describe a transfer of the inner table of the iliac crest to the anterior surface of the glenoid, which is a better match with the congruency of the glenoid surface.[16] Another technique is the use of a J-shaped iliac crest bone graft which can be placed as a wedge in the anterior glenoid, without the use of fixation material.[17]

Available literature and quality of the evidence

A systematic review of level IV studies did not show differences in recurrence in different bony procedures.[18] A recent level I study showed no difference in clinical scores and recurrence between the Latarjet procedure and iliac crest graft (J-graft). The Latarjet group had a significant worse internal rotation; the iliac crest group had a high donor site morbidity.[19]

Findings

There is no evidence, that either technique of bone grafting is clinically superior in treating shoulder instability with considerable bone loss.

Resolution of clinical scenario

- Level I evidence demonstrates a similar effect on stability of both the Latarjet procedure and an iliac crest bone graft (J-graft).

Question 3: In recurrent post-traumatic anterior shoulder instability with a large Hill–Sachs lesion without considerable glenoid bone loss, is a remplissage combined with a labrum repair superior to a labrum repair alone?

Rationale

Since the introduction of the remplissage technique, it has not been proven that it leads to less recurrence compared to labrum repair alone.

Clinical comment

In the past, several techniques have been reported to treat the humeral head defect (he Hill–Sachs lesion) in shoulder instability. Osteochondral allograft, humeral head osteotomy, humeroplasty, partial resurfacing arthroplasty are described.[20–23] Connolly introduced a soft tissue procedure, which describes an open approach with a transfer of the infraspinatus tendon with a piece of the greater tuberosity to the Hill–Sachs defect.[24]

Wolf adapted this technique for an arthroscopic approach, whereby filling (remplissage) the humeral head defect through a capsulotenodesis of infraspinatus and teres minor transforms the Hill–Sachs defect extra-articularly, thus preventing engagement.[25]

One study has shown that in most cases only capsule or muscle is attached to the Hill–Sachs defect.[26]

Availability and quality of the evidence

A meta-analysis of three comparative studies (level III) showed superior results in the group of combined labrum repair and remplissage versus the only labrum repair group in shoulders with up to 25% glenoid bone loss, regarding redislocation rate, recurrent instability, and clinical scores. A comparison between postoperative range of motion, especially of external rotation, could not be made.[27]

Findings

There is low evidence that in patients with a large Hill–Sachs lesion a combined procedure of labrum (Bankart) repair combined with remplissage leads to less recurrence than labrum repair alone.

Resolution of clinical scenario

- Level III evidence demonstrates that, with glenoid bone loss of maximally 25%, remplissage combined with labrum repair is superior to labrum repair alone regarding redislocation and recurrent instability. No data are available to demonstrate loss of external rotation in the remplissage group.

Summary of answers

- Two- (2D) and three-dimensional (3D) CT as well as 2D and 3D magnetic resonance imaging (MRI) are equally adequate in measuring glenoid bone defects in shoulder instability. The best-fit circle method is reliable and accurate.
- The Latarjet procedure is superior to open or arthroscopic labrum repair regarding re-dislocation and recurrence of instability. There is no evidence for a higher complication rate after Latarjet procedure

compared to open or arthroscopic labrum repair. There is no difference in recurrence between labrum repair combined with remplissage versus Latarjet procedure.

- An iliac crest bone graft has a similar effect on stability as the Latarjet procedure.
- In glenoid bone loss more than 25% a labrum repair with remplissage is superior to labrum repair alone regarding redislocation and recurrence of instability.

123 Rotator Cuff Tears

Alberto Blanco MD[1], Montserrat García-Portabella MD[2], Lledó Batalla MD[2] and Josep Massons MD[3]
[1] Moisès Broggi Hospital, Barcelona, Catalonia, Spain
[2] Clínica Corachan, Barcelona, Catalonia, Spain
[3] Vall d'Hebron University Hospital, Barcelona, Spain

Clinical scenario

- A 63-year-old man complains of three days of shoulder pain after overexertion when lifting a weight.
- He describes the pain as mostly mechanic, with progressive worsening throughout the day. Furthermore, it wakes him up in the middle of the night.
- The patient is active both in terms of his profession (a painter) and recreationally (swimming).

Top three questions

1. Among patients with rotator cuff tears, does older age, compared to younger age, have an impact on the success of rotator cuff repair?
2. In patients with an acute rotator cuff tear, does early surgery, compared to delayed surgery, result in better functional outcomes?
3. Among patients undergoing rotator cuff repair, does double row repair, compared to single row repair, have an advantage in terms of outcomes?

Question 1: Among patients with rotator cuff tears, does older age, compared to younger age, have an impact on the success of rotator cuff repair

Rationale

When deciding on the management of a rotator cuff tear, the patient's age is an important variable to assess.[1] A number of studies have evaluated the role of age as a prognostic factor when repairing chronic rotator cuff pathology.[2] An analysis of the published evidence about this topic will help us to decide if there is an age limit after which the patient does not benefit from surgical repair.

Clinical comment

In order to focus properly the management of a degenerative rotator cuff tear, we must decide whether the lesion is surgical or should be treated conservatively.[3] In this sense, age has been suggested not only as a predisposing factor but also as prognostic of outcome of the result, being associated with a higher rate of repair failure.[4],[5]

It is critical to first determine if a tear is of a traumatic or degenerative nature. Hybrid lesions often exist, that is traumatic injuries on a background of an already degenerative rotator cuff. The intrinsic structure of the tendon can be affected by many factors, but primarily by professional activity, gender, and age. The degeneration of the tendon fibers not only predisposes the patient to a rotator cuff tear but also has a decisive influence on the tendon's healing after surgical repair.[6]

Given this relationship between age, fibrillar degeneration, and lower healing potential, the question arises regarding the age cutoff, if one exists, above which the net benefit does not exceed the surgical risk. Other critical prognostic factors include size of the lesion, the degree of muscular atrophy, fatty infiltration at the time of diagnosis, and the tendon's retraction distance.[7]

Available literature and quality of the evidence

In spite of the high number of publications that try to offer some light to this question, only a few reach a high level of evidence. Although the majority of the studies are of level IV evidence, in the last 10 years there have been some level III studies, numerous studies of level IIB, a systematic review (IIA), and a randomized controlled trial (RCT; level IB).

Findings

In the only blinded RCT (multicenter study) conducted thus far, Flurin et al. compared bursectomy and subacromial decompression versus bursectomy, decompression, and arthroscopic repair in 143 patients older than 70 years (70 and 73, respectively).[8] This study concluded that both groups presented a significant clinical improvement at one-year follow-up. However, the group undergoing arthroscopic repair obtained better clinical results in all evaluation scales, with a statistically significant difference. Interestingly, this difference was accentuated in the patients who presented a greater retraction of the tendon cape and was smaller in the patients who presented a greater degree of fat infiltration based on the Goutallier classification.[9]

Along the same lines, Dezaly et al. performed a very similar RCT (level IIB) in which they reached the same conclusion

after randomizing 142 patients: acromioplasty and biceps tenotomy group versus acromioplasty, biceps tenotomy, and cuff repair group.[10] The acromioplasty, biceps tenotomy, and rotator cuff group obtained statistically significant improvements in clinical scores and overall satisfaction.

In a 2017 study, Silva et al. conducted a literature review of studies published involving patients over 65 years of age.[11] They concluded that, despite the lack of RCTs, the data obtained in the different studies are consistent. The healing rate after one year varies depending on the studies from 58%[12] to 81.5%,[7] obtaining an average of 71.7%. However, the improvement in the clinical evaluation scales and in overall patient satisfaction is even higher.

Oh et al. published in 2010 a case series that, despite being level IV evidence, was very statistically robust.[13] They demonstrated that in a multivariate regression analysis, age is not an independent determining factor of Constant score, while the degree of retraction of the proximal end and the fatty degeneration of the infraspinatus were indeed independent factors affecting the integrity of the repair.

Resolution of clinical scenario

- Studies published to date show that increasing age is associated with prevalence of larger rotator cuff tears. The size of the tear is closely related to a risk of re-rupture following rotator cuff repair.
- The rate of healing in patients over 70 years after one year exceeds 70% on average, reaching in some studies up to 81%.
- In patients in whom there has been a re-rupture of the repair after one year, the functional and overall patient

satisfaction scores still show a statistically significant increase compared to decompression alone.

- Based on the evidence published thus far, we can affirm that age should not exclude patients from undergoing rotator cuff repair. This indication should be made around other factors, such as the degree of retraction and the degree of fatty infiltration degree.

Question 2: In patients with an acute rotator cuff tear, does early surgery, compared to delayed surgery, result in better functional outcomes?

Rationale

In general terms, when we treat an acute tendon injury, we understand that early repair is a key factor to be taken into account to avoid muscle hypotrophy and tendon retraction.[14] Some clinical guidelines recommend that acute lesions should be repaired in a period of less than three weeks.[15] But is there true evidence to support such a claim? And if so, what is the critical period for treating it?

Clinical comment

Making a distinction between an acute rupture, acute symptoms of a chronic rupture or the acute extension of an existing chronic rupture are very difficult, if not impossible.[16] We define acute ruptures as those in which a previously asymptomatic patient identifies a traumatic incident leading to a sudden onset of symptoms such as severe pain, functional limitation, and loss of strength in the affected limb.[17] However, the diagnosis is rarely immediate, either because it takes time to consult a

physician or due to delays in referrals and wait times for nonurgent issues.[18]

Extrapolating the pathophysiology of tendon lesions in other parts of the body, several studies have tried to provide scientific support to the hypothesis that truly acute tendon ruptures should be treated immediately, similar to how they are for other parts of the body (e.g. Achilles, flexor tendons).[19],[20]

Available literature and quality of the evidence

The majority of the available studies published as far are level IV.[14][16]–[27]

Findings

The first study that directly addressed the issue dates from 1983. Basset et al. conducted a cohort study with 37 patients separating them into three groups: early surgery (ES) <3 weeks, 3–6 weeks, and delayed surgery (DS) >6 weeks.[21] They concluded that the earlier patients underwent surgery, the greater range of motion they ultimately achieved.

In 2011, Hantes et al. conducted a retrospective cohort study with 35 patients (ES <3 weeks vs DS >3 weeks).[22] They found a significantly greater improvement in the University of California Los Angeles (UCLA) and Constant scales in the ES group compared to the DS group. In a very similar study, however, Petersen et al. established that there were no differences among patients operated on any time in the first four months postinjury.[23]

Tan et al. performed a retrospective cohort study with the largest sample size to date.[24] They analyzed the results of 1200 patients divided into two groups: ES <24 months and DS >24 months. They found that patients operated on

within 24 months after the traumatic event had a lower rate of re-rupture (13%) compared to the DS group (20%). In contrast, Zhaeentan et al. demonstrated no advantages between the ES and DS groups.[27] The discrepancy in this case may be due to the fact that the latter study performed repairs using a mini-open approach rather than arthroscopy.

The only systematic review (grade IIIA) to date was carried out by Mukovozov et al. in 2013.[17] For this study they used seven studies in the ES group (<3 months) and eight studies in the DS group (>3 months). They concluded that the patients in the ES groups had a statistically significant increase in the UCLA and Constant scores; however, given that low-quality data were pooled, this should be interpreted with caution.

Resolution of clinical scenario

Common sense leads us to think that early repair has advantages (e.g. less atrophy) compared to delayed repair (e.g. increased lesion size, loss of cuff elasticity). However, true common sense is to apply scientific evidence to our clinical practice. From the studies published to date, it appears early repair increases the rate of healing and clinical outcomes. However, there is currently insufficient evidence, which is often of poor quality and sometimes even contradictory. To determine the balance between benefits and prejudices, higher-quality studies and larger statistical power studies are needed. Likewise, there is no consensus regarding the definition of *early surgery*.

Question 3: Among patients undergoing rotator cuff repair, does double row repair, compared to single row repair, have an advantage in terms of outcomes?

Rationale

The optimal tendon repair technique has been a topic of debate. Single row, double row, transosseous, and bridged repairs are some of the options currently in the therapeutic arsenal and are applied depending on the surgeon's preference.

Clinical comment

The controversy about which suture technique is best suited to repair the cuff arose at the beginning of this century, with the aim of anatomically restoring the insertional footprint.[28] A cadaveric study conducted in by Meier et al. confirmed not only the increase in tendon–bone contact but also the mechanical advantage of the double row repair compared to the single row repair.[29] Despite a plethora of evidence on the topic since then, the question remains: which technique is best for a given patient?

Available literature and quality of the evidence

Seven cadaveric studies were available, which formed the basis for in vivo trials that followed. In vivo, there is abundant level IV and level III evidence (14 studies). There are also six level IIB studies, with their corresponding systematic reviews of level IIA (five reviews and meta-analyses). Focusing on level I evidence, seven RCTs (IB) have been published thus far. In addition, three systematic

reviews/meta-analyses (IA) focusing on these trials have been published.

Findings

Curtis et al. carried out a descriptive anatomical study in cadavers, describing the insertional footprint.[30] It concluded that the footprint followed a consistent and identifiable pattern through anatomical references, which allowed the evaluation of size and location of the cuff lesion. In a subsequent study, Lo et al. formulated the hypothesis that the restoration of the footprint would provide better biology and a biomechanical advantage.[28]

Meier et al. subjected 30 cadaveric shoulders to a cyclic load. The endpoints were established in 10 mm gap or 5000 cycles.[29] Two conclusions were reached from this study: the anchor suture is superior to the transosseous suture, and the double row was biomechanically and anatomically superior to single row. Subsequent cadaveric studies further corroborated these findings.[31],[32]

Grasso et al. performed the first randomized clinical trial (level IB), in which 80 patients were randomized to single row versus double row repair (40 patients in each group).[33] Outcomes included the Disabilities of the Arm, Shoulder, and Hand (DASH) scale, the Constant score, and the Strength score. The study concluded that in the short term there were not clinically significant differences between the two techniques.

In the following years seven further high-quality trials all reached very similar conclusions: no differences in clinical outcome, and marginal (nonsignificant) superiority for healing rate in favor of double row repair.

Carbonel et al. carried out the RCT with the greatest statistical power.[34] They randomized 160 patients, 80 for

each therapeutic group. Outcomes included the UCLA score, American Shoulder and Elbow Surgeons (ASES) scores, and the Constant score. Multiple independent variables were analyzed. Healing was evaluated by magnetic resonance imaging (MRI) and the follow-up was up to two years postoperatively. The study concluded that, although there were no differences in healing rate, patients undergoing double row repair did have better clinical outcomes after two years, a difference that was more evident in lesions >3 cm. These conclusions were in contrast to the previously published studies.

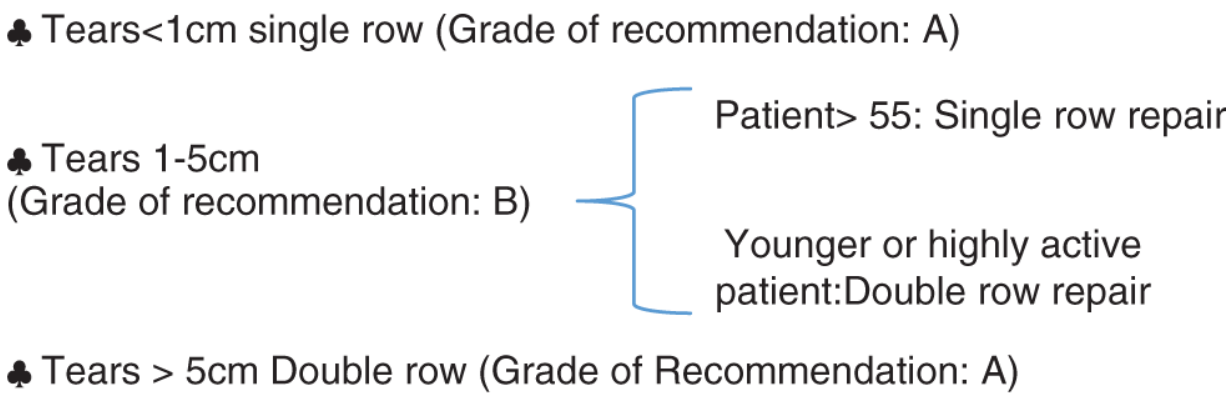
In 2016, Spiegl et al. performed a systematic review of the meta-analyses published until then, including eight papers with level I–III studies.[35] After analyzing all the information, the authors concluded that in the short-term there were no statistically significant clinical differences for small and medium rotator cuff injuries. However, there was a higher re-rupture rate in the single row patients. It also suggested a tendency to obtain better clinical results in large and massive cuff tears.

The most complete meta-analysis performed to date analyzed seven clinical trials.[36] The UCLA score was the only outcome which significantly favored double row repair. Other outcomes (ASES, Constant, Western Ontario Rotator Cuff [WORC], and Single Assessment Numeric Evaluation [SANE]) scores showed no significant differences.

Resolution of clinical scenario

- Double row suture and bridge double row configurations have demonstrated biomechanical, biological, and anatomical superiority in cadavers.

- This superiority does not translate in clinical outcomes as expected, although imaging studies do seem to show a higher rate of healing and lower rates of re-rupture with double row repair.
- The latest systematic reviews also suggest a tendency to obtain better clinical results in large and massive cuff tears with double row repair.
- With the evidence published to date, the recommendations are:



Summary of answers

- Increasing age is associated with prevalence of large rotator cuffs.
- Age alone should not exclude patients from undergoing rotator cuff repair.
- There is currently insufficient evidence to demonstrate that early repair increases rates of healing and/or clinical outcomes.
- Double row suture configurations have demonstrated biomechanical superiority.
- Double row repair has not translated into clinical outcomes.

124 Massive and Irreparable Rotator Cuff Tears

Brandon J. Erickson MD[1] and Joshua S. Dines MD[2]
[1] Rothman Orthopaedic Institute, Division of Sports and Shoulder, New York, NY, USA
[2] Hospital for Special Surgery, Division of Sports and Shoulder, New York, NY, USA

Clinical scenario

- A 52-year-old male laborer presents with chronic, dominant shoulder pain.
- Magnetic resonance imaging (MRI) demonstrates a massive rotator cuff tear with retraction of the rotator cuff tendon medial to glenoid, and grade 3 Goutallier atrophy.

Top three questions

1. In active patients with a full thickness, massive, retracted rotator cuff tear, does single row rotator cuff repair (RCR) result in better clinical outcomes than double row RCR?
2. In middle-aged active men with full thickness, massive, retracted rotator cuff tears, does RCR with patch augmentation result in better clinical outcomes than RCR in isolation?
3. In middle-aged men with irreparable rotator cuff tears, does superior capsular reconstruction (SCR) result in better functional outcomes than tendon transfers?

Question 1: In active patients with a full thickness, massive, retracted rotator cuff tear, does single row rotator cuff repair (RCR) result in better clinical outcomes than double row RCR?

Rationale

With the current focus on minimizing expenses in healthcare, it is important to understand when additional costs are truly beneficial to clinical outcomes, and when the cost may be unnecessary. Double row RCR is more costly than single row RCR, so the cost must be justified with improved outcomes.

Clinical comment

The number of RCR performed each year is increasing. There are many ways to perform an RCR, but the most common is either via a single or double row configuration. It is imperative that these RCR techniques be closely compared and scrutinized so treating surgeons can choose the correct procedure that offers the best outcome. Furthermore, the patient in this scenario has a massive, retracted rotator cuff tear. This must be distinguished from an irreparable rotator cuff tear. An irreparable rotator cuff tear is one that, despite soft tissue releases, muscle relaxation, etc., is too degenerated, with too much fatty atrophy, and not enough excursion that it cannot physically be repaired. Other factors that aid in the decision-making process would be co-morbidities that have potentially negative effects on healing. For example, if the tendon were able to be mobilized to the tuberosity but was of poor

quality and the patient was a diabetic smoker with osteoporosis, the tear could also be classified as irreparable (in that it would be unlikely to heal).

Available literature and quality of the evidence

The evidence supporting the answer to this question is good with several level I and II studies.[1–7]

Findings

In the middle-aged patient represented in this scenario with a massive rotator cuff tear, the evidence suggests that a double row RCR offers better results in regards to strength (specifically shoulder abduction and external rotation) and tendon healing than a single row repair.[1,2] Studies found that patients with intact rotator cuff tendons following RCR (as confirmed by MRI) have better clinical outcome scores than patients who had a re-tear following RCR.[2] Furthermore, double row RCR leads to decreased re-tear rates accelerated postoperative rehabilitation.[6] A systematic review of overlapping meta-analyses found improved healing rates in double row RCR compared to single row.[8] These results were similar to a systematic review and meta-analyses that similarly found improved healing rates in double row RCR over single row.[9] In the majority of studies there were no differences in clinical outcome scores between the groups.[7] One level I study did find a significant difference in clinical outcome scores, with patients who underwent double row RCR demonstrating higher scores than those who underwent single row repair.[10] This difference was most pronounced with large and massive rotator cuff tears. Hence, in middle-aged, active, laboring patients who undergo RCR on their dominant shoulder and are at increased risk for re-tear, a double row RCR (transosseous equivalent) would be the

treatment of choice. This would allow a faster rehabilitation process with a decreased chance that the repair would fail.

Resolution of clinical scenario

- In massive rotator cuff tears, double row RCR leads to decreased re-tear rates.
- There are conflicting results with regards to clinical outcome scores between groups. In massive rotator cuff tears, double row RCR may improve clinical outcome scores.

Question 2: In middle-aged active men with full thickness, massive, retracted rotator cuff tears, does RCR with patch augmentation result in better clinical outcomes than RCR in isolation?

Rationale

There has been a significant amount of recent attention given to augmentation strategies for RCR. Prior to recommending a patch augmentation, the surgeon should be familiar with what the evidence shows.

Clinical comment

Several companies have developed patches to be used as augments during RCR. These patches are used in an attempt to promote healing of the RCR. If these patches improve healing rates and functional outcomes following RCR, they may be worthwhile using as an augmentation technique.

Available literature and quality of the evidence

The evidence supporting the answer to this question is mediocre with three level III studies and several level IV studies.[11–15]

Findings

The porcine dermal xenograft used as an augment to supraspinatus tendon repair does not appear to improve radiographic healing or clinical outcomes at two years.[11] The poor performance of the xenograft was seen in multiple studies, and augmentation with this graft should be used with caution.[16] Yoon et al. compared standard RCR to marrow stimulation and patch-augmented RCR.[15] The authors found no difference in clinical outcome scores, but a significantly lower re-tear rate in the patch-augmented group. These results should be evaluated with caution, however, because the patch group also underwent marrow stimulation. Ciampi et al. compared a standard RCR without patch augmentation, an RCR with a collagen patch augmentation, and an RCR with a nonabsorbable, synthetic polypropylene patch augmentation.[12] The authors found a reduced 12-month re-tear rate as well as increased UCLA scores, abduction strength, and elevation at three-year follow-up. In the level IV studies without control groups, all studies reported significant improvements in outcome scores, pain, and shoulder motion following patch-augmented RCR, but given the lack of control groups, it is difficult to discern whether these improvements would be more significant than outcomes following RCR without patch augmentation.[13,14,16] Hence, as the literature currently stands, augmentation of an RCR with a patch in a middle-aged, active laborer may decrease re-tear rates but does not improve clinical outcomes. Good clinical judgment

must be utilized when deciding whether to augment a repair with a patch.

Resolution of clinical scenario

- There does not appear to be a difference in clinical outcome scores between patients who undergo isolated RCR and those who undergo RCR plus patch augmentation.
- Patch augmentation may decrease re-tear rates following RCR compared to patients who undergo RCR without patch augmentation.

Question 3: In middle-aged men with irreparable rotator cuff tears, does superior capsular reconstruction (SCR) result in better functional outcomes than tendon transfers?

Rationale

There are some rotator cuff tears that cannot be fixed. In a young patient who would be a poor candidate for an arthroplasty procedure, the surgeon should choose the treatment option that will afford the patient the best outcome.

Clinical comment

Young, active patients with irreparable rotator cuff tears represent a very difficult patient population for treating surgeons. In this scenario, the rotator cuff, despite soft tissue releases, etc., cannot be repaired, and a salvage operation must be attempted. These patients have limited options for success, and their options are often somewhat

technically demanding and have unpredictable outcomes. It is important to understand the pros and cons of each procedure.

Available literature and quality of the evidence

The evidence supporting the answer to this question is poor with several level IV studies.[17–24]

Findings

Unfortunately, there are no studies that have directly compared SCR to tendon transfers. However, there are several studies that have reported results of both individually. Pennington et al. reported the one-year results of 86 patients who underwent SCR for massive, irreparable rotator cuff tears.[17] Significant improvements in Visual Analog Scale (VAS) and American Shoulder and Elbow Surgeons (ASES) scores, as well as strength and range of motion (ROM), were seen. Several other level IV studies have corroborated these results.[18–20] Complications following SCR include failure and/or resorption of the graft.

There are a few options for tendon transfers in patients with irreparable posterosuperior rotator cuff tears including the latissimus dorsi, lower trapezius, and teres major.[21,23,25,26] Boileau et al. reported the results of an isolated latissimus dorsi transfer to restore external rotation in massive, irreparable rotator cuff tears.[21] The authors found significant improvements in Constant and Simple Shoulder Value (SSV) scores as well as a significant increase in shoulder external rotation following latissimus transfer (there was a 26° increase in external rotation with the arm at the side and 18.5° increase in external rotation with the arm in 90° of abduction).

Similarly, Kanatli et al. reported the outcomes of 15 patients with irreparable rotator cuff tears and pseudoparalysis treated with latissimus dorsi transfer and found significant improvements in all clinical outcome scores as well as all shoulder ROM.[22] Elhassan et al. reported the results of lower trapezius transfers in 33 patients (average age 53) at an average of 47 months' follow-up.[23] The authors found significant improvements in pain and SSV scores, and significant improvements in ROM. Complications following tendon transfers include seroma formation, harvest site morbidity, neuropraxias, etc. Therefore, both SCR and tendon transfers are viable options when treating middle-aged, active, laborer patients with massive, irreparable rotator cuff tears. SCR may be slightly less technically demanding with fewer potential complications (harvest site issues, neuropraxias, etc.).

Resolution of clinical scenario

- Direct comparison between SCR and tendon transfers for treatment of massive irreparable rotator cuff tears cannot be made.
- Both SCR and tendon transfers help restore ROM and improve clinical outcome scores in this difficult patient population.

Summary of answers

- In massive rotator cuff tears, double row RCR results in lower re-tear rates and possibly improved outcome scores compared to single row RCR.
- Patch augmentation to RCR may decrease re-tear rates, but it has no effect on clinical outcome scores.

- Both SCR and tendon transfer (using a variety of tendons) are viable treatment options in the middle-aged patient with a massive, irreparable rotator cuff tear.

125 Subacromial Pain Syndrome

Egbert J. D. Veen MD and Ron L. Diercks MD
Department of Orthopedics, University of Groningen, University Medical Center Groningen, The Netherlands

Clinical scenario

- A 48-year-old male presents to an orthopedic surgeon with shoulder complaints.
- He works in a hardware store and has had progressive pain in his right shoulder for five months. The pain is located anterolateral and radiates to the upper arm. There is no history of trauma, overhead activities are painful, and sleeping is disturbed.
- At examination there is a painful arc between 70 and 120°. The Neer sign and Hawkins–Kennedy test are positive.
- The orthopedic surgeon doubts whether he uses an magnetic resonance imaging (MRI) or ultrasound (US) to investigate the persistent complaints.
- A subacromial injection with local anesthetic and steroids gave relieve.

Top three questions

1. Does the Hawkins–Kennedy test predict subacromial pain syndrome (SAPS) better in patients with shoulder pain compared to other physical tests?
2. How sensitive is an MRI scan in comparison to US for diagnosing SAPS in patients with shoulder pain?

3. Does surgery lead to a better functional outcome compared to conservative treatment (physiotherapy, infiltrations) in patients with SAPS?

Question 1: Does the Hawkins–Kennedy test predict subacromial pain syndrome (SAPS) better in patients with shoulder pain compared to other physical tests?

Rationale

SAPS causes pain, impairment in daily activities and work, and a clear and unambiguous anatomical substrate is lacking.[1] It is a frequently encountered condition in daily practice of orthopedic surgeons; between 7 and 34% of adults have shoulder pain at times and the incidence of shoulder pain in is estimated to be 19 per 1000 person-years, and is highest in women over 45 years and lowest in young adults. In the general practice the incidence is 0.8–2.3%, with a lifetime prevalence of up to 66.7%.[2] A thorough physical examination is an essential diagnostic tool and can help to rule out other shoulder pathologies. Though often associated with rotator cuff tears, the discussion of SAPS in this chapter will not include cuff tears. Please see Chapters 123 and 124 for a full discussion of rotator cuff pathology.

Clinical comment

Many shoulder tests are available to test a variety of diagnoses of the shoulder. One commonly used test is the Hawkins–Kennedy test.[3] The patients is examined while sitting with their shoulder flexed to 90° and their elbow

flexed to 90°. The examiner grasps and supports proximal to the wrist and elbow to ensure maximal relaxation. The examiner and the patient then quickly rotate the arm internally. The test is considered positive when the pain is located below the acromioclavicular joint with internal rotation. It would be helpful to have a specific test for SAPS as it is a clinical diagnosis.

Available literature and quality of the evidence

A Cochrane review by Hanchard et al. from 2013 investigated all physical tests for subacromial pain syndrome.[4] They reviewed various tests for shoulder pain but five were selected specific for *impingement* with a total of 356 patients. Only two studies could answer the question with both level II evidence.[5,6]

Findings

The review included five studies for specific *impingement* tests. They showed a sensitivity of 0.92 (0. 72–0.99) with specificity from 0.26 (0.13–0.43) to 0.44 (0.32–0.58) but this raised to 0.96 (0.79–1.00) when the Hawkins–Kennedy test or the Neer sign (pain produced by maximal passive abduction in the scapula plane, with internal rotation whilst stabilizing the scapula by the examiner)[7] was positive with specificity 0.41 (0.29–0.54). This is also confirmed in another review which stated that one physical sign cannot sufficiently differentiate between the various shoulder disorders and so a combination of tests should be used.[8]

Resolution of clinical scenario

- Clinical examination is the hallmark for diagnosing SAPS.

- The Hawkins–Kennedy has a very high sensitivity for testing SAPS.
- The test should be combined with other tests to differentiate between different conditions.

Question 2: How sensitive is an MRI scan in comparison to US for diagnosing SAPS in patients with shoulder pain?

Rationale

SAPS is a clinical diagnosis and can be caused or accompanied with different traumatic or degenerative changes of the shoulder. Surgical intervention is, in these patients, not recommended in most cases. If a rotator cuff tear is of traumatic origin, if the patients is young, or very active, if there is an invalidating loss of function, then a rotator cuff repair should be considered.[9] To differentiate between a bursitis or tendinopathy, or to judge the size, retraction, atrophy, or fatty infiltration of a torn rotator cuff, different imaging techniques are available. MRI and US are widely used in investigating patients with complaints of their shoulder.

Clinical comment

In a number of patients with SAPS, complaints may be of a more serious character, as described above, A reparable lesion in the shoulder that can mimic impingement need to be ruled out as this may lead to a different line of treatment (e.g. surgery). As well, appropriate diagnostic tests need to be performed in order to accurately diagnose SAPS.

Available literature and quality of the evidence

Two systematic reviews and meta-analyses assess ultrasonographic performance in terms of diagnosing subacromial conditions. A review by Manzoor et al. (level IV) included 14 studies, three of which specifically looked at the use of US in diagnosing SAPS.[10] Another study, by Ottenheijm et al., included 23 studies, seven of which assess subacromial pathologies.[11] Two diagnostic studies (both level III) assessed the role of MRI in diagnosing SAPS.[12],[13]

Findings

In their systematic review and meta-analysis, Manzoor et al. identified three studies which looked at the diagnostic performance of US in terms of SAPS. There were a total of 177 patients included in the studies. They found that sensitivity for *subacromial impingement* ranged from 35.7 to 79%, whereas specificity ranged from 58.8 to 84.4%. No pooled analysis was performed due to significant heterogeneity, and no positive or negative predictive values were reported.[10] Ottenheijm et al. separated studies on the specific type of subacromial pathologies analyzed. They also did not pool data due to heterogeneity and small sample sizes; they found that in diagnosing subacromial bursitis, US had a sensitivity of 79–81% and a specificity of 94–98%. For tendinopathy, they found a sensitivity of 67–93% and a specificity of 88–100%; finally, for calcific tendonitis, they found a sensitivity of 100% and a specificity of 85–98%.[11]

Birtane et al. enrolled 125 patients in their study, with the subacromial injection test serving as a reference standard. All patients underwent MRI testing as well as functional evaluation. They found that, in diagnosing *subacromial impingement*, MRI had a sensitivity of 98.9% and a specificity of 36.8%, along with positive and negative

predictive values of 78.2 and 93.3%, respectively.[12] Iannotti et al. evaluated MRI performance in 91 patients and 15 asymptomatic volunteers. They found that, in diagnosing impingement syndrome, MRI had a sensitivity of 93% and a specificity of 87%. All shoulders were evaluated arthroscopically as a gold standard reference.[13]

Resolution of clinical scenario

- The diagnostic performance of US is somewhat variable, though it appears to be relatively specific and sensitive for most subacromial pathologies.
- MRI is highly sensitive for SAPS, though it may lack specificity in this regard.

Question 3: Does surgery lead to a better functional outcome compared to conservative treatment (physiotherapy, infiltrations) in patients with SAPS?

Rationale

Evidence is rising that surgery doesn't lead to better results in the treatment of SAPS in the absence of a rotator cuff tear. Patients may have the same results after conservative treatment.

Clinical comment

Subacromial decompression for SAPS is one of the most widely performed surgical procedures of the shoulder. Increasing evidence does not support this treatment for the majority of patients.

Available literature and quality of the evidence

A multicenter, pragmatic, parallel group, placebo-controlled, three-group, randomized surgical trial of level I evidence was recently published.[1] The investigators included 313 patients divided over three groups (arthroscopic subacromial decompression, investigational arthroscopy only, or no treatment). All patients had had at least six months of conservative treatment before inclusion. Surgical patients were blinded for intervention with the *arthroscopy only* as a placebo. Primary outcome was the Oxford Shoulder Score at six months and an intention to treat analysis was performed. A recent systematic review and meta-analysis of RCTs (level I) analyzed 13 RCTs (n = 1062).[14]

Findings

The RCT showed no difference in outcome, measured by the Oxford Shoulder Score, at six months between the arthroscopic subacromial decompression (ASAD) and arthroscopy only (sham) groups – ASAD mean 32.7 (standard deviation [SD] 11.6) vs SHAM mean 34.2 (SD 9.2); mean difference: −1.3 points (95% confidence interval [CI]: 3.8–1.3). In the no-treatment group only a single advice from a consultant was offered and a rehabilitation program was not followed.[15] Comparing the no-treatment to the ASAD and sham groups, no difference was seen in the same outcome at six months. No treatment group Oxford Shoulder Score 29.4 (SD: 11.9) mean differences: 2.8 (95% CI: 0.5 to −5.2) and 4.2 (95% CI: 1.8–6.6). This study failed to show any clinical important advantage of ASAD and questioned the value of surgery for SAPS. The effect of a rehabilitation program was not investigated. Finally, the meta-analysis by Khan et al. found no benefit to surgery in terms of pain relief (mean difference: −0.07;

95% CI: −0.40 to 0.26), or short-term functional outcomes (standardized mean difference: −0.09; 95% CI: −0.27 to 0.08).[14] In accordance with the above, a BMJ Clinical Practice Guideline advised against subacromial decompression surgery in patients with SAPS.[16]

Resolution of clinical scenario

- The patient was treated by conservative treatment with guided training with a physiotherapist, nonsteroidal anti-inflammatory drugs, and a subacromial injection with analgesics and steroids.
- After temporarily adjusting his daily work to desk tasks, he could resume his above-head work after six months and the pain was relieved.

Summary of answers

- The Hawkins–Kennedy test can be used for diagnosing SAPS because of its high sensitivity. It should be used combined with other shoulder tests because this will lead to rising sensitivity and specificity.
- An MRI scan of the shoulder can effectively detect other abnormalities (like RCTs). US can also be used, but only by experienced practitioners.
- Patients with SAPS, in the absence of a rotator cuff tear, should be treated with conservative treatment as it has equal results to surgery. Therefore, surgery should be reserved for patients with persistent complaints.

126 Pathology of the Long Head of the Biceps

Daniel Wang BA, David Ring MD PhD, and Matt Driscoll MD
Department of Surgery and Perioperative Care, Dell Medical School – The University of Texas at Austin, Austin, TX, USA

Clinical scenario

- A 58-year-old self-employed electrician has right shoulder pain that started six months ago after he put together a swing set in his backyard.
- On examination, he is tender over the bicipital groove. He has positive Speed and Yergason tests (Box 126.1).
- There is no weakness of the rotator cuff to suggest a large rotator cuff defect.

Top three questions

1. What is the role of clinical examination and imaging in isolating biceps tendinopathy in patients with shoulder symptoms?
2. What is involved in the decision-making to perform a biceps tendon debridement versus tenodesis or tenotomy in patients with biceps tendinopathy?
3. In patients undergoing biceps tenodesis, are there any differences in the clinical outcome and complication rates among various techniques used for biceps tenodesis? Between arthroscopic biceps tenodesis versus open biceps tenodesis?

Question 1: What is the role of clinical examination and imaging in isolating biceps tendinopathy in patients with shoulder symptoms?

Rationale

It can be difficult to discern the precise anatomical source of shoulder pain.

Clinical comment

Many shoulder surgeons believe they can distinguish pain from the LHB from other types of shoulder pain, and that it is worthwhile to do so.

Available literature and quality of the evidence

- Level I: 3 prospective blinded studies of consecutive patients.[4–6]
- Level II: 1 randomized cohort study,[7] 1 prospective nonrandomized clinical trial,[8] 2 cohort studies,[9,10] and 6 independent, blinded comparisons with a reference standard among non-consecutive patients or confined to a narrow population of study patients.[7,11–15]
- Level IV: 1 diagnostic study with poor reference standard,[16] 1 independent, unblinded comparison with a reference standard,[17] independent, unblinded comparison with poor reference standard.[18]
- Level V: 3 expert opinions.[19–21]

Findings

For diagnosis of LHB tendinopathy, tenderness in the bicipital groove has a sensitivity of 53% and a specificity of 54%; Speed test has a sensitivity from 32 to 69% (with one outlier of 90%) and a specificity from 48 to 81% (with one outlier of 14); Yergason test has a sensitivity of 41% and a specificity of 79%. It is important to note that many of the studies listed below also utilized the same tests to evaluate and diagnose rotator cuff and/or labral pathology, which indicates that these exam maneuvers do not provide a reliable or accurate distinction between LHB pathology and other common causes of shoulder pain.

Ultrasound has a sensitivity between 53 and 100% and a specificity between 97 and 100% for diagnosis of discrete

Box 126.1 Description of physical examination tests

Tenderness of the long head of the biceps (LHB) as it exits the intra-articular space, through the intertubercular groove, and down to a point approximately 7 cm below the acromion.[1]

Speed test: The externally rotated (supinated) arm with an extended elbow is forward elevated. The examiner resists this forward elevation of the arm and checks for pain.[2]

Yergason test: The elbow is flexed to 90° and the patient is asked to supinate the forearm against resistance. The test is considered positive if this resistance produces pain referred to the bicipital groove.[3]

pathology of the LHB such as dislocation, subluxation, and rupture. In patients with near-normal body habitus, imaging is not required to diagnose LHB rupture, making all studies that include ruptures misleading and unhelpful. Tendinopathy of the LHB tendon is not detectable with ultrasound. Biceps tendon sheath effusions detected sonographically are not specific to LHB pathology.[19,20]

The oblique sagittal plane magnetic resonance imaging (MRI) gives the best image of the intra-articular portion of the biceps tendon in the rotator cuff interval, but there is still a discrepancy with other diagnostic methods such as direct visualization at arthroscopy. For instance, Dubrow and colleagues evaluated concordance rate (defined as both modalities achieving a diagnosis of the exact same pathological classification) between noncontrast MRI and arthroscopy in 66 patients with LHB pathology, with equivalent findings only 35% of the time.[22] Mohtadi et al. (level I) similarly found that MRI and arthroscopy were concordant in 38% of patients (n = 58).[5]

Urita et al. (level II) found that MRI imaging demonstrating a medial spur of the bicipital groove and presence of a subscapularis tear were significant predictors of higher-grade LHB pathology (utilizing the Lafosse classification of LHB tendon disorder).[15]

Resolution of clinical scenario

- Physical examination maneuvers have limited ability to distinguish pain from biceps pathology from other types of shoulder pathology (overall quality: moderate).
- Diagnostic imaging has limited and variable sensitivity and specificity for LHB tendon pathology, most of which is either obvious on examination (e.g. rupture) or associated with other, more pressing pathologies such

as subscapularis rupture (with LHB subluxation). Imaging is not adequately studied for its use in distinguishing LHB pain from rotator cuff pain in general or other sources of shoulder pain (overall quality: moderate).

Question 2: What is involved in the decision-making to perform a biceps tendon debridement versus tenodesis or tenotomy in patients with biceps tendinopathy?

Rationale

The role and type of surgical treatment for tendinopathy of the LHB is debated.

Clinical comment

Tenotomy or tenodesis are considered when there is tendinopathy, subluxation, or dislocation of the LHB. Tenotomy is a safer, more expedient, and less technically demanding option in patients who are comfortable with a prominent biceps. Tenodesis is considered based on the rationale that it provides better aesthetics and less postoperative discomfort.

Available literature and quality of the evidence

Level I: 1 systematic review, meta-analysis.[23]

Level III: 2 retrospective cohorts.[24],[25]

Level IV: 5 case series.[26]–[30]

Findings

A 2015 systematic review and meta-analysis of three randomized controlled trials among patients with various diagnoses (not just LHB tendinopathy) and four cohort studies found that the incidence of categorical *cramping pain* was slightly, but significantly, decreased in 192 patients undergoing tenodesis (6%) when compared to tenotomy (13%, n = 198). One wonders what this would look like on a more appropriate measure of pain on its continuum. Prominence of the biceps was noted in 5% of patients undergoing tenodesis (n = 314) and 31% of patients undergoing tenotomy (n = 308). Patients were equally satisfied.[23]

Data from three retrospective case series that assessed tenotomy were pooled together (n = 377), with 73% of the patients categorized as a good or excellent outcome and satisfaction in spite of prominence of the biceps in most.[26–28] In cohort studies comparing tenotomy and tenodesis, there were expected differences in biceps deformity that were not a concern for any patients.[24]

A case series by Delle Rose found that 17% of patients who underwent tenotomy experienced muscle cramping at a mean postoperative time of one month, whereas no patients who underwent tenodesis had muscle cramping. Thirty-seven percent of patients in the tenotomy cohort had a prominent biceps; 5% of patients in the tenodesis cohort experienced biceps deformity, but only due to failure of the tenodesis.[29] In one case series (level IV) 40 patients were treated with tenotomy had decreased elbow flexion and supination strength compared with age, sex, and dominance-matched controls, but 86 percent were satisfied.[30]

Another comparison (level III) noted that 16 of 80 patients (20%) had near normal strength after tenotomy compared to 51 of 80 (64%) patients who underwent tenodesis.[24]

Boileau et al. (level III) found no changes in preoperative and postoperative Constant score between tenotomy and tenodesis.[25]

Resolution of clinical scenario

- Patients that want a less prominent biceps and are willing to take additional risks and invest more money might consider tenodesis, but tenotomy is effective (overall quality: low).
- It's important to note that the role of any operative treatment specifically for the biceps is debatable.

Question 3: In patients undergoing biceps tenodesis, are there any differences in the clinical outcome and complication rates among various techniques used for biceps tenodesis? Between arthroscopic biceps tenodesis versus open biceps tenodesis?

Rationale

The optimal tenodesis approach is debated.

Clinical comment

The surgical approach is based on the physician's preferences and skills. There are advocates for subpectoral tenodesis.

Available literature and quality of the evidence

Level III: 7 retrospective cohorts.[31_37]

Level IV: 7 case series.[3138_40]

Findings

Case series of patients treated with arthroscopic tenodesis report an average of 88% categorically good results.[3138_40]

A (level III) retrospective cohort study comparing open (25 patients) and arthroscopic (20 patients) tenodesis found slightly better active forward elevation in those treated via open tenodesis when compared to arthroscopic tenodesis (171.3 ± 11.7° vs 177.8 ± 9.3°; p = 0.049). Otherwise, there were no other differences in motion or strength one year after treatment. The percentage of patients with persistent bicipital groove tenderness was 15.6%, with no significant difference in frequency between the open and arthroscopic tenodesis groups.[33] Other cohort studies drew similar conclusions.[34_36]

Several retrospective cohort studies (level III) compared different techniques for open tenodesis. One comparing open subpectoral biceps tenodesis with either interference screw fixation (34 patients) or suture anchor fixation (54 patients) an average of 13 months after surgery found that both techniques offered significant pain relief and functional improvement without significant difference in these outcomes between the two methods. Additionally, there were no failures of fixation or complications with either method of fixation.[32]

Another comparing tenodesis to the rotator cuff with suture with (11 patients) and without (11 patients) resection of the intra-articular tendon found no difference in the UCLA (University of California Los Angeles) scores.[31] A third study noted more repeat surgery without release of the transverse humeral ligament during the initial tenodesis

procedure, with 20.6% of patients (n = 68) requesting subsequent surgery when the biceps sheath was not initially released compared to 6.8% of patients (n = 59) in which the sheath was released.[37]

The case series above amount to technique articles and are not otherwise detailed.

Resolution of clinical scenario

- There are no clear benefits to arthroscopic over open tenodesis, or vice versa (overall quality: low).
- In the absence of evidence in favor of one tenodesis technique over another we recommend the simplest, safest, least costly technique and we recommend that efforts be directed not at technique but rather at whether surgery is better than simulated surgery (overall quality: low).

Summary of answers

- Physical examination and imaging cannot distinguish pain from LHB tendinopathy specifically from rotator cuff tendinopathy in general.
- There are no specific nonoperative treatments. Operative treatment may not be better than simulated operative treatment.
- Surgery for an LHB rupture is largely aesthetic.
- Diagnosis and treatment of LHB should be considered experimental until better and more applicable data are produced.
- If LHB tendon fraying or subluxation is encountered at the time of arthroscopy, either tenotomy or tenodesis (arthroscopic or open) is an acceptable treatment.

127 Superior Labral Tears and Throwing Shoulder Injuries

Michael T. Freehill MD[1], Jacob M. Kirsch MD[2], Hiroyuki Sugaya MD[3], and Jon J. P. Warner MD[4]
[1] Department of Orthopaedic Surgery, Stanford University, Stanford, CA, USA
[2] Boston Sports & Shoulder Center, Waltham, MA, USA
[3] Funabashi Orthopaedic Sports Medicine Center, Funabashi, Chiba, Japan
[4] Massachusetts General Hospital, Boston, MA, USA

Clinical scenario

- A 25-year-old baseball pitcher has several months of atraumatic shoulder pain in his dominant arm.
- He has decreased throwing velocity and ability locating pitches. He also reports occasional “popping” and “clicking” in his shoulder while throwing.
- On examination, he has a positive O'Brien's, Biceps Load II and modified Dynamic Labral Shear test. Magnetic resonance arthrogram (MRA) demonstrates increased signal in the superior labrum.

Top three questions

1. In overhead throwing athletes, how reliable is the physical exam compared to imaging studies in the diagnosis of symptomatic superior labral tear anterior to posterior (SLAP) tears?
2. In overhead throwing athletes with symptomatic SLAP tears, does primary operative intervention result in

improved return to play (RTP) compared to nonoperative treatment?

3. Are overhead nonthrowing athletes better able to return to competition following surgical treatment of SLAP tears compared to overhead throwing athletes?

Question 1: In overhead throwing athletes, how reliable is the physical exam compared to imaging studies in the diagnosis of symptomatic superior labral tear anterior to posterior (SLAP) tears?

Rationale

The clinical presentation and evaluation of SLAP tears in overhead athletes can be highly variable. Physical examination and imaging studies may be inconsistent and unreliable for predictably diagnosing these injuries.

Clinical comment

Shoulder pain in the overhead throwing athlete may be difficult to isolate. Physical examination is important;[1,2] however, it has questionable utility in reliably diagnosing SLAP tears.[3–5] The role of advanced imaging may be limited by high false-positive rates reported in asymptomatic overhead athletes[6] and concomitant pathology frequently associated with SLAP tears.[7] Accurate diagnosis is paramount prior to directing any surgical or nonsurgical treatment.

Available literature and quality of the evidence

Imaging

- Level I: 1 study[8]
- Level II: 2 studies[9,10]
- Level III: 6 studies[11–16]
- Unassigned level of evidence: 1 study.[17]

Physical exam

- Level I: 1 study[18]
- Level II: 3 studies[19–21]
- Level III: 4 studies.[22–25]
- Unassigned level of evidence: 2 studies.[26,27]

Findings

We sought to evaluate the role of physical examination and advanced imaging in diagnosing SLAP tears in overhead athletes. Surprisingly, we were unable to identify a single study that exclusively evaluated solely symptomatic throwing athletes. Rather, all studies consisted of a heterogeneous population. The diagnosis of symptomatic SLAP tears in overhead athletes remains challenging given the striking inconsistency in evaluating and diagnosing SLAP tears coupled with the lack of literature evaluating exclusively overhead athletes.[1,2,28]

Among the available literature, the evidence evaluating the diagnosis of SLAP tears remains poor. Cook et al. concluded that neither a single exam in isolation nor a combination of exam findings provided any substantial value in diagnosing a SLAP tear.[18] Similar results were reported by Oh et al.[25] and Michener et al.[21] Several systematic reviews and meta-analyses have demonstrated

minimal clinical utility for physical exam findings in accurately diagnosing SLAP tears.[19,22–24,26,27]

For studies evaluating advanced imaging, several authors noted the superiority of MRA over conventional MRI for detecting SLAP tears.[9–12,15] A meta-analysis by Arirachakaran et al. evaluating over 2000 shoulders reported a sensitivity of 0.87 (95% confidence interval [CI]: 0.82–0.91), specificity of 0.92 (95% CI: 0.85–0.95) and a positive likelihood ratio of 10.28 (95% CI: 5.84–18.08) with MRA.[11] Other authors, such as Modi et al., have demonstrated improved diagnostic accuracy with abduction external rotation positioning of the arm during MRA.[14]

Resolution of clinical scenario

- Physical examination alone adds limited diagnostic value for detecting clinically relevant SLAP tears.
- Advanced imaging with MRA appears to be more reliable compared to noncontrast MRI for diagnosing SLAP tears. Positioning the arm in the abduction external rotation position may increase the diagnostic abilities of MRA.

Question 2: In overhead throwing athletes with symptomatic SLAP tears, does primary operative intervention result in improved return to play (RTP) compared to nonoperative treatment?

Rationale

Reported outcomes following operative treatment of SLAP tears are highly variable and include heterogeneous patient populations and treatment techniques.[29–31]

Clinical comment

SLAP tears can result in significant disability among overhead throwing athletes. Optimal treatment of SLAP tears in this patient population remains controversial.

Available literature and quality of the evidence

Operative

- Level III: 2 studies[32,33]
- Level IV: 5 studies.[34–38]

Nonoperative

- Level IV: 1 study.[35]

Findings

Overall, pooled RTP for an overhead athlete following operative treatment of SLAP tears was 56.5% (156/276, range 32–85%). Additionally, 7–64% of athletes were able to return to their prior performance (RTPP)/level of competition following operative intervention. Several authors evaluated RTP in baseball pitchers compared to position players.[35–37] Fedoriw et al. reported a RTP and RTPP of 48 and 7%, respectively, in professional pitchers compared to 85 and 54% respectively in position players.[35] Gilliam et al. similarly reported lower RTP in pitchers compared to position players (59% vs 83%),[36] whereas Chalmers et al. reported only 17% RTP in pitchers compared to 80% in position players.[37] Interestingly,

Gilliam et al. reported that only 41% of pitchers felt the same or better following surgical repair of their SLAP tear.[36]

Only Fedoriw et al. reported exclusively on throwers treated nonoperatively for SLAP tears.[35] Nonoperative management focused on addressing glenohumeral internal rotation deficit (GIRD) if present, scapular dyskinesis, posterior capsular contracture, and concomitant shoulder pathology. Overall, 40% of pitchers RTP and 22% RTPP with nonoperative management compared to 39% RTP and 26% RTPP in position players. Interestingly, 40% of athletes who previously failed nonoperative management were able to RTP with this specific treatment algorithm, of which 24% RTPP.

Resolution of clinical scenario

- Outcomes following operative treatment of SLAP tears in overhead throwing athletes are highly variable.
- Operative treatment of SLAP tears results in poor RTP/RTPP.
- Pitchers appear to have worse RTP/RTPP compared to position players.
- Nonoperative treatment addressing GIRD, scapular dyskinesis, and other concomitant shoulder pathology can result in similar RTP/RTPP, even among athletes that have previously failed nonoperative treatment.

Question 3: Are overhead nonthrowing athletes better able to return to competition following surgical treatment of SLAP tears compared to overhead throwing athletes?

Rationale

The demands on overhead athletes are often variable and unique to the nature of their sport. Previous reports on SLAP tears in overhead athletes often consist of a heterogeneous population, which limits interpretation for throwers and nonthrowers alike.

Clinical comment

In order to best counsel overhead athletes with SLAP tears, a better understanding of the ability to return to competition in throwers and nonthrowers is needed.

Available literature and quality of the evidence

Throwers

- Level III: 2 studies[32],[33]
- Level IV: 8 studies.[34]–[41]

Nonthrowers

- Level III: 2 studies[42],[43]
- Level IV: 5 studies.[39]–[41],[44],[45]

Findings

Overall, 57.7% (195/338) of overhead throwing athletes were able to RTP following operative treatment of SLAP tears compared to 68.5% (187/273) of overhead nonthrowing athletes. All studies of throwing athletes with the exception of two[33,35] characterized athletes as returning to the same/higher level of competition. One may argue that returning an athlete to the same preinjury level of competition is not sufficient enough, but rather assessing their ability to return to the same level of prior athletic performance may better assess the success of surgery. Smith et al. and Fedoriw et al. used specific criteria and previous seasons statistics to assess the RTPP.[33,35] The pooled RTPP from these studies is only 37.5% (24/64), compared to 62.4% (171/274) when looking at studies assessing return to the same/higher level.[32,34,36–41] Of note, all studies of nonthrowers assessed return to the same/higher level of competition without further qualitative analysis.[39–45]

Resolution of clinical scenario

- Overhead throwing athletes may have lower RTP compared to overhead nonthrowing athletes.
- Studies which quantitatively assess RTPP report significantly lower RTPP compared to those which only characterize athletes as returning to the same/higher level of competition.

Summary of answers

- Neither physical exams nor imaging studies alone are sufficient for diagnosing symptomatic SLAP tears in overhead throwing athletes.

- RTP following operative treatment of SLAP tears in overhead throwing athletes is highly variable, with pooled analysis demonstrating 56.5% RTP. There is limited data evaluating nonoperative treatment of SLAP tears in overhead throwing athletes.
- Overhead throwing athletes appear to have lower RTP compared to overhead nonthrowing athletes.
- More research is necessary to more accurately define outcome assessment in this unique patient population.

128 Ulnar Collateral Ligament Injuries of the Elbow

Frank G. J. Loeffen MD[1], Izaäk F. Kodde MD PhD[2], and Denise Eygendaal MD PhD[2,3]

[1] Department of Sports Medicine, Onze Lieve Vrouwe Gasthuis, Amsterdam, The Netherlands

[2] Department of Orthopedic Surgery, Academic Medical Center, Amsterdam, The Netherlands

[3] Amphia Hospital, Breda, The Netherlands

Clinical scenario

- A 23-year-old professional baseball pitcher presents with longstanding medial-sided pain in his right, dominant, elbow for six months.
- A “wrong” pitch two months ago has severely increased the pain, resulting in an inability to pitch.
- At physical examination an extension deficit of 10°, a positive moving valgus test and a positive milking test are found.

Top three questions

1. Is magnetic resonance arthrography (MRA) a more accurate test to diagnose ulnar collateral ligament (UCL) injury in adult athletes than conventional magnetic resonance imaging (MRI)?
2. Do UCL reconstructions performed with a docking technique result in a higher return-to-sport rate compared to the “classical” Jobe technique in athletes with UCL injury?

3. Is there any difference in pitching performance in athletes after UCL reconstruction compared to matched uninjured pitchers?

Question 1: Is magnetic resonance arthrography (MRA) a more accurate test to diagnose ulnar collateral ligament (UCL) injury in adult athletes than conventional magnetic resonance imaging (MRI)?

Rationale

It is important to distinguish complete UCL tears from partial tears and other medial elbow pathology to establish the right treatment. Recent studies suggest that MRI-based grading systems may provide diagnostic and prognostic information on the outcome of (non)operative management.[1]

Clinical comment

Athletes with UCL injury generally present with medial-sided elbow pain and valgus instability or apprehension on stress testing. However, the injury severity may vary from a simple sprain to a total rupture. Operative management is indicated in athletes with complete disruption of the UCL, but less severe types of injury may recover with conservative treatment.[1–3] Therefore, assessment of the severity of UCL injury is important in order to apply for the optimal treatment algorithm.

Recent studies suggest that MR-based classification systems for UCL injury provide information on outcome and, eventually, return-to-sports.[1] Thus, the importance of

MR may evolve from a diagnostic test toward a prognostic test. The addition of intra-articular contrast may provide additional information, but – as an invasive procedure – adds a (small) risk for complications. The question therefore is whether MRA substantially improves the diagnostic accuracy of MRI.

Available literature and quality of the evidence

- Level I: 0 randomized controlled trials (RCTs).
- Level II: 0prospective cohort studies.
- Level III: 5 retrospective cohort/case-control studies.

Findings

There are only a few comparative studies on MRI in UCL injuries in the current literature. Three studies compared MRI of UCL injury in athletes to surgical findings.[4–6] Furthermore, there were two cadaveric studies,[7,8] four studies compared MRI and arthrography,[4,5,7,8] and one study presented the results of MRA only.[6]

The aforementioned studies showed a sensitivity and specificity of MRI for UCL tears of 63–100 and 89–100%, respectively. In a study by Nakanishi et al., MRIs were interpreted as abnormal in all patients (10/10); however, the observers were not able to differentiate between a tear or scarring of the UCL.[4]

Sensitivity and specificity of MRA for UCL tears in the selected studies was 88–100 and 80–100%, respectively. Most authors concluded that conventional MRI is sufficient to detect pathology of the UCL. However, the addition of arthrography provides more information on injury severity, for example partial thickness tears of the UCL. An advantage of MRI in general, as compared to ultrasound or

computed tomography (CT) arthrography, is the ability to identify associated pathology, such as medial epicondylitis or osteochondral lesions.

Resolution of clinical scenario

- The sensitivity of MRA is superior to conventional MRI, but specificity is similar for both image modalities.
- To decrease the rate of false-negative findings with advanced imaging, MRA is recommended for the evaluation of athletes with suspicion for UCL injury. However, the addition of arthrography seems not to be necessary to prevent surgical intervention in athletes with a false-positive MR scan.

Question 2: Do UCL reconstructions performed with a docking technique result in a higher return-to-sport rate compared to the “classical” Jobe technique in athletes with UCL injury?

Rationale

Frank Jobe performed the first ulnar collateral ligament reconstruction (UCLR) in 1974, with his figure-of-eight technique.[9] Many other techniques have been described since then. The importance is to identify which frequently performed technique results in the best outcome for the athlete.

Clinical comment

For (professional) athletes, the most important outcome after UCL injury is return to previous level of play. The two

most frequently reported UCLR techniques are the Jobe technique and the docking technique (including modifications).[9],[10] Therefore, we will further evaluate the rate of return to previous level of sport for these two techniques.

Available literature and quality of the evidence

- Level I: 6 randomized controlled trials.
- Level II:0 prospective cohort studies.
- Level III:0 retrospective cohort/case-control studies.
- Level IV:16 case series.

Findings

Last three decades, numerous surgical techniques for reconstruction of the UCL have been described. The majority of studies are from the US, focusing on the surgical treatment of UCL injuries in baseball pitchers. The most commonly used graft is a palmaris longus or hamstring autograft. Some recent studies have described the use of cortical buttons and interference screws, but the two traditional UCLR techniques – the Jobe and docking technique – used bone tunnels and sutures for graft fixation.[9],[10] The original Jobe technique involved a figure-of-eight reconstruction in which the graft was passed through bone tunnels in the ulna and humerus and sutured to itself. Furthermore, Jobe detached the flexor pronator mass and performed an ulnar nerve transposition. Modifications of this technique include a flexor muscle splitting approach, alternative handling of the ulnar nerve, and the addition of elbow arthroscopy.

The original docking technique involved a triangular reconstruction in which the graft was passed through a bone tunnel in the ulna and humerus and then sutured over

a bony bridge on the posterior side of the humerus. The authors used a muscle splitting approach, routinely performed an elbow arthroscopy and transposed the ulnar nerve only when there were clinical symptoms. Modifications on the docking technique included the addition of elbow arthroscopy on indication (posteromedial impingement) and the use of triple-stranded grafts.

Three systematic reviews concluded that the outcomes of the docking technique were superior compared to the Jobe technique.[11–13] One original research article described the results of both the docking and (modified) Jobe technique,[14] seven articles described the outcome of the docking technique,[10,15–20] and eight articles focused on the outcomes of the (modified) Jobe technique.[9,21–27] Combined, a total of 278 patients underwent UCLR using a docking technique. After a mean of 35 months, 90% of patients returned to their previous level of sport, and 6% of patients endured a complication. The (modified) Jobe technique is described in a total of 1082 patients. On average, 82% of patients returned to their previous level of play after 42 months, and 18% of patients endured a complication.

The (modified) docking technique appears to result in superior outcomes compared to the (modified) Jobe technique. However, the results of the (modified) Jobe technique are based on more patients, with a slightly longer follow-up. Moreover, five out of eight articles on the (modified) docking technique were from the institution of the original developer of the technique (Dr. David Altchek). In conclusion, many articles have been published on UCLR, but there is a need for an RCT to adequately compare the different techniques and acquire a high level of evidence to answer this question.

Resolution of clinical scenario

- The return to previous level of play after UCLR according to the (modified) docking technique is 90% and therefore superior to the (modified) Jobe technique with 82%.
- More complications are seen after the (modified) Jobe technique (18%) compared to the (modified) docking technique (6%).
- A possible source of bias in current literature is the high number of studies performed by or at the institutions of the original inventors of the surgical techniques.

Question 3: Is there any difference in pitching performance in athletes after UCL reconstruction compared to matched uninjured pitchers?

Rationale

UCLR allows most overhead athletes to return to sports. However, the number of athletes who truly return to their preinjury level of performance is unclear.

Clinical comment

Over the past decade, the number of UCLRs has significantly increased, especially in adolescent overhead athletes.[28] The public perception of UCLR is positive, with up to 42% of athletes, 20% of coaches, and 35% of parents believing that UCLR leads to enhanced pitching performance beyond that of the preinjury level.[29] Traditionally, surgical outcomes in sports medicine are

measured in conventional terms, such as return to play or (semiquantitative) patient-reported assessments.

Most studies reported return to play rates >80% following UCLR.[30] However, there is no standard to determine whether an athlete has truly successfully returned to play. The abundance of performance metrics in baseball allows us to assess outcomes after UCLR independent of subjective symptoms or return-to-play rates. These metrics may better demonstrate the true number of athletes who returned to their previous level of play, especially when compared to preinjury levels or matched uninjured control athletes.

Available literature and quality of the evidence

- Level I: 0 randomized controlled trials.
- Level II: 0 prospective cohort studies.
- Level III: 8 retrospective cohort/case-control studies.
- Level IV: 2 case series.

Findings

In total, 10 studies evaluated pitching performance after UCLR.[31–40] One study in 178 Major League Baseball (MLB) pitchers reported improved performance postoperatively.[31] Both *earned run average* (ERA) and *walks plus hits per inning pitched* (WHIP) were lower than before UCLR and lower compared with matched controls. Five other studies found no significant differences in common performance metrics between pitchers after UCLR and controls.[32–36] As expected, the average number of innings pitched in the first season after reconstruction was significantly lower in the surgical group compared to the healthy controls, reflecting the long duration of rehabilitation after UCLR.[33]

However, the mean number of innings pitched was similar between the two groups in the second and third season after UCLR. In addition, other key performance measures, including ERA, WHIP, pitch selection, velocity, and accuracy, also returned to preinjury levels and were comparable to matched uninjured pitchers.[33–36] Fleisig et al. compared the biomechanics of 40 professional pitchers after UCLR with 40 matched uninjured pitchers.[32] They observed no significant differences in shoulder and elbow range of motion and no significant differences in pitching kinetics.

Four studies found a decline in pitching performance after UCLR,[37–40] although these declines were not statistically different from the decline in pitching performance observed in uninjured controls in two of the four studies.[37,40] In other words, postoperative performance was similar to that of pair-matched peers who did not undergo UCLR. More specific, one study found a small, but statistically significant, decrease in fastball velocity following UCLR (mean: −0.7 mph), but did not compare this to a healthy control group.[39] The clinical relevance of this observed decrease in fastball velocity is unclear. Pitch velocity for other pitch types did not change significantly after surgery. Keller et al. evaluated performance data of 168 MLB pitcher who had undergone UCLR (averaged over three years before and after surgery) and that of 178 age-matched uninjured MLB pitchers.[38] Compared to presurgical data, pitching performance after UCLR significantly declined in terms of innings pitched, WHIP, and ERA. The control pitchers had a significant higher winner percentage than the UCLR pitchers in the first and third after surgery. All other performance metrics after surgery were similar between the cohorts. Most performance metrics were significantly higher before surgery in the UCLR pitchers than in the controls. This

suggest that most pitchers who underwent UCLR make it back to acceptable levels (i.e. comparable to uninjured controls) but do not fully return to their preinjury level of performance. More recent, novel pitching performance measures, such as f*ielding independent pitching*, that are largely independent from teammate performance may further increase our ability to assess the true functioning of pitchers after UCLR.

Resolution of clinical scenario

- Contrary to popular belief, pitching performance does *not* increase after UCLR.
- Most (professional) pitchers return to performance levels similar to that of matched uninjured controls after UCLR.

Summary of answers

- The sensitivity of MRA is superior to conventional MRI, but specificity is similar for both image modalities.
- To decrease the rate of false-negative findings with advanced imaging, MRA is recommended for the evaluation of athletes with suspicion for UCL injury. However, the addition of arthrography seems not to be necessary to prevent surgical intervention in athletes with a false-positive MR scan.
- The return to previous level of play after UCLR according to the (modified) docking technique is 90% and therefore superior to the (modified) Jobe technique with 82%.
- More complications are seen after the (modified) Jobe technique (18%) compared to the (modified) docking technique (6%).

- A possible source of bias in current literature is the high number of studies performed by or at the institutions of the original inventors of the surgical techniques.
- Contrary to popular belief, pitching performance does *not* increase after UCLR
- Most (professional) pitchers return to performance levels similar to that of matched uninjured controls after UCLR.

129 Lateral Epicondylitis (Tennis Elbow)

Neeru Jayanthi MD[1]
Emory Healthcare, Johns Creek, GA, USA

Clinical scenario

- A 45-year-old right-hand-dominant woman who is a recreational tennis player can no longer play.
- She comes to your practice with complaints of pain at the lateral side of her right elbow. The pain has been present for three months, and is worse while hitting a backhand.
- At physical examination she has pain with pressure on the origin of the common extensor tendon of the wrist at the lateral epicondyle of the humerus. There is mild wrist extension weakness with the elbow in full extension.

Top three questions

1. In adult patients with lateral epicondylitis, does advanced imaging result in improved diagnosis compared with clinical exam with or without radiography?
2. In adult patients with lateral epicondylitis, does conservative management result in improved pain and function compared to therapy with injections?
3. In adult patients with lateral epicondylitis, does surgery result in improved pain and function compared to nonoperative treatments?

Question 1: In adult patients with lateral epicondylitis, does advanced imaging result in improved diagnosis compared with clinical exam with or without radiography?

Rationale

It is important to know if diagnostic imaging is necessary or worthwhile for patients with a clinical presentation consistent with lateral epicondylitis. If imaging is warranted, we need to know if ultrasound findings are comparable to MRI results. Furthermore, with the ease of use and cost-effectiveness of musculoskeletal ultrasound, we may be able to better diagnose the stage of epicondylitis initially which can influence clinical decision-making.

Clinical comment

Generally, radiography is often unnecessary for the initial diagnosis and treatment of lateral epicondylitis. However, it is reasonable to obtain a standard three-view plain radiograph if symptoms persist after initial management. This should include an axial view if there is posterior pain to evaluate for posterior osteophytes and calcifications within the tendon.[1]Advanced diagnostic imaging has typically been reserved for cases resistant to conservative treatment. Magnetic resonance imaging (MRI) and ultrasonography (US) have been used to evaluate the extent of disease, detect associated pathological processes, exclude other primary sources of elbow pain, and quantify the degree of tendon injury in lateral epicondylitis.[2–7]

Available literature and quality of the evidence

- Overall, there is little high-quality evidence regarding the role of imaging studies in management plans and detection of lateral epicondylitis. Advanced imaging for this problem is primarily limited to MRI and US. Apart from the reviews discussed below, there are a number of studies addressing MRI and ultrasound imaging for lateral epicondylitis with data quality ranging from level II to level VI.
- There are a multitude of systematic reviews regarding MRI of the elbow. However, none of these reviews is focused solely on MRI in the evaluation of lateral epicondylitis. MRI can be regarded as the gold standard of advanced imaging; however, due to cost and availability, MRI cannot be considered a screening tool for all patients with clinically suspected lateral epicondylitis.
- There are two systematic reviews addressing US and lateral epicondylitis. Both indicate that there is evidence to support the use of ultrasound in the detection of lateral epicondylitis.[8],[9] Latham and colleagues warn that its accuracy is highly dependent on numerous variables such as operator experience, quality of equipment, and extent of pathology. However, Dones et al. determined that US is recommended to objectively diagnose lateral epicondylitis.[9] Furthermore, ultrasound allows localization of pathology, which can assist in the design of treatment plans.

Findings

Magnetic resonance imaging

Qi et al. evaluated the MRI findings and clinical symptoms in 96 patients with lateral epicondylitis. They determined

that MRI is a valid tool in assessing the clinical severity of lateral epicondylitis with a significant positive correlation (Pearson's r = 0.920, p <0.01) between MRI results and clinical symptoms.[10]

Similarly, Jeon and colleagues compared MRI findings in 60 patients with lateral epicondylitis treated conservatively or with surgery. MRI-assessed common extensor tendon abnormalities, muscle edema, pain frequency, and pain intensity differed significantly between the two groups (p <0.05) with increased severity in operative group. Persistent pain (odds ratio [OR] = 12.2, p <0.01), common extensor tendon abnormality (OR = 7.5, p = 0.03 for grade 2; OR = 22.4, p <0.01 for grade 3), and muscle edema (OR = 6.7, p = 0.03) were major factors associated with operative treatment.[11] Therefore, MRI findings combined with clinical assessment could better facilitate appropriate operative management planning for patients with lateral epicondylitis as opposed to clinical exam alone.[11]

Conversely, although Walton et al. confirmed the findings of previous studies that the majority of patients with a clinical diagnosis of chronic lateral epicondylitis have signal changes on MRI, they found no statistically significant correlation between the grade of tendinosis and any clinical symptoms (QuickDASH, p 0.496; UEFS, p = 0.970; maximum pain, p = 0.491; grip strength, p = 0.465).[4,6,12–14] Therefore, they conclude that this is further evidence that the role of MRI is not to confirm a diagnosis of lateral epicondylitis, which can be accomplished by the gold standard of clinical examination.[14]

Ultrasound

Levin et al. reported that sensitivities of US in the detection of symptomatic lateral epicondylitis ranged from 72 to 88% and specificities from 36 to 48.5%. Odds ratios between

symptoms and US findings were statistically significant ($p < 0.05$) for calcification of common extensor tendon, tendon thickening, adjacent bone irregularity, focal hypoechoic regions, diffuse heterogeneity, and lateral epicondyle enthesophytes. These findings indicate that US has a high sensitivity but low specificity in the detection of symptomatic lateral epicondylitis and that the relationship between ultrasound findings and symptoms is significant.[15]

Similarly, Clarke and colleagues used ultrasound to evaluate 62 patients with a clinical diagnosis of lateral epicondylitis. A positive correlation was identified between the presence of a lateral collateral ligament tear ($p < 0001$) and the size of the largest intra-substance tear ($p < 0001$) and poor outcome. Patients with these findings were less likely to respond to conservative treatment. Therefore, the identification and size of intra-substance tears and presence of a lateral collateral ligament tear on ultrasound can be used to assess lateral elbow tendinopathy severity, indicate those who may not respond to conservative therapy, and potentially guide more invasive treatment.[16]

Regarding the use of power Doppler, du Toit et al. conducted a cross-sectional study to determine the diagnostic accuracy of ultrasound with power Doppler for tennis elbow. Thirty-two affected elbows and 56 unaffected elbows were evaluated. Power Doppler had a strong positive likelihood ratio of 45.39, whereas a combined negative finding in power Doppler and grayscale US resulted in a robust negative likelihood ratio of 0.05. These findings indicate significant diagnostic accuracy of power Doppler US for ruling in lateral epicondylitis, whereas the absence of tendon neovascularity and grayscale ultrasound changes should raise the question of an alternative cause for lateral elbow pain.[17]

In their review, Latham and colleagues[8] reported that the majority of the papers reviewed concluded that the use of ultrasound was beneficial to assist with the detection of lateral epicondylitis.[17–22] Amongst these, sensitivity ranged from 76.5 to 100% and specificity from 76.2 to 100%. However, the use of ultrasound in the detection of lateral epicondylitis is recommended with caution since its accuracy appears to be highly dependent on numerous variables, such as operator experience, quality of equipment, and extent of disease.[8]

In their review of 15 previous studies, Dones et al. concluded that the use of grayscale US is recommended in objectively diagnosing lateral epicondylitis. The presence of hypoechogenicity and bone changes indicates the presence of a stressed common extensor origin-lateral epicondyle complex. In addition to diagnosis, detection of these abnormal ultrasound findings allows localization of pathologies to the tendon or bone that would assist in designing an appropriate treatment suited to a patient's condition.[9]

Magnetic resonance imaging versus ultrasound

Bachta and colleagues found good sensitivity (64.52%), accuracy (72.73%), and very good specificity (85.19%) with US (vs MRI) in detecting common extensor tendon pathology. All patients with high-grade common extensor tendon tear on US had confirmed tear on MRI. No patient without common extensor tendon tear on US had high-grade common extensor tendon tear on MRI. Thus, high-grade tear on US can be considered a reliable equivalent of confirmed tear on MRI. On the other hand, lack of evident tear on US virtually excludes the presence of high-grade common extensor tendon tear.[23] These results are in agreement with several other previous studies showing US

as a reliable method to evaluate tendinoligamentous structures of the lateral elbow region and the results of an US assessment are comparable to those of MRI.[24–26] Determination of high-grade common extensor tendon pathology with imaging is important in predicting disease outcome and may be helpful in determining optimal treatment strategy, as Clarke et al. suggested a lower threshold for surgery in patients with high-grade tears.[16]

Resolution of clinical scenario

- Advanced imaging is often unnecessary for the initial diagnosis and treatment of lateral epicondylitis. Prior to advanced imaging, we may obtain a standard three-view elbow x-ray series, which should include an axial view to evaluate for posterior osteophytes and calcifications within the tendons. MRI and US have been used to evaluate the extent of disease, exclude other primary sources of elbow pain, and quantify the degree of tendon injury (overall quality: moderate).
- US is reliable in confirming the diagnosis of lateral epicondylitis. Lack of pathology on US in chronic cases can reliably exclude the presence of lateral epicondylitis. In experienced hands, ultrasound can identify abnormal tendon appearance and neovascularity when color flow Doppler is used. Current evidence emphasizes the advantages of the noninvasive, cheap, quick, and accessible nature of diagnostic ultrasound compared to MRI or arthroscopy. Nonetheless, ultrasound requires extensive skill and experience to operate effectively (overall quality: low).
- MRI is beneficial in recalcitrant cases to localize lesions, to confirm the diagnosis of lateral epicondylitis, or to particularly aid in surgical planning (overall quality: low).

- Identified pathology with ultrasound can be considered equivalent to pathology identified on MRI given an experienced ultrasound practitioner (overall quality: low).
- Data are mixed as to whether MRI or US findings correlate with clinical symptoms (overall quality: low).

Question 2: In adult patients with lateral epicondylitis, does conservative management result in improved pain and function compared to therapy with injections?

Rationale

Once diagnosed, it is important to know the best treatment strategy for the condition and what the effectiveness of a certain treatment will be compared to other treatments. Treatment strategy will vary for each patient, depending on prior therapies, degree of disability, and activity goals.

Clinical comment

Generally, initial treatment of lateral epicondylitis is conservative including activity modification, nonsteroidal anti-inflammatory drugs (NSAIDs), bracing, and physical therapy with eccentric exercises. However, many patients present seeking rapid improvement in symptoms, and clinicians are frequently asked about the use of injections, including glucocorticoid injections and treatments under study such as ultrasound-guided percutaneous tenotomy and platelet-rich plasma (PRP) injections.

Available literature and quality of the evidence

- When approaching lateral epicondylitis, there are a number of different treatment options. Several systematic reviews and meta-analyses (level II, therapeutic) have analyzed these different nonsurgical treatment options without any high-quality evidence to support a specific treatment strategy.[27,28]
- When assessing the efficacy of glucocorticoid injections, three systematic reviews (level II, therapeutic) reviewing glucocorticoid injections all came to the same conclusion, glucocorticoid injections are effective in the short term but may have diminishing or negative effects in the intermediate and long term.[29] Two of these reviews compared glucocorticoid injections to physical therapy and found that physical therapy was more effective at intermediate- and long-term follow-up.[30,31]
- There has been growing interest in the use of PRP for tendinopathy, although the lack of high-quality evidence has deemed its use controversial. There are systematic reviews that demonstrate efficacy with the use of PRP in lateral epicondylitis (level II, therapeutic),[32] while others have not demonstrated significant benefit (level II, therapeutic).[33] One of the largest randomized controlled trials (RCTs) (level II, therapeutic) of patients with lateral epicondylitis treated with PRP demonstrated significant differences in pain in the PRP group at 24 weeks.[34]
- Lastly, needle tenotomy has been suggested as a technique for recalcitrant lateral epicondylitis to augment or supersede PRP injections. There are no high-level studies, but observational uncontrolled data (level IV, therapeutic) demonstrate encouraging results.[35,36]

Findings

Nonsurgical treatment versus no treatment

A systematic review of 58 RCTs of patients with lateral epicondylitis treated with nonsurgical techniques demonstrated that best evidence synthesis found no conclusive evidence of one preferred treatment method.[28] Another meta-analysis of 22 RCTs containing 2280 patients reviewing any form of nonsurgical treatment with either observation only or placebo at follow-up for at least six months demonstrated no significant difference between nonsurgical treatment versus no treatment in regards to overall improvement (risk ratio [RR] = 1.05; 95% confidence interval [CI]: 0.96–1.15), need for escape treatment (RR = 1.50; 95% CI: 0.84–2.70), DASH (Disabilities of the Arm, Shoulder, and Hand) scores (mean difference [MD]: −2.69; 95% CI: −15.8 to 10.4), overall function using change-from-baseline data (standardized mean difference [SMD]: 0.11; 95% CI: −0.14 to 0.36), maximum grip strength using change-from-baseline data (SMD: 0.12; 95% CI: −0.11 to 0.35), and pain-free grip strength using change-from-baseline data (SMD: −0.20; 95% CI: −0.84 to 0.43).[27] While the aggregation of multiple nonsurgical treatments allowed the possibility of less effective treatments countering those that are more effective and the author cautioned that certain nonsurgical treatments may be more effective than others, this meta-analysis concluded that watchful waiting may be a practical alternative to nonsurgical treatments.

When evaluating individual treatment strategies, a meta-analysis of 12 RCTs in patients with lateral epicondylitis treated with physical therapy demonstrated that, compared with sham control groups, physical therapy resulted in a significant decrease in pain (SMD: −7.50; 95% CI: −14.94 to −0.07) and significant increase in handgrip strength

(SMD: 3.47; 95% CI: 0.17–6.76).[37] Another systematic review of 12 RCTs and one systematic review evaluated patients with lateral epicondylitis treated with physical therapy.[38] Best-evidence synthesis demonstrated evidence for short-term effectiveness of strengthening. Lastly, a systematic review of 12 studies (eight RCTs and four controlled clinical trials) of 616 participants with lateral epicondylitis treated with eccentric exercise performed best-evidence synthesis and determined that an eccentric exercise program resulted in decreased pain and improved function and grip strength in comparison to baseline measures.[39]

Glucocorticoid injection versus physiotherapy

A systematic review of 13 RCTs of patients with lateral epicondylitis treated with glucocorticoid injection has been reported.[29] All studies reported statistically significant short-term ($\leq$6 weeks) results in favor of glucocorticoid injections. None of the studies that performed intermediate (six weeks to six months) or long-term ($\geq$6 months) outcome assessments found statistically significant results in favor of corticosteroid injections.

A systematic review of 11 RCTs including 1161 patients with lateral epicondylitis comparing glucocorticoid injection versus nonelectrotherapeutic physiotherapy (stretching, mobilization, manipulation, massage, exercise, or home training) has been reported.[30] In short-term follow-up, glucocorticoid injection significantly reduced pain compared to NSAIDs or no intervention (SMD: −1.43; 95% CI: −1.64 to −1.23). At intermediate follow-up; however, glucocorticoid injections demonstrated increased pain (SMD: 0.32; 95% CI: 0.13–0.51), reduction in grip strength (SMD: −0.48; 95% CI: −0.73 to −0.24) and a negative effect on the overall improvement effect (RR =

0.66; 95% CI: 0.53–0.81). Manipulation and exercise versus no intervention demonstrated beneficial overall improvement at short-term follow-up (RR = 2.75; 95% CI: 1.30–5.82) but no significant improvement at intermediate- or long-term follow-up. Eccentric exercise and stretching demonstrated moderate evidence at short- and long-term follow-up.

A systematic review of five RCTs of patients with lateral epicondylitis treated with corticosteroid injection versus physiotherapeutic interventions demonstrated large effect sizes in favor of corticosteroids at short-term follow-up, but medium- to large-effect sizes in favor of physiotherapeutic interventions at intermediate- and long-term follow-up.[31]

Advanced treatment options: platelet-rich plasma and percutaneous needle tenotomy

When assessing all injections, one systematic review of 27 RCTs of patients with lateral epicondylitis treated with injection therapies found that most injection treatments showed a trend toward better effects than placebo.[40] The review could not recommend one injection over the other, though the article mentioned that the benefits of glucocorticoid injection were only short-term, thus the author would recommend other injections over glucocorticoid injections. Another systematic review of 17 RCTs of 1381 patients with lateral epicondylitis treated with injection therapies demonstrated that botulinum toxin, autologous blood, PRP, prolotherapy, and hyaluronic acid were all statistically superior to placebo.[41]

PRP continues to generate controversy. A systematic review of four RCTs of patients with lateral epicondylitis treated with PRP demonstrated improvements in pain and disability at 6 and 12 months in two of the four studies.[32] Another systematic review of six RCTs of patients with

lateral epicondylitis treated with PRP used best-evidence synthesis to determine that there is strong evidence that PRP injections are not efficacious in chronic lateral epicondylar tendinopathy.[33] However, these systematic reviews are limited by heterogeneity, and studies with small sample sizes and high risk of bias. One point of contention has been short duration of follow-up in many studies, as the effects of PRP may take up to six months to take effect. One of the largest RCTs,[34] a double-blind, prospective, multicenter RCT of 230 patients with lateral epicondylitis who had failed either a local steroid injection, physical therapy, or NSAIDs of PRP versus bupivacaine (control) demonstrated no significant differences between the PRP and control group at 12 weeks but significant differences in pain (29.1% in PRP group vs 54.0% in the control group, p = 0.009) and success rates (83.9% in PRP group vs 68.3% in the control group, p = 0.37) at 24 weeks.

Needle tenotomy has been suggested as a technique for recalcitrant lateral epicondylitis to augment or supersede PRP injections. There are no high-level studies, but an observational case series of 55 patients with recalcitrant lateral epicondylitis treated by percutaneous tenotomy reported that 80% of patients reported good to excellent outcomes at average follow-up of 28 months.[35] Another observational case series of 20 patients with lateral epicondylitis treated with percutaneous needle tenotomy demonstrated 100% patient satisfaction with sustained pain relief and functional improvement at three-year follow-up.[36]

Resolution of clinical scenario

- Initial treatment of lateral epicondylitis is conservative consisting of a combination of activity modification, NSAIDs, bracing, and physical therapy with eccentric exercises (overall quality: low).

- Patients who do not improve after initial conservative treatments can continue conservative treatment or be treated with more invasive nonsurgical treatments, including glucocorticoid injection, ultrasound-guided percutaneous tenotomy, and PRP injection (overall quality: low).
- Glucocorticoid injections may be effective at improving pain in the short term (<6 weeks) but have diminishing and possibly negative effects in the intermediate and long term (overall quality: low).
- Although treatment with ultrasound-guided percutaneous tenotomy and PRP injections is conflicting, multiple studies have demonstrated success with these interventions in patients with recalcitrant lateral epicondylitis (overall quality: very low).

Question 3: In adult patients with lateral epicondylitis, does surgery result in improved pain and function compared to nonoperative treatments?

Rationale

Patients with lateral epicondylitis can be frustrated by slow improvement or failure to respond to conservative treatments. It is important to know when, if ever, a surgical referral should be placed, and the effectiveness of surgical therapy compared to nonoperative treatments.

Clinical comment

The majority (90%) of patients with lateral epicondylitis can be managed with nonoperative treatments. However,

surgical referral may be considered for patients who do not respond to at least six months of nonoperative treatment with continued severe pain or dysfunction.

Available literature and quality of the evidence

- There are not many studies that address surgical management of lateral epicondylitis. A Cochrane systematic review (level II, therapeutic) deemed that there was insufficient evidence to support or refute the efficacy of surgery for lateral epicondylitis.[42] A recent systematic review (level II, therapeutic) concluded that surgery for lateral epicondylitis was no more effective than nonsurgical treatment.[43] Comparing newer treatment modalities to surgery, a retrospective review (level IV) of patients with lateral epicondylitis treated with either PRP or surgery demonstrated similar outcomes in pain and return to work.[44] An RCT (level II) of patients with chronic lateral epicondylitis who received arthroscopic release or PRP injection demonstrated effective short- and medium-term results in pain and function; however, patients in the arthroscopy group had better long-term outcomes in pain and grip strength.[45]
- Regarding the different types of surgical procedures, two systematic reviews compared open, arthroscopic and percutaneous surgical techniques for treating lateral epicondylitis.[46],[47] One of these systematic reviews (level IV) reported improved functional outcomes with open and arthroscopic surgery, but less pain with arthroscopic and percutaneous techniques.[46] The other (level II) reported no clinically significant differences between the three techniques.[47]

Findings

Surgical treatment versus nonoperative treatments

- A Cochrane systematic review analyzing five trials of 191 patients with lateral epicondylitis who failed conservative treatment and had persistent symptoms of at least five months' duration found insufficient evidence to support or refute the efficacy of surgery given the small number of studies and large heterogeneity across the trials.[42] A more recent systematic review of 12 RCTs of 490 patients with lateral epicondylitis treated with surgery performed a best-evidence analysis and determined that surgery for lateral epicondylitis was no more effective than nonsurgical treatment or sham interventions.[43]
- A retrospective review of 78 patients with lateral epicondylitis treated with either PRP (n = 28) or surgery (n = 50) demonstrated similar outcomes in pain and return to work.[44] One hundred percent of the PRP group and 98% of the surgical group tried conservative therapy prior to intervention. No statistical difference in measured outcomes was found in regards to pain improvement (89.3% vs 84%), numbness, paresthesias, and weakness with gripping ($p > 0.05$). No significant difference was found on tenderness to palpation or pain with wrist extension following intervention between the two groups ($p > 0.05$), or return to full activity (82% vs 82%, $p > 0.05$). An RCT of patients with chronic lateral epicondylitis who received arthroscopic release (n = 50) or ultrasound-guided PRP injection (n = 51) demonstrated similar improvements in pain and function scores between groups at short- and medium-term follow-up, but at week 104 the arthroscopy group had significant decrease in pain scores (2.1 vs 7.1, $p = 0.0021$),

improvements in grip strength (p <0.001), and functional evaluation (p = 0.0013) compared to PRP.[45]

- Three different types of surgical procedures have been described: open, arthroscopic, and percutaneous. One systematic review of 30 level III and IV studies of patients with lateral epicondylitis who underwent surgery evaluated patients who underwent open (n = 848), arthroscopic (n = 578), and percutaneous (n = 178) releases.[46] Functional outcomes measured with the mean DASH scores were better with open (19.9 vs 29, p <0.001) and arthroscopic techniques (21.3 vs 29, p<0.001) compared to percutaneous release. Less pain was reported in the arthroscopic (1.9 vs 1.3, p <0.0001) and percutaneous (1.4 vs 1.3, p <0.0001) groups compared to open. Another systematic review of six RCTs of patients with lateral epicondylitis compared patients who underwent open (n = 83), arthroscopic (n = 14), and percutaneous (n = 82) surgeries.[47] There were no significant differences between the three techniques in regards to functional outcome, pain intensity, and patient satisfaction at one-year follow-up.

Resolution of clinical scenario

- There is not enough high-level evidence to recommend for or against surgery for recalcitrant lateral epicondylitis; however, surgical referral may be considered for patients who do not respond to at least six months of nonoperative treatment with continued severe pain or dysfunction (overall quality: very low).
- When considering surgery, it is reasonable to consider PRP injection, as low-quality evidence demonstrates similar outcomes compared to surgery (overall quality: very low).

- If the decision is made to pursue surgery, there is not enough high-level evidence favoring one type of surgical technique, though low-quality evidence suggests possible improved functional outcomes with open and arthroscopic techniques (overall quality: very low).

Summary of answers

- Advanced imaging is often unnecessary for the initial diagnosis and treatment of lateral epicondylitis.
- Initial treatment of lateral epicondylitis is conservative consisting of a combination of activity modification, NSAIDs, bracing, and physical therapy with eccentric exercises.
- There is not enough high-level evidence to recommend for or against surgery for recalcitrant lateral epicondylitis.
- If the decision is made to pursue surgery, there is not enough high-level evidence favoring one type of surgical technique.

130 Osteochondritis Dissecans Lesions of the Elbow

Matthew Smith MD[1] and Mitchel Obey MD[2]
[1] Department of Orthopaedic Surgery, University of Missouri, Columbia, MO, USA
[2] Department of Orthopaedic Surgery, Washington University, St. Louis, MO, USA

Clinical scenario

- A 14-year-old with posterior lateral elbow pain for over one year.
- The pain is sharp during loading of the elbow with throwing, and with axial loading with the elbow in extension.
- Plain radiographs show radiolucency in the capitellum and magnetic resonance imaging (MRI) shows a 1 × 1.2 cm capitellar osteochondral defect.

Top three questions

1. In patients with osteochondritis dissecans (OCD) of the capitellum, are outcomes with nonoperative treatment better in patients with an open capitellar physis compared to patients with a closed capitellar physis?
2. In patients with a clinically and radiographically unstable capitellar OCD, are clinical outcomes better after surgical debridement in patients with small defects compared to patients with large defects?

3. In patients with a clinically and radiographically unstable capitellar OCD, does osteochondral autograft transfer result in superior outcomes compared to debridement for pain and return to sport?

Question 1: In patients with osteochondritis dissecans (OCD) of the capitellum, are outcomes with nonoperative treatment better in patients with an open capitellar physis compared to patients with a closed capitellar physis?

Rationale

Nonoperative management is considered the first step in the treatment of patients with a clinically and radiographically stable OCD lesion of the humeral capitellum; however, studies suggest differences in outcomes and healing related to skeletal maturity of the capitellum.

Clinical comment

Although nonoperative management is commonly the first step in the treatment of many osteochondral injuries, not all patients are appropriate candidates for nonoperative treatment. It is important to understand and identify which patients can be considered good candidates for nonsurgical management and which patients have a higher likelihood of needing surgical treatment.

Available literature and quality of the evidence

- The literature reviewed and summarized to address the clinical question above includes level III retrospective cohort studies and level IV case series studies.

Findings

Early studies on nonoperative management of elbow OCD lesions reported generally poor outcomes.[1–3] Takahara et al. reported 50% of patients had residual symptoms in their elbow with daily activity and displayed radiographic evidence of degenerative changes, and no patients returned to previous sport.[2] In subsequent studies, outcomes with nonoperative treatment have been stratified by radiographic and clinical findings at presentation.[4,5] Takahara et al. and Mihara et al. characterized a lesion as "stable" if patients had an open capitellar physis, flattening or radiolucency of the subchondral bone, and normal elbow range of motion.[4,5] A radiographically "early" defect was considered grade I (localized flattening or radiolucency without sclerosis) or grade II (nondisplaced fragment with sclerosis). A radiographically "advanced" defect showed grade III (displaced or detached fragment) changes.[4,5] Early stable lesions in skeletally immature patients often heal with nonoperative management;[4,5] therefore, a trial of nonoperative management was indicated in these patients. Nonoperative treatment typically included activity restriction, a brief period of immobilization, oral nonsteroidal anti-inflammatory drugs (NSAIDs), and physical therapy exercises.[4–6] Currently, no universal guidelines exist on duration of nonoperative treatment, but rather it is guided by symptoms. Generally, it involves six weeks of strict rest from activities that cause pain, with a gradual return to activity and sport over a three- to six-month period.[6,7]

While patients with early stable lesions often healed with rest alone, more advanced defects and defects in patients with a closed capitellar physis are at higher risk of failure with nonsurgical treatment.[4,5] In general, patients with a closed physis typically have more advanced OCD lesions at presentation.[5] Mihara et al. reported significantly higher healing rates after nonoperative management in patients with early-stage OCD lesions and an open physis when compared to patients with a more advanced OCD and a closed physis. They were unable to demonstrate a statistical difference in healing rates between early-stage OCD lesions between patients with open versus closed physes, but the number of patients was small.[5] In other reports, the healing rate with nonoperative management in patients with closed growth plates and unstable, advanced lesions has been low.[3,5,6,8,9] Therefore, patients with an open capitellar physis and stable OCD lesions have greater healing potential with nonoperative management than patients with advanced OCD lesions with a closed physis.

Resolution of clinical scenario

- Outcomes of nonoperative management in patients with capitellar OCD lesions depend on the combination of the skeletal maturity of the capitellar physis, the radiographic grading of the defect, and the clinical stability of the defect.
- Better outcomes after nonoperative management are seen in patients with early lesions with open capitellar growth plates, localized flattening or radiolucency of the subchondral bone, and good elbow range of motion.
- Poor outcomes after nonoperative management are seen in patients with unstable, radiographically advanced lesions, and a closed capitellar physis.

Question 2: In patients with a clinically and radiographically unstable capitellar OCD, are clinical outcomes better after surgical debridement in patients with small defects compared to patients with large defects?

Rationale

There have been several surgical treatments (i.e. fixation, debridement) described for unstable OCD lesions in the elbow. Debridement of the defect has shown good short-term results, but larger defects may not do as well with debridement.

Clinical comment

Studies suggest that lesion stability, size, and location are important factors to consider when selecting the most appropriate form of treatment. Debridement procedures are a commonly considered treatment in patients with small, unstable OCD lesions, and in patients with stable lesions who have failed a nonoperative therapy. With advances in arthroscopic technique, debridement has become a mainstay of treatment in patients with unstable lesions and those refractory to nonoperative management.

Available literature and quality of the evidence

- The literature reviewed and summarized to address the clinical question above includes level III retrospective cohort studies and level IV case series studies.

Findings

Takahara et al. classified OCD lesions as unstable if they were associated with closed growth plates, radiographic fragmentation, or restricted elbow range of motion ≥20° at the time of diagnosis.[4] Surgical intervention is generally recommended in patients with unstable lesions, in addition to those refractory to nonoperative treatment.[10],[11] Many different surgical techniques have been described for treatment of OCD lesions in the elbow. They include lesion debridement (open vs arthroscopic), bone marrow stimulation (drilling vs microfracture), fragment fixation, and removal of loose bodies. In general, arthroscopic debridement is the mainstay of surgical treatment in patients when fragment fixation is not possible.

Previous studies have reported outcomes in short- to medium-term follow-up after arthroscopic debridement, and the results have been good.[12–19] In a study by Mihara et al., 25 of 27 patients returned to baseball at near or full previous performance levels.[20] Similarly, Brownlow et al. reported all patients were able to perform activities of daily living, and nearly all reported good to excellent outcomes.[19] When OCD lesions are stratified according to size, results in patients with moderate to large sized OCD lesions have been worse. Takahara et al. reported all patients with large lesions (≥70% of capitellum surface), and 24% with moderate sized lesions (55–70% of capitellum surface) had poor outcomes.[2] Bauer et al. reported 43% of patients treated for large lesions had persistent mild symptoms, and 61% displayed radiographic evidence of osteoarthritis in the radiocapitellar joint.[9] Overall, outcomes after arthroscopic debridement are poor in patients with defects that involve >50% of the articular surface, are >1 cm in diameter, or violate the lateral edge of the capitellum.[2],[4],[20],[21] Therefore, patients with small

lesions (<1 cm) that involve <50% of the articular surface are generally good candidates for debridement procedures. Cartilage restoration procedures should be considered for large defects.

Resolution of clinical scenario

- Good outcomes are seen after debridement in patients with lesions <1 cm, involving <50% of the articular surface, and not involving the lateral edge of the capitellum.
- In patients returning to sport, such as baseball, debridement provided better relief in pain symptoms, increased range of motion, and higher rates of return to baseball at near or full previous performance levels.
- Long-term follow-up results revealed high rates of radiocapitellar osteoarthritis, and mild pain being common in nearly half of patients.

Question 3: In patients with a clinically and radiographically unstable capitellar OCD, does osteochondral autograft transfer result in superior outcomes compared to debridement for pain and return to sport?

Rationale

Few surgical treatments have been described for the treatment of large OCD lesions. However, recent studies have reported good outcomes in patients after

osteochondral autograft transfer due to its ability to restore articular surface and congruity of the radiocapitellar joint.

Clinical comment

Studies suggest that lesion stability, size, and location are important factors to consider when selecting the most appropriate form of treatment. The technique of osteochondral autograft transfer in the elbow has gained popularity due to high success rates seen after similar procedures in the knee and ankle.[22] It represents an effective treatment option in patients with larger OCD defects, OCD defects along the lateral capitellar rim, and in patients who have failed prior debridement.

Available literature and quality of the evidence

- The literature reviewed and summarized to address the clinical question above includes level III retrospective cohort studies and level IV case series studies.

Findings

Due to its increasingly proven success rates in the knee,[22] the operative technique of osteochondral autograft transfer has gained popularity for the treatment of OCD lesions in the elbow. Patients with large capitellar OCD defects (>1 cm) that involve a significant portion of the articular surface (>50%), extend into the lateral margins of the capitellum, or have radial head engagement have worse outcomes after debridement.[2],[4],[20] Although the indications for osteochondral autograft transfer are still evolving, these patients may benefit from osteochondral autograft transfer. The procedure includes the transfer of single or multiple bone and cartilage plugs to restore the capitellar articular surface.

In an early study, Takahara et al. reported that fragment fixation or bone graft or osteochondral autograft transfer provided significantly better results ($p < 0.05$) than fragment debridement alone in larger unstable defects of the articular surface.[4] Recently, several studies have evaluated the technique's efficacy and reported very encouraging clinical outcomes.[23–27] The majority of patients became pain-free, and were able to return to previous activity levels, while few experienced persistent mild occasional pain.[23–27] Donor-site morbidity after autologous osteochondral transplantation is an additional concern to take into consideration when performing these procedures. Autografts may be harvested from the femoral condyle of the knee or costal–osteochondral junction of the ribs. A recent systematic review analyzed differences in outcomes between the two donor sites, and there was no significant difference in donor-site morbidity seen between both harvest techniques.[28]

With regards to baseball, studies have reported that six of eight patients[23] and 17 of 19[29] patients returned to previous level of play, and furthermore 17 of 18[30] experienced no pain with throwing six months after surgery. Authors have also evaluated its impact on prevention of joint degeneration, and nearly all showed little to no degenerative changes at a mean follow-up of up to five years.[31] Overall, osteochondral autograft transfer has proven a reasonable treatment option with good clinical outcomes, and should be considered in patients with the appropriate indications.

Resolution of clinical scenario

- Osteochondral autograft transfer is indicated in large (>1 cm), unstable OCD lesions involving >50% of the

articular surface, or the lateral margins of the capitellum.

- Near complete resolution of pain symptoms, and return to previous activity level is commonly experienced by patients.
- Radiographic evidence of degenerative changes is rare at time of follow-up.

Summary of answers

- Nonoperative management provides good outcomes, and is indicated in patients with stable OCD lesions, open capitellar growth plates, localized flattening or radiolucency of the subchondral bone, and good elbow range of motion.
- Arthroscopic debridement is indicated in patients with unstable, small OCD lesions (<1 cm), involving <50% of the articular surface, and not involving the lateral edge of the capitellum. Patients often report good pain relief, improved range of motion, and return to activity or sport.
- Osteochondral autograft transfer is indicated in patients with unstable, large OCD lesions (>1 cm), involving >50% of the articular surface or the lateral margins of the capitellum. Patients often report good pain relief, and return to previous activity or sport.

131 Labral Tears

Chetan Gohal MD[1], Nolan S. Horner MD[1], and Marc R. Safran MD[2]

[1] Division of Orthopaedic Surgery, Department of Surgery, McMaster University, Hamilton, ON, Canada

[2] Department of Orthopedic Surgery, Stanford University, Redwood City, CA, USA

Clinical scenario

- An athletic 38-year-old woman presents with insidious onset, moderately severe, groin pain that is activity related, especially when she is walking or pivoting on the right leg.
- Pain is worse going from sitting to standing. She also has night pain.
- The patient's pain is reproduced when her hip is positioned in a flexed, adducted, and internally rotated (FADIR) position. X-rays are unremarkable.
- A magnetic resonance arthrogram (MAR) is performed of her right hip which reveals a labral tear.

Top three questions

1. In patients undergoing surgical treatment for a labral tear of the hip, do patients treated with labral repair have superior functional outcome scores to those treated with labral debridement?
2. In patients undergoing surgical treatment for an irreparable labral tear of the hip, do patients treated with labral reconstruction have superior functional

outcome scores to those treated with labral debridement or a match-controlled labral repair group?

3. In patients undergoing surgical treatment for a labral tear of the hip, do younger patients have superior functional outcome scores and lower rates of conversion to hip arthroplasty compared to older patients?

Question 1: In patients undergoing surgical treatment for a labral tear of the hip, do patients treated with labral repair have superior functional outcome scores to those treated with labral debridement?

Rationale

Compelling data on labral repair versus debridement will allow surgeons to perform the procedure which yields better results.

Clinical comment

The labrum of the hip has multiple functions, including increasing the surface area and volume of the acetabulum,[1] acts as a seal against synovial fluid flow in and out of the hip central compartment,[2] and may assume a load-sharing and stabilization role.[3] Therefore, when deciding how much labrum to debride and whether to repair the labrum, one should consider the function of the intact labrum and therefore the possible consequences of a partial or complete labrectomy.

Available literature and quality of the evidence

- Level I: 1 randomized controlled trial (RCT).
- Level III: 2 retrospective comparative cohort studies.

Findings

Krych et al. published an RCT comparing arthroscopic labral repair versus selective labral debridement in female patients with femoroacetabular impingement (FAI). At a mean 32 months' follow-up the repair group had significantly better Hip Outcome Scores (HOS) and subjective outcome scores.[4] Larson et al. had similar findings in their retrospective comparative cohort study comparing labral repair versus debridement.[5] The labral repair group was found to have improved Visual Analog Scale (VAS) scores and functional outcome scores at 3.5 year follow-up.

A retrospective comparative cohort study published by Chen et al. compared outcomes between a labral debridement group using narrow indications and a matched-pair labral repair group.[6] Patients were only eligible for labral debridement in this study if they had a stable labrum with minor damage, and minimal intrasubstance abnormalities. In this study there was no significant difference in a number of functional outcome scores and patient satisfaction between the two groups.

Resolution of clinical scenario

- Level I evidence suggests that patients treated with labral repair will in general have superior outcomes to those treated with labral debridement.
- Level III evidence suggests that labral debridement provides comparable outcomes to labral repair in patients with a stable labrum with minor damage, and minimal intrasubstance abnormalities.

Question 2: In patients undergoing surgical treatment for an irreparable labral tear of the hip, do patients treated with labral reconstruction have superior functional outcome scores to those treated with labral debridement or a match-controlled labral repair group?

Rationale

Identifying which surgical procedure produce superior outcomes for patients with irreparable labral tears will allow surgeons to provide the best treatment option.

Clinical comment

Arthroscopic labral repair has evolved over the years as an effective treatment for hip labral tears, with consistent results of high patient satisfaction, decreasing revision rates, and improved patient-reported outcome (PRO) scores.[5],[7],[8] Certain tear patterns or poor tissue quality are not always amenable to repair, in which case surgical options include labral reconstruction or labral debridement.[9] Labral reconstruction is a more costly and technically demanding procedure than labral debridement. Labral reconstruction aims to restore the natural biomechanics of the labrum while decreasing pain associated with resection of damaged labral tissue.[10] Determining whether labral reconstruction produces superior outcomes is important to determine its overall effectiveness in comparison to labral debridement.

Available literature and quality of the evidence

- Level III: 3 retrospective comparative cohort studies and 2 prospective comparative cohort studies.

Findings

A prospective comparative cohort study by Domb et al. matched 11 patients who underwent arthroscopic acetabular labral reconstruction to 22 patients who had segmental labral resection.[11] It found greater improvement in Non-Arthritic Hip Scores (NAHS) and HOS in the reconstruction group ($p = 0.046$ and 0.045, respectively).

Three cohort studies compare arthroscopic hip labral reconstruction to a match-controlled labral repair group. A comparative retrospective review of 54 patients was done by Matsuda et al. and included a nested case-control analysis within the review.[12] They reported that patients who underwent labral reconstruction with gracilis autograft and those who had labral repair both had significant increases in NAHS with no significant difference between groups. A nested match-paired retrospective cohort study by Domb et al. similarly found comparable survivorship and improvements in PROs between reconstruction and repair groups, except patients in the reconstruction group had lower satisfaction at five-year follow-up.[13] White et al. used patients as their own controls by identifying those who had primary labral repair in one hip and primary labral reconstruction with iliotibial band allograft in the other hip by a single surgeon. There was no significant difference in functional outcome scores between the labral repair and reconstruction groups.[14]

Scanaliato et al. reported in a prospective comparative cohort study of 99 labral repairs and 63 labral reconstructions that both procedures had a similar failure rate (5% for repair and 8% for reconstruction) and no statistical difference in PROs (modified Harris Hip Score,

International Hip Outcome Tool, VAS).[10] It is important to note that this study did not have a matched control analysis, and the patients in the labral reconstruction group had less favorable preoperative characteristics.

Resolution of clinical scenario

- Level III evidence suggests that both arthroscopic labral reconstruction and labral debridement for irreparable labral tears result in improvement in PROs, but greater improvement can be seen with reconstruction.
- Level III evidence suggests that arthroscopic hip labral reconstruction and labral repair have similar survivorship and PROs when comparing matched controls with similar baseline characteristics.

Question 3: In patients undergoing surgical treatment for a labral tear of the hip, do younger patients have superior functional outcome scores and lower rates of conversion to hip arthroplasty compared to older patients?

Rationale

Patient selection is key when determining who to offer surgery to for optimal results. If evidence suggested that patients over a particular age do not benefit from labral repair, surgeons could avoid performing unnecessary procedures on these patients.

Clinical comment

Labral repairs of the hip are most commonly performed through hip arthroscopy. Hip arthroscopy is generally thought of as being a procedure reserved for a young, athletic patient population.[15] Numerous studies have shown positive outcomes in athletes.[16] However, the literature on hip arthroscopy in the middle-aged population has been limited and several studies have advised caution when considering hip arthroscopy in older individuals, particularly in the presence of osteoarthritis (OA).[17]

Available literature and quality of the evidence

- Level III: multiple retrospective case-control studies.
- Level IV: 1 systematic review.

Findings

Horner et al. published a systematic review of 17 level III and IV studies in 2017 on the outcomes of hip arthroscopy in patients aged 40 or older.[18] The systematic review found that patients over 40 who had a labral repair had significant improvement in their postoperative functional outcome scores. However, the rate of conversion to total hip arthroplasty (THA) was significantly higher in patients over 40 than in patients under 40. The presence of OA was found to be a more significant predictor of a poor outcome after hip arthroscopy than increased age.

A retrospective case control published by McCormick et al. in 2012 found that patients <40 and those without osteoarthritic changes were significantly more likely to have a *good* or *excellent* outcome after hip arthroscopy for the treatment of a labral repair.[19]

A study by Domb et al. in 2015 compared patients over the age of 50 with those under 30 undergoing hip arthroscopy. They found that at a mean follow-up of 32 months the under 30 group had a 98.1% survivorship rate, whereas the over 50 group had only an 82.7% survivorship rate. However, there was no significant difference in PROs between the survivors in the two groups.[20]

Honda et al. found that patients aged 50–60 and 60–70 were significantly more likely to have progression of OA after hip arthroscopy than patients under age 50.[21] The presence of preoperative mild OA changes and/or severe cartilage damage on the acetabulum further increased the risk of OA progression.

Resolution of clinical scenario

Older patients may still benefit from labral repair; however, they should be counselled about their increased risk of conversion to THA compared to younger patients. Furthermore, older patients with OA are less likely to have a positive outcome after hip arthroscopy and more likely to have progression of their OA than patients without preoperative osteoarthritic changes. It should be noted that much of the literature on this topic combines all patients undergoing hip arthroscopy regardless of indication, and is in many cases not specific to labral tears.

Summary of answers

- Patients with hip labral tears who undergo labral repair generally have superior functional outcome scores than those treated with labral debridement, except in patients with minimally damaged stable labrums, for whom outcomes of both treatments are comparable.

- For patients with irreparable labral tears, level III evidence suggests that arthroscopic hip labral reconstruction results in greater improvements in PROs than labral debridement. However, both still result in significant improvements overall.
- When comparing matched controls of patients receiving labral reconstruction and labral repair for labral tears, similar survivorship and PROs are seen, according to level III evidence
- Patients over the age of 40 see improvements in outcome scores with hip arthroscopy but experience a higher conversion rate to THA than patients under 40.
- Patients with osteoarthritic changes of the hip are less likely to have a positive outcome after hip arthroscopy for many indications, including labral repair. OA is a greater predictor of outcome than age.

132 Femoroacetabular Impingement

Marc J. Philippon MD, Ioanna K. Bolia MD, and Karen K. Briggs MPH
The Steadman Philippon Research Institute, Vail, CO, USA

Clinical scenario

- A 25-year-old male hockey goalie complains about right hip pain.
- The pain is intermittent, is aggravated with activity, and peaks when he obtains the butterfly stance during hockey. Prolonged sitting also reproduces his hip pain.
- He has tried conservative management (physical therapy, oral analgesics, activity modification) with no resolution of symptoms.

Introduction

Femoroacetabular impingement (FAI) is a common source of hip pain in patients who participate in sports.[1] FAI results from an abnormal biomechanical relationship between the proximal femur and the acetabulum which leads to bony impingement and is associated with soft tissue injury and chondral damage.[2],[3] Certain sport activities, including hockey, predispose the hip joint to the development of FAI due to overuse injury.[4] Such sports include repetitive hip flexion and rotational movements which generate conflict between the femur and the acetabulum.[5]

Cam and pincer impingement are the two main types of FAI. *Pincer impingement* refers to the acetabular component and it is less understood than the *cam FAI*, which refers to the femoral component.[6] Studies have shown the association between the cam lesion and labral or chondral damage in the hip.[2,3,6] Untreated FAI has been associated with hip labral tears and early osteoarthritis, and therefore early diagnosis and prompt therapy are necessary to avoid this complication in young, active individuals.[3,7,8] Hip arthroscopy is an expanding procedure which treats FAI and the associated lesions with minimal intervention.[9] Hip arthroscopy has been reported to result in superior general health-related quality of life (HRQoL) in the Short Form 12 (SF-12) physical health component compared to open FAI surgery, although the hip-specific outcomes were not different based on a recent study.[10]

Top three questions

1. In young adults with hip pain, which physical examination maneuvers are most accurate in the diagnosis of FAI, compared to others?
2. In patients with cartilage defects of the hip, do some treatment options, compared to others, result in better outcomes?
3. In young patients who have undergone treatment for FAI, what are the timelines for return to sport?

Question 1: In young adults with hip pain, which physical examination maneuvers are most accurate in the diagnosis of FAI, compared to others?

Rationale

The young hockey player had a positive anterior impingement sign and he had an increased flexion, abduction, and external rotation (FABER) distance test on the painful hip. Before prescribing advanced imaging, exam results should provide a strong suspicion of FAI.

Clinical comment

A thorough physical exam is critical in order to determine the source of the patient's symptoms. Physical exam findings should guide the clinician in the ordering of further diagnostic investigations.

Available literature and quality of the evidence

- Level of evidence I or II: 3 systematic reviews.
- Most other studies are descriptive or have limited analysis of the accuracy of the physical exam tests.

Findings

Several studies have investigated the physical exam for diagnosis of hip pain.[11–16] One systematic review on physical examination test for FAI found that the accuracy of exam tests are limited due to the heterogenicity of studies.[11] They found that the FABER test had sensitivity of greater than 0.8 and the anterior impingement test had specificity and positive predictive value (PPV) of 1.0.[11] Another systematic review with meta-analysis found the sensitivity of flexion–adduction–internal rotation, which can be compared with the anterior impingement test, equal to 0.99 and a PPV of 0.90.[12] This study also concluded that the current research did not support exam tests for diagnosis.[12]

The other systematic review looked at diagnosis in the skeletally immature patient.[13] Of the six articles included on hip arthroscopy, five reported the physical exam. All five reported using the impingement test for diagnosis. The study made no conclusions on the best physical exam test.[13] The FABER test has been modified to the FABER distance test. One study showed that the FABER distance test was associated with higher alpha angle, which is a common radiographic measurement associated with FAI.[14]

The use of ultrasound has become more popular for diagnosis; however, the literature is limited on its diagnostic capability for FAI.[15] In addition, new three-dimensional models may assist with accurate diagnosis and preoperative planning.[16] While the anterior impingement test is very examiner specific, it has been shown to have good diagnostic characteristics. The FABER distance can provide a measurement to compare both hips with greater interobserver reliability. When used in combination, these tests (anterior impingement and FABER distance test) can be helpful in identifying patients who are at high risk for chondrolabral dysfunction due to FAI and may need addition imaging.

Resolution of clinical scenario

- A thorough clinical exam is necessary as there is no evidence to support the use of specific tests for the diagnosis of FAI.
- It is our experience that the FABER distance test and the anterior impingement test are relatively specific for the diagnosis of FAI.

Question 2: In patients with cartilage defects of the hip, do some treatment options, compared to others, result in better outcomes?

Rationale

There is insufficient evidence to support the effectiveness of currently available cartilage restoration techniques in the hip. Only short- and medium-term outcomes have been published and the superiority of one technique over the other has not been showed. In athletes, only microfractures have been reported to result in improved outcomes and high return to sport rate.

Clinical comment

Anterosuperior labral tears are associated with adjacent acetabular cartilage delamination in patients with FAI. The cam lesion, which is common finding in young hockey players, has been associated with hip cartilage defects. An Outerbridge grade IV cartilage defect was present on the acetabulum and a grade II defect was present on the femoral head. Acetabular microfractures were performed, whereas the femoral defect was treated with chondroplasty.

Available literature and quality of the evidence

- There is not enough literature to propose the ultimate cartilage repair technique to restore the cartilage defects in the hip.
- Level IV: 2 studies.
- Level III: 3 studies.

- Systematic review of Level III and IV studies: 1 study.

Findings

A recent systematic review reported more than 10 cartilage repair techniques in the hip, but the authors concluded that more research is necessary to support one technique over another.[17] The most recent studies have focused on intra-articular bone marrow mesenchymal stem cells injection and the Autologous Matrix-Induced Chondrogenesis (AMIC) procedure with satisfactory two- to five-year outcomes.[18–20] None of the recent studies has focused exclusively on athletes, except from McDonald et al. in 2013 who had reported that elite athletes who underwent hip arthroscopy for FAI with microfractures had a similarly high return to sport rate with a control group of elite athletes who did not have microfractures.[8] In the last study, the return to sport rate was 77 and 84% in the microfracture group and the control group, respectively. McDonald et al. reported an 82% return to sport rate in professional hockey players who underwent hip arthroscopy for FAI, labral repair and microfractures.[21]

Resolution of clinical scenario

- Performance of hip microfractures in athletes with severe chondral defects results in improved outcomes and a high return to sport rate.
- Severe chondral defects can be treated with microfractures or newer cartilage repair techniques.

Question 3: In young patients who have undergone treatment for FAI, what are the timelines for return to sport?

Rationale

In the sports medicine population, return to activity is what the patients expect following surgery. Many patients do not have surgery due to the severity of symptoms but due to their inability to participate in their sport. The last is especially true for professional athletes. Hip arthroscopy has been reported to result in a high return to sport rate in athletic individuals, but this has been supported by only level IV evidence data in the literature.

Clinical comment

After eight weeks of postoperative rehabilitation, this patient passed the hip sport test and could return to full activity. The patient returned to the ice at eight weeks and completed full training sessions at nine weeks. It is important to establish evidence-based, return-to-play protocols for athletes undergoing hip arthroscopy to reduce the re-injury rate and prolong the athlete's career.

Available literature and quality of the evidence

- Not many studies have reported successful outcomes following hip arthroscopy in hockey players.
- Level IV: 3 studies.
- Systematic review of level IV studies that include hockey players: 1 study.
- Case reports: 2 studies.

Findings

The most recent systematic review (1296 patients, 1442 hips) reported the return to sport rate following hip arthroscopy to be 84.6% at a mean follow-up of 25.8 months.[22] Philippon et al. reported that the time to return to play following hip arthroscopy and labral repair in professional hockey players was 3.4 months on average.[4] McDonald et al. reported a high return to sport rate and no difference in games played and number of seasons in the league following hip arthroscopy with or without microfractures, in professional hockey players.[21] In addition, the authors did not find a significant difference between number of seasons in the league between the microfracture and the nonmicrofracture group. In a group of 60 professional hockey players, Menge et al. reported that 5.9 years following hip arthroscopy for FAI, 67% (40/60 athletes) of the athletes were still playing.[23] Case reports have showed that hockey players who undergo hip arthroscopy with proper rehabilitation can safely return to sport and continue their career.[24],[25]

Resolution of clinical scenario

- Hockey players with FAI, labral tears, and/or cartilage defects have a high chance to return to sport following hip arthroscopy with or without microfractures.
- Postoperative rehabilitation is critical to optimize the surgical outcome and allows for an early return to sport.

Summary of answers

- Diagnosis of FAI begins with the physical exam; however, the literature does not support specific exams

as part of a diagnostic algorithm.

- The anterior impingement test and the FABER distance test are commonly used for the preliminary diagnosis of FAI.
- Performance of hip microfractures in athletes with severe chondral defects results in improved outcomes and a high return to sport rate.
- Severe chondral defects can be treated with microfractures or newer cartilage regeneration techniques.
- Hockey players with FAI, labral tears, and/or cartilage defects have a high chance to return to sport following hip arthroscopy with or without microfractures.
- Postoperative rehabilitation is critical to optimize the surgical outcome and allows for an early return to sport.

Conclusion

FAI and the commonly associated labral or hip cartilage lesions are common diagnostic findings in young athletes. Early diagnosis and treatment of the hip structural lesions in symptomatic athletes are necessary to reduce the prevalence of early degenerative joint disease and prolong their participation in sports.

133 Initial Management of the Sports Injured Knee

Marc Aguilar Garcia MD[1], Carla Carbonell Rosell MD[2], and Joan Pijoan Bueno MD[2]
[1] Vall d'Hebron University Hospital, Barcelona, Spain
[2] Clínica Corachan, Barcelona, Catalonia, Spain

Clinical scenario

- A 27-year-old female presents at the Emergency Department after she twists her knee during a basketball game.
- The patient reports pain and acute functional limitation.
- At the time she is evaluated, an effusion can be detected.

Top three questions

1. In patients with an acutely injured knee, does magnetic resonance imaging (MRI) performed acutely provide greater diagnostic ability compared to delayed MRI?
2. In patients with an acutely injured knee, does MRI, compared to diagnostic arthroscopy, provide sufficient diagnostic capability?
3. In acute post-traumatic hemarthrosis, does aspiration, compared to no aspiration, play a diagnostic or therapeutic role?

Question 1: In patients with an acutely injured knee, does magnetic resonance imaging (MRI) performed acutely provide greater diagnostic ability compared to delayed MRI?

Rationale

The role of MRI in acute trauma has classically been controversial; this section aims to resolve these doubts by shedding light with the help of currently published literature.

Clinical comment

Knee injury secondary to sports is a common reason for presentation to the Emergency Department. The majority of injuries are often due to extra-articular soft tissue injury. Despite this, sometimes we find severe knee effusion which suggests hemarthrosis, and may involve injury to intra-articular structures.

A large intra-articular effusion after trauma often points directly to a diagnosis of hemarthrosis through physical examination. Physical examination has great sensitivity to detect knee injuries, although the specificity is very low because it is difficult to perform specific maneuvers given that the patient often has significant pain and guarding. This is accentuated more at an early age, due to fear, guarding, or difficulty in expressing current symptoms.

Traditionally, a delayed MRI was the gold standard treatment due to concerns about missed intra-articular injuries in an early MRI. However, new studies have demonstrated that perhaps there is a role for early MRI.

Available literature and quality of the evidence

There is a wide spectrum of articles that discuss timing of MRI following injury, though most are level III–IV studies. At the moment, no randomized clinical trials have been published.

Findings

One of the characteristics that should matter most about a diagnostic test is the ability to detect injuries and the ability to distinguish between them, that is a test that minimizes false-negatives and false-positives. Munshi et al. published a prospective double-blind study performing MRI on a 1.5 T magnet and comparing the results to knee arthroscopy.[1] They reported sensitivity and specificity for early MRI of 90 and 67%, respectively, for detecting any anterior cruciate ligament (ACL) injury, 50 and 86% for detecting medial meniscal tears, and 88 and 73% for detecting lateral meniscal tears. The overall detection of injury requiring surgical intervention yielded a sensitivity of 100% and a specificity of 71%.

As previously mentioned, there are injuries that can may go unnoticed in the Emergency Department. Askenberger et al. conducted a prospective study in a pediatric hospital with children aged between 9 and 14 years;[2] they observed that, even though 77% of children who visited the Emergency Department with knee trauma had serious intra-articular injuries, 56% of these patients had no apparent lesion on plain radiography. Therefore, if there is a suspicion of serious injury, an MRI is recommended even in the context of normal X-rays.

Phelan et al. published a systematic review of the articles that correlated the initial MRI findings with findings during knee arthroscopy.[3] They found that a positive finding on

MRI doubled the probability of an ACL tear from 35.7 to 85.8%. They found several confounding factors: (i) the magnetic field strength of the MRI, (ii) the year of publication of the article, since MRI techniques have evolved, (iii) the ability to differentiate between complete and partial ACL tear, (iv) the radiologist's experience, and (v) the blinding of the arthroscopist. A similar study conducted by Monaco et al. compared MRI findings with intraoperative anterolateral exploration in the acute ACL-injured knee.[4] They concluded that MRI evaluation demonstrated high sensitivity, specificity, and accuracy for the detection of abnormalities of the anterolateral ligament complex. For other parameters, the sensitivity and specificity were not as high, such as whether there was a complete tear or not.

Abbasi et al. conducted a prospective study that aimed to describe the MRI findings in adolescents with traumatic knee effusions and to compare injuries based on age, sex, and physeal maturity.[5] They found that severe intra-articular knee injuries occur in young patients with ACL tears and patellar dislocations accounting for the majority of injuries. Injury patterns were affected by age with significantly more ACL tears occurring in the 15- to 18-year-old age group (40% vs 22%, $p < 0.05$).

Resolution of clinical scenario

As has been observed, the MRI diagnosis has an acceptable sensitivity and specificity detecting intra-articular knee injuries in the acute setting. In contrast to traditional texts, it seems the rate of missed occult injuries may be as low as 5%.

- MRI is necessary when a knee with severe swelling occurs after sports trauma.

- The false-negative rate is low with the techniques and knowledge of the current MRI.
- MRI acceptably identifies potentially surgical lesions.

Question 2: In patients with an acutely injured knee, does MRI, compared to diagnostic arthroscopy, provide sufficient diagnostic capability?

Rationale

The patient is concerned regarding the potential for intra-articular injury but is reluctant to proceed with surgical intervention. She wants to be sure that surgery is necessary and asks for further diagnostic testing.

Clinical comment

Diagnostic arthroscopy was a very popular procedure a few decades ago because of the immediacy of the diagnosis and its therapeutic possibilities;[6] however, it is still an invasive procedure not free of possible adverse effects. As with many other procedures, the accuracy of diagnostic arthroscopy, particularly in the context of acute injury and hemarthrosis, depends on the surgeon's skill level. Varying blind areas arise depending upon the arthroscopic approach such as peripheral and posterior parts of the menisci, although the experienced arthroscopist may overcome this problem by using a hook for palpation of the intra-articular structures. The role of diagnostic arthroscopy is losing popularity with a more common tendency to perform MRI studies.[7],[8]

Available literature and quality of the evidence

- Level II: 2 systematic reviews.

Findings

Rappeport et al. performed a systematic review[9] and a prospective study,[10] which concluded that MRI is in many respects equal or even preferable to diagnostic arthroscopy. It has a high ability to detect lesions of the major and most commonly affected structures of the knee joint. Furthermore, information is obtained about other structures like the collateral ligaments and the patellar ligament that are not visualized at arthroscopy. They advocated its use as a first-line investigation after clinical examination.

Crawford et al. performed a systematic review of largely level II evidence (47 prospective studies and a total of 59 articles) to assess the difference between MRI and arthroscopy in the diagnosis of knee pathology.[11] The findings indicated that MRI was highly accurate in diagnosing ligament and meniscal pathology. Furthermore, performing an early MRI prior to diagnostic arthroscopy has been reported to avoid unnecessary surgical intervention in 22–51% of cases.[12] Avoid unnecessary arthroscopic procedures is crucial to minimize the possibility of adverse effects or other complications, as well as to ensure appropriate use of limited healthcare uses.

Resolution of clinical scenario

- In a large proportion of patients management can be planned on the basis of MRI findings with arthroscopy deferred in the presence of a normal examination.

- Routine MRI avoids unnecessary diagnostic arthroscopy in more than 20% of cases.

Question 3: In acute post-traumatic hemarthrosis, does aspiration, compared to no aspiration, play a diagnostic or therapeutic role?

Rationale

The patient is suffering from significant pain and limited active range of motion (ROM). She desires to know whether an aspiration would reduce her symptoms without taking any further risks.

Clinical comment

Joint aspiration of acute injury hemarthrosis has always been seen as an easy and helpful technique, but it is uncertain if it may alleviate the initial pain and increase function of the knee. Furthermore, its role in diagnosis is becoming less necessary with the previously discussed improvements in MRI. The related risks of iatrogenic infection and recurrence effusion should also be taken into account.

Available literature and quality of the evidence

- Level I: 1 randomized trial.
- Level III: 1 retrospective cohort study.

Findings

A randomized trial conducted by Paschos et al. analyzed 167 patients with a knee effusion (95 traumatic) and

divided them into two groups: aspiration versus nonaspiration.[13] In the traumatic group, aspiration showed a temporary improvement in pain relief ($p < 0.05$), ROM, and reduction in swelling ($p < 0.05$ for all) compared with nonaspiration. However, the improvement lasted less than one week regarding pain and approximately three days regarding edema and function. Moreover, trauma effusions recorded higher rates of re-accumulation (37% of patients reoccurred within the first week) compared with nontraumatic effusions. Concerning the analgesic intake and required time to return to normal activities, no differences were observed. Two patients showed signs and symptoms of infection and were treated with antibiotics, but it was not specified if they were traumatic or nontraumatic effusions.

On the other hand, Wang et al. published a retrospective cohort study of 60 patients that underwent ACL reconstruction.[14] All participants were divided into two groups based on the presence or absence of joint aspiration in the Emergency Department. It should be emphasized that there was not strict selection criteria for aspiration. In fact, the aspiration group showed a higher mean pain score on Visual Analog Scale (VAS) and effusion and a reduced ROM at the initial examination. It was observed that the aspiration group had a significantly greater decrease in VAS at follow-up than the nonaspiration group (2.8 ± 1.9 vs 1.0 ± 2.5, $p < 0.05$). ROM was re-established in the aspiration group by $28.2 \pm 23.1°$ versus $3.5 \pm 38.3°$ in the nonaspiration group ($p < 0.05$). Additionally, it was showed a higher sensitivity of Lachman and Pivot Shift tests at the second visit: 76.5% (13/18) of positive Lachman test in the aspiration group versus 47.6% (20/42) in the nonaspiration group ($p = 0.047$) and 76.5% (13/18) of positive Pivot Shift test versus 31% (13/42) ($p = 0.001$). The incidence of iatrogenic infection was not mentioned.

Overall, there is a shortage of literature to define the benefit of the arthrocentesis in the acutely injured knee with hemarthrosis and its inherent risks.

Resolution of clinical scenario

- Post-traumatic knee joint aspiration may be effective in reducing the immediate pain and edema but a prompt re-accumulation of the effusion seems frequent.
- The aspiration of acute hemarthrosis remains of questionable value.

Summary of answers

- In a large proportion of patients management can be planned on the basis of MRI findings with arthroscopy deferred in the presence of a normal examination.
- Routine MRI avoids unnecessary diagnostic arthroscopy in more than 20% of cases.
- Post-traumatic knee joint aspiration may be effective in reducing the immediate pain and edema but a prompt re-accumulation of the effusion seems frequent.
- The aspiration of acute hemarthrosis remains of questionable value.

134 Meniscal Tears

Nicola Maffulli MD MS PhD FRCS (Orth)[1,2], Domiziano Tarantino MD[1], and Rocco Aicale MD[1]
[1] Department of Musculoskeletal Disorders, School of Medicine and Surgery, University of Salerno, Salerno, Italy
[2] Queen Mary University of London, Barts and the London School of Medicine and Dentistry, Centre for Sports and Exercise Medicine, Mile End Hospital, London, UK

Clinical scenario

- A 28-year-old soccer player comes to the Emergency Department with right knee pain after sustaining direct trauma during a match. Clinical examination reveals an effusion, locking, tenderness, and painful flexion/extension of the knee, suggesting a meniscal lesion. Magnetic resonance imaging (MRI) is proposed as the primary tool for the tear detection, but the primary care physician suggests ultrasound (US) for a quick examination.
- After the imaging confirmation of meniscal tear, meniscal repair is proposed as the most suitable surgical technique.
- After a failed meniscal repair, the patient undergoes an arthroscopic partial meniscectomy, and asks about the best way to recover knee function and muscle strength in the operated leg.

Table 134.1 Correlation between MRI, arthroscopy, and ultrasonography.

Top three questions

1. In patients with suspected meniscal lesions, is US preferable for tear detection compared to arthroscopy and MRI?
2. In patients with meniscal lesions, does a specific repair technique result in better surgical outcomes compared to others?
3. In patients with meniscal lesions, does a specific rehabilitation protocol result in better clinical outcomes compared to others?

Question 1: In patients with suspected meniscal lesions, is US preferable for tear detection compared to arthroscopy and MRI?

Rationale

MRI is the gold standard for the diagnosis of meniscal tears. USs are a suitable noninvasive and safe alternative tool to establish a diagnosis of meniscal tear.

Clinical comment

Current opinion suggests that MRI is preferable to diagnostic arthroscopy in most patients because it avoids the surgical risks of arthroscopy with high accuracy in diagnosing meniscal and anterior cruciate ligament (ACL) tears.[1] US has been proposed in case of contraindications for MRI, such as the presence of indwelling cardiac pacemakers, metal implants, patient intolerance due to claustrophobia, and delay in treatment due to long wait periods.[2]

Available literature and quality of the evidence

A number of different studies have evaluated the role of US for meniscal tear diagnosis, both alone or in comparison with MRI and/or arthroscopy. Three systematic review and meta-analyses evaluated the diagnostic accuracy of US for meniscal tears.[3–5] One trial (n = 70 patients) provided the correlation between arthroscopy and US,[6] stating that US may be used for screening for meniscal tears (Table 134.1). Three trials (n = 71, n = 15, and n = 50 patients, respectively) determined the clinical usefulness of US for diagnosis of meniscal injuries and compared its diagnostic accuracy to MRI (Table 134.1).[7–9] Two trials (n = 74 and n = 35 patients, respectively) provided the correlation between MRI, US, and arthroscopy for meniscal tears diagnosis (Table 134.1).[10,11]

Findings

Dai et al. and Xia et al. found that US has high specificity (0.90; 95% confidence interval [CI]: 0.86–0.93 and 0.838; 95% CI: 0.818–0.857, respectively) and moderate sensitivity (0.88; 95% CI: 0.84–0.91 and 0.775; 95% CI: 0.747–0.801, respectively),[3,4] while Dong et al. found that two-dimensional US has higher sensitivity (0.888; 95% CI: 82.83–92.87) than specificity (0.846; 95% CI: 75.89–90.64).[5] All three studies agreed that the diagnostic accuracy of US for meniscal injury was acceptable, and that US could be routinely used to diagnose meniscal tears.

Cook et al. stated that US is a useful tool for diagnosis of meniscal pathology with potential advantages over MRI.[7] Mahdy et al. and Mostafa et al. pointed out that US (especially high resolution US) examination may be suitable for screening for meniscal

tears, but detection of the morphology of meniscal tears seems insufficient, with MRI being more sensitive in detection and determination of tear type.[8,9]

Alizadeh et al. stated that US could be effective as an initial investigation for tears of medial meniscus for patients aged 30 or less,[10] while Unlu et al. concluded out that US is not a suitable alternative for MRI in the routine diagnostic evaluation of meniscal tears, and that only in selected cases, such as young patients, traumatic cases, and cases with a contraindication for MRI, US may find a role as a quick exam to stratify patients for further evaluation.[11]

Overall, there is consensus about the usefulness of US for meniscal tears detection. Level I evidence suggests that US could be used as a reliable tool, with a good diagnostic accuracy.[3,10] However, level I evidence also suggests that US cannot completely replace MRI for meniscal tear diagnosis, particularly for classifying tear type.[11]

Resolution of clinical scenario

- Level I evidence demonstrates that US could be useful screening tool for the detection of meniscal tears, especially if high-resolution US is used. Since the available data about US sensitivity and specificity are discordant, US cannot replace MRI, which remains the mainstay for the diagnosis of meniscal pathologies.

Question 2: In patients with meniscal lesions, does a specific repair technique result in better surgical outcomes compared to others?

Rationale

MRI shows an extended vertical longitudinal meniscal tear. Meniscal repair could represent an option for this patient.

Current comment

Several techniques have been proposed to optimize the healing of a repairable meniscal tear. Meniscectomy is one of the most popular orthopedic procedures, but long-term results are not entirely satisfactory and the concept of meniscal preservation has therefore progressed over the years because of its functional importance to the knee and risk of long-term osteoarthritis associated with meniscectomy.[12,13] Arthroscopic meniscal repair surgery includes inside-out, outside-in, and all-inside techniques. All-inside meniscal repair devices are an attractive option owing to cosmesis, surgical time, and decreased risk of injury to neurovascular structures.

Available literature and quality of the evidence

The inside-out technique is considered the gold standard for meniscal repair, although all-inside techniques continue to evolve.[14] Studies available to answer this question include a meta-analysis,[15] a laboratory study,[16] a randomized controlled trial (RCT),[17] and a systematic review.[18]

Findings

A meta-analysis by Mutsaerts et al. found that the only surgical treatments compared in homogeneous fashion across more than one study were the arrow and inside-out technique, which showed no difference in terms of re-tear or complication rate.[15]

A controlled laboratory study investigated the biomechanical response to cyclic loading (up to 100 000 cycles) of all-inside meniscal repairs compared with inside-out suture controls, and showed comparable biomechanical properties, even after 100 000 cycles.[16] In this study, 72 porcine menisci were repaired using the Omnispan and Fast-Fix 360 (all-inside devices) and Orthocord 2-0 and Ultrabraid 2-0 sutures (inside-out sutures). Initial displacement and displacement after cyclic loading were not different between the groups, but the Omnispan repair demonstrated significantly higher load-to-failure force compared with all the other constructs, and the Orthocord vertical inside-out mattress repair was significantly stronger than the FAST-FIX 360 repair.

An RCT by Kise et al. compared an all-inside suture device to meniscal arrows.[17] They treated 46 patients either by Biofix (n = 21, 45.7%) or FAST-FIX (n = 25, 54.3%) with two-year follow-up. Their results indicate that FAST-FIX suture is superior to Biofix arrows with significantly lower failure; the risk of reoperation was 3.6 times higher for the Biofix (95% CI: 1.1–11.5). It should be noted, however, that patients in the Biofix group had higher activity scores preoperatively and at three-month follow-up, and thus activity level may also influence risk of reoperation.

A recent systematic review by Fillingham et al. pointed out that the quality of the evidence comparing inside-out and all-inside meniscal repair is low, and that there were no significant differences in terms of anatomical and clinical failure rates, functional outcome scores, and complication rates.[18]

Given the paucity of RCTs, no definite conclusions could be drawn regarding the difference in clinical outcomes of various meniscal repair devices. For this reason, more evidence is needed to reduce the numbers of ineffective interventions and support potentially beneficial surgery.[19]

Overall, there is consensus about the absence of a specific repair technique which results in better surgical outcomes for meniscal tears. Level I studies suggest that there is a lack of evidence to guide the surgical management of meniscal tears, with no significant differences between the repair techniques in terms of clinical or surgical outcomes.[15,18,19] For these reasons, the choice of a particular repair technique is unlikely to improve outcomes.[1]

Resolution of clinical scenario

- Level I evidence demonstrates that there are no reasons to believe that the choice of a particular repair technique would improve outcomes following meniscal repair.

Question 3: In patients with meniscal lesions, does a specific rehabilitation protocol result in better clinical outcomes compared to others?

Rationale

After a failed meniscal repair and subsequent arthroscopic partial meniscectomy, an appropriate rehabilitation program is a key point for the overall success of surgery.

Clinical comment

Type of lesion, type of surgery, timing of biological healing, and the patient's symptoms determine the appropriate rehabilitation program for a full recovery.[20] After partial meniscectomy, the rehabilitation protocol can be aggressive, because the knee joint anatomical structure does not need to be protected.[20]

Available literature and quality of the evidence

A large meta-analysis,[21] a laboratory study,[22] and two RCTs[23],[24] exist to answer this question.

Findings

A meta-analysis by Dias et al. evaluated 18 RCTs and six meta-analyses of patients treated with arthroscopic meniscectomy, and pointed out that outpatient physical therapy plus a home exercise program improves function and knee flexion range of motion when compared to a home program alone.[21] Moreover, inpatient physical therapy alone compared to inpatient plus outpatient physical therapy reduced the likelihood of effusion.

A descriptive laboratory study by Hsu et al. compared single-leg hop performance (distance and landing mechanics) between limbs to examine the association of single-leg hop performance with quadriceps strength and psychosocial factors in patients with meniscectomy.[22] A total of 22 subjects who underwent meniscectomy for traumatic meniscal tears received either standard rehabilitation alone or with additional quadriceps strengthening. Greater quadriceps strength was associated with greater single-leg hop distance and better landing mechanics at both postrehabilitation and one-year postsurgery.

An RCT by Zhang et al. aimed to determine an effective knee function rehabilitation program for athletes undergoing partial medial meniscectomy.[23] Participants were randomly assigned to neuromuscular training (NT) or strength training (ST) and subjected to functional assessments before surgery and again at four and eight weeks *postoperation*. Functional knee assessment, such as Lysholm knee scoring scale, Star Excursion Balance Test, and BTE PrimusRS isokinetic performance tests were evaluated in each group. All postoperational symptoms were significantly improved after four and eight weeks of NT and ST. Both NT and ST programs showed effective knee function recovery seen as an increase in muscular strength and endurance. However, the NT program showed the most significant functional improvement of dynamic balance and coordination.

A recent RCT by Vidmar et al. compared the effects of conventional (constant load) eccentric training and isokinetic eccentric training on quadriceps muscle mass, strength, and functionality of recreational athletes following partial meniscectomy.[24] Thirty-two recreational male athletes who underwent partial meniscectomy and performed a six-week quadriceps ST program were divided into a conventional group (CG) or an isokinetic group (IG). Both groups had enhanced muscle mass, strength, and functional outcomes. The IG patients had significantly higher increases for muscle mass, strength, and Lysholm knee scoring system. These results suggested that, after partial meniscectomy, isokinetic eccentric training is more effective than conventional eccentric training to restore quadriceps muscle mass, strength, and functional capacity.

Overall, many different types of rehabilitation protocols reported good outcomes. Level I evidence suggests that physical therapy plus a home exercise program in outpatients treated with arthroscopic meniscectomy improves function and knee flexion, and that neuromuscular, strength, and isokinetic programs ensure the best results in terms of clinical improvement.[21],[23],[24] Level IV evidence suggests that greater quadriceps strength was associated with greater single-leg hop distance and better landing mechanics compared with rehabilitation alone.[22]

Resolution of clinical scenario

- Level I evidence demonstrates that muscle strengthening is an integral part of rehabilitation programs after meniscectomy, resulting in a better landing mechanism.

NT showed better results in dynamic balance and coordination.

- Level I evidence demonstrates that isokinetic eccentric training is more effective than conventional eccentric training to restore quadriceps muscle mass, strength, and functional capacity.

Summary of answers

- US is a useful screening tool for the detection of meniscal tears, especially if high-resolution US is used. Since the available data about US sensitivity and specificity are discordant, US cannot replace MRI, which remains the mainstay for the diagnosis of meniscal pathologies.
- There are no reasons to believe that the choice of a particular repair technique would improve the outcomes following meniscal repair.
- Muscle strengthening is an integral part of rehabilitation programs after meniscectomy, resulting in better landing mechanics. NT improves dynamic balance and coordination.
- Isokinetic eccentric training is more effective than conventional eccentric training to restore quadriceps muscle mass, strength, and functional capacity.

135 Anterior Cruciate Ligament Injuries

Aaron Gazendam MD[1], Darren de SA MD[1], and Freddie Fu MD[2]

[1] Division of Orthopaedic Surgery, Department of Surgery, McMaster University, Hamilton, ON, Canada

[2] University of Pittsburgh Medical Center, Pittsburgh, PA, USA

Clinical scenario

- An 18-year-old varsity football player presents to clinic complaining of right knee pain and instability after sustaining an injury in practice one month ago. The patient describes that he planted his foot on the turf and sustained a twisting injury.
- Physical exam demonstrates a grade 3 Lachman's test and a 2+ Pivot Shift test.
- MRI demonstrates an acute, full thickness anterior cruciate ligament (ACL) tear.

Top three questions

1. In patients undergoing ACL reconstruction, does autograft result in improved outcomes compared to allograft?
2. In patients undergoing ACL reconstruction, does hamstring or quadriceps tendon autograft result in differences in outcomes compared to conventional bone patellar tendon bone (BPTB) autograft?

3. In patients undergoing ACL reconstruction, does early surgical intervention improve outcomes compared to delayed reconstruction in both skeletally mature and immature patients?

Question 1: In patients undergoing ACL reconstruction, does autograft result in improved outcomes compared to allograft?

Rationale

The choice of graft can have important implications for outcome and function after ACL reconstruction. Both allograft and autograft have their respective advantages and disadvantages, which need to be discussed with the patient.

Clinical comment

ACL ruptures are devastating injuries and can lead to recurrent instability, degenerative changes, and chronic pain.[1–4] Although is consensus that arthroscopic reconstruction is the treatment of choice in active individuals, there is still debate as to whether autograft or allograft should be used.[5–8]

Autograft options consist of bone patellar tendon bone (BPTB), hamstring tendon (HT) and less commonly, quadriceps tendon (QT).[9] Allograft is generally acquired from cadaveric BPTB, anterior tibial tendon, or Achilles tendon.[9] Autografts have been found to have faster graft incorporation and are free of the potential for disease transmission.[10] However, this comes at a cost of donor site morbidity depending on the site of harvest. Allografts avoid

donor site morbidity, but come with the risk of delayed incorporation, altered biomechanics secondary to sterilization processes, risk of disease transmission, as well as increased cost.[9],[10]

Available literature and quality of the evidence

Multiple randomized controlled trials (RCTs) have compared the efficacy of various autografts compared to both irradiated and nonirradiated allografts in different populations.[11]–[14] Gorschewsky et al. (level II) randomized 268 patients to autograft BPTB or irradiated allograft BPTB.[12] They found significantly higher re-rupture rates in the allograft group compared to the autograft group (20.6% vs 4.8%). Subgroup analysis demonstrated even higher re-rupture rates in the allograft group when evaluating young, active patients. More recently, Sun et al. (level II) randomized 208 patients to hamstring autograft versus nonirradiated fresh-frozen HT allograft.[13] They found no significant differences in outcomes at an average of 7.8 years of follow-up.

A meta-analysis by Zeng et al. (level IV) evaluated the results of nine RCTs comparing allograft and autograft for ACL reconstruction.[15] They demonstrated that autograft was favored over allograft with regards to clinical failure rates (risk ratio [RR] = 0.47; p = 0.0007), the Lachman test (RR = 1.18; p = 0.03), the instrumented laxity test (weighted mean difference: −0.88; p = 0.004). However, when a subgroup analysis was performed comparing autograft with nonirradiated allograft no significant differences were found. Wei et al. (level II) performed a meta-analysis of 12 RCTs comparing nonirradiated allograft with autograft and found no significant differences in postoperative knee stability, function, or side effects.[16]

Given that younger, active patients have a significantly higher re-rupture rate, there has been an interest in determining differences in graft success rates in this specific population. Bottoni et al. (level I) randomized 100 active-duty military personnel with ACL-deficient knees to hamstring autograft or nonirradiated tibialis posterior allograft.[17] At a minimum of 10-year follow-up, they found there was a significantly increased number of failures (26.5% vs 8.3%, $p = 0.03$) in the allograft group when compared to autograft. Wasserstein et al. (level III) performed a meta-analysis on seven studies comparing autograft to allograft in young or active populations.[18] Pooled results of 788 patients treated with autograft tissue and 228 with various allografts demonstrated a significantly higher failure rate in the allograft group (25% vs 9.6%, $p < 0.00001$).

Findings

Overall, level II–IV evidence suggests that autograft has low failure rates when compared to irradiated allografts.[12],[15] There are significant limitations in the literature including low patient numbers, varying graft substances, and differences in follow-up length. There is level I–III evidence that demonstrates higher failure rates in allograft when compared to autograft in young, active patients.[17],[18] This is a particularly important subgroup that has historical seen higher failure rates and may benefit from autograft for primary ACL reconstruction.[19]

Resolution of clinical scenario

- Level II evidence suggests that autograft has lower failure rate when compared to irradiated allograft.[12]

- Level II evidence suggests that there is no differences in clinical outcomes when autograft is compared to nonirradiated allograft.[16]
- Level I evidence suggests that in young, active patients, autograft has significantly lower failure rates when compared to allograft.[17]

Question 2: In patients undergoing ACL reconstruction, does hamstring or quadriceps tendon autograft result in differences in outcomes compared to conventional bone patellar tendon bone (BPTB) autograft?

Rationale

Autograft remains the most common choice for ACL reconstruction.[20] There remains controversy over the most favorable graft selection with the most commonly utilized autografts being BPTB and four-strand HT.[20] Recently, there has been renewed interest in quadriceps tendon autograft. There are advantages and disadvantages of each graft choice, which should be discussed with the patient preoperatively.

Clinical comment

Some experts favor BPTB because of faster graft incorporation, potential for lower risk of graft rupture, and postoperative hamstring weakness.[21] However, BPTB is generally considered to have higher donor site morbidity.[9] Experts favoring HT autograft cite lower donor site

morbidity, particularly reduced incidence of anterior knee pain, osteoarthritis, and extensor mechanism weakness.[9]

The quadriceps tendon is the least investigated and used autograft for primary anterior cruciate ligament reconstruction (ACLR).[20] However, there has been increased interest due to the potential for larger cross-sectional area, less extensor mechanism disruption, and overall lower donor-site morbidity.[22,23]

Available literature and quality of the evidence

A meta-analysis by Samuelsen et al. (level III) analyzed 14 RCTs, 10 prospective comparative studies, and one high-quality national data study with a total of 47 613 patients undergoing either BPTB or HT reconstruction.[21] They found a small but statistically significant higher failure rate in HT when compared to BPTB (2.84% vs 2.80%; odds ratio [OR] = 0.83; 95% confidence interval [CI]: 0.72–0.96; p = 0.01).

A recent RCT with excellent follow-up performed by Mohtadi et al. (level I) compared the results of 315 patients undergoing ACL reconstruction with BPTB, double-stranded HT, or single-bundle quadruple-stranded HT.[24] They reported significantly higher traumatic re-tear rates in both HT groups when compared to BPTB (4% vs 10%, p = 0.01). However, they also reported a significantly greater proportion of patients undergoing BPTB reconstruction reporting moderate to severe kneeling pain at five years (p = 0.029).

Literature surrounding the young, active population has demonstrated differences in re-rupture rates between BPTB and HT. Kaeding et al. (level II) prospectively followed 839 young (aged 14–22) active patients undergoing ACLR and found at six-year follow-up there was

a significant increase of re-rupture rate in HT versus BPTB (OR = 2.1; 95% CI: 1.3–3.5; p = 0.004).[25] Similarly, Salem et al. (level II) prospectively followed 256 young female athletes and found an increased re-rupture rate in HT versus BPTB in younger patients (15–20 years old, 6.4% vs 17.5%, p = 0.02) but not in older patients (20–25).[26]

The utilization of quadriceps tendon in primary ACLR has gained traction recently. Lund et al. (level I) randomized 51 patients to either BPTB or QT and found no differences in rupture rates or laxity at two-year follow-up.[27] They demonstrated significantly lower prevalence of anterior kneeling pain in QT versus BPTB (7% vs 34%). Cavaignac et al. (level III) reviewed 86 patients undergoing QT versus HT ACLR and reported improved functional outcomes with the QT with no differences in re-operation.[28] Mouarbes et al. (level II) performed a meta-analysis comparing failure rates and functional outcomes of QT versus BPTB and QT versus HT.[29] They demonstrated no difference in failure rates of QT when compared to BPTB or HT. They found that QT showed significantly less harvest site pain when compared to BPTB (RR for QT vs BPTB groups, 0.25; 95% CI: 0.18–0.36; p = 0.00001). They also demonstrated improved functional outcome scores when comparing QT to HT (mean difference between QT and HT groups, 3.81; 95% CI: 0.45–7.17; p = 0.03).

When utilizing HT autograft, smaller graft size has been associated with increased failure rates in ACLR.[30] This has prompted investigation into combined autograft–allograft hybrid HT to increase graft diameter, increasing strength, and potentially reducing failure rates.[31],[32] The only RCT published to date, by Li et al. (level I), to compare HT autograft with a hybrid autograft–allograft HT demonstrated no significant differences between the two groups at five-year follow-up.[33] Similarly, a meta-analysis

by Abouljoud et al. (level III) demonstrated no evidence of differences in graft failure between HT autograft and hybrid graft despite a significantly larger graft diameter in the hybrid group.[34]

Findings

Overall, there is level I–II evidence demonstrating lower failure rates when comparing BPTB to HT autografts in ACLR.[21,24] However, both appear to have high success rates and are acceptable options. In young, active populations there is level II evidence demonstrating significantly higher re-rupture rates in HT versus BPTB.[25,26] There is level I evidence demonstrating higher prevalence of anterior knee pain in BPTB versus HT autografts.[24,35] There is level II evidence suggesting that QT is a viable autograft alternative when compared to HT and BPTB autografts when comparing re-tear rates. QT has lower donor site morbidity compared to BPTB and higher functional outcome scores when compared to HT autograft.[27–29] There is level I evidence demonstrating that hybrid graft does not affect graft failure rates when compared to HT autograft.[33]

Resolution of clinical scenario

- Level I–II evidence suggests slightly higher rupture rates in HT when compared to BPTB.[21,24] Level II evidence exists suggesting higher re-rupture rates with HT when compared to BPTB in a young, active population.
- Level I evidence demonstrates higher prevalence of anterior knee pain in BPTB versus HT autograft.[24]
- Level II evidence suggests that QT is a viable alternative to both BPTB and HT and has low re-tear

rates and a more favorable donor site morbidity profile.[27,29]

- Level I evidence demonstrating no difference in graft failure when comparing hybrid graft with HT autograft.[33]

Question 3: In patients undergoing ACL reconstruction, does early surgical intervention improve outcomes compared to delayed reconstruction in both skeletally mature and immature patients?

Rationale

There is still considerable debate regarding the optimal timing of ACL reconstruction in both the skeletally mature and immature populations.

Clinical comment

In the skeletally mature population, proponents of delayed reconstruction cite the risk of arthrofibrosis, subsequent postoperative stiffness and loss of terminal extension which is associated with poor outcomes.[36,37] In contrast, some experts advocate for early reconstruction to reduce the risk of further meniscal or cartilage damage second to instability.[38,39] There is considerable heterogeneity in the literature regarding the definition of early versus delayed reconstruction.[40–43]

In skeletally immature patients, some experts advocate for delayed reconstruction to avoid iatrogenic disturbances to the growth plate as well as the ability to comply with

postoperative rehabilitation.[44],[45] Those in favor of early reconstruction cite the concern of secondary meniscal and chondral damage as a result of ongoing instability.[46]–[49]

Available literature and quality of the evidence

Bottoni et al. (level I) randomized 69 patients to either acute (<3 weeks) or delayed (>6 weeks) ACLR and found no significant differences in postoperative range of motion, articular cartilage damage meniscal between the two groups at an average of one-year follow-up.[41] Lee et al. (level II) performed a meta-analysis on six level I RCTs and one level II cohort study comparing early (nine days to five months) and delayed (10 weeks ≥24 months, mean of 10 weeks).[40] Pooled analysis of included level I studies demonstrated no difference in postoperative clinical outcomes or stability. Differences in chondral or meniscal damage was not assessed.

Granan et al. (level II) performed a cohort study using registry data to assess the relationship between timing of repair and risk of meniscal tears or cartilage damage.[39] A total of 3475 patients were evaluated and they determined that in the adult population (>16) the odds of a cartilage lesion increased by 1.006 (95% CI: 1.003–1.010) for each month that elapsed from injury to surgery. Church and Keating (level III) retrospectively reviewed the incidence of meniscal tears and degenerative changes in patients undergoing ACL reconstruction within 12 months of the injury compared to beyond 12 months.[50] They found a significant increase in both meniscal tears (71.2% vs 41.7%; $p < 0.001$) and degenerative changes (31.3% vs 10.7%; $p < 0.001$) in the delayed group.

There are currently no modern RCTs evaluating the effects of timing of reconstruction in the skeletally immature population. Dumont et al. (level III) retrospectively

reviewed 370 skeletally immature patients undergoing early (<150 days) versus delayed (>150 days) treatment and compared rate of meniscal and chondral injuries.[47] They found a significant increase in medial meniscal tears in the delayed group compared to early reconstruction (53.5% vs 37.8%, p = 0.014; OR = 1.8; 95% CI: 1.12–2.83). The presence of chondral injuries was significantly associated with the presence of meniscal tear in the same compartment. A meta-analysis by Kay et al. (level IV) pooled the results of nine level III–IV studies of 1353 children and adolescents undergoing early or delayed ACLR.[49] There was a significant reduction in medial meniscal tears in early compared to delayed reconstruction (26% vs 47%, pooled RR = 0.49; 95% CI 0.36–0.65, p <0.00001). There was a significant reduction in chondral lesions in the early reconstruction group compared to the delayed group.

Findings

Overall, in the adult population, there appears to be no difference in postoperative functional outcomes or stability in early versus delayed reconstruction. There is level I evidence that there is no difference in chondral or meniscal damage when reconstruction takes place at three versus six weeks postinjury. There are registry data indicating that there is increased risk of chondral and meniscal damage when reconstruction is delayed in the adult population. In the pediatric population, the evidence suggests that early reconstruction is associated with reduced meniscal and chondral injuries.

Resolution of clinical scenario

- Level I–II evidence demonstrates that there is no differences in postoperative functional outcomes or

stability in early versus delayed ACL reconstruction in the adult population.[40],[41] There is considerable heterogeneity in the definition of delayed or early reconstruction.

- Level II–III evidence demonstrates that delayed reconstruction is associated with higher rates of meniscal and chondral damage in skeletally mature patients.[39],[50]
- Level III–IV demonstrates that in the pediatric and adolescent population there is increased risk of meniscal and chondral damage with delayed reconstruction.[47],[49]

Summary of answers

- Autografts may have a lower failure rate when compared to allografts, especially in the young, active population. However, autografts have higher donor site morbidity.
- BPTB have a slightly lower re-rupture rate when compared to HT. QT has comparable re-rupture rates when compared to BPTB and HT with lower donor site morbidity.
- BPTB autografts have a higher prevalence of long-term anterior knee pain when compared to allografts, HT autograft, and QT autograft.
- Delaying reconstruction does not seem to affect postoperative functional outcomes in an adult population. There may be a reduction in concomitant medial meniscal tears with early reconstruction.
- In a pediatric and adolescent population, early reconstruction is favored and has been shown to reduce

the prevalence of meniscal tears and chondral damage.

- Concomitant anterolateral ligament reconstruction or lateral extra-articular tenodesis reduces postoperative instability and re-rupture rates in young patients at a high risk of graft failure.

136 Posterior Cruciate Ligament Injuries

Chetan Gohal MD[1], Nolan S. Horner MD[1], Jihad Abouali MD[2], and John Theodoropoulos MD MSc[2]
[1] Division of Orthopaedic Surgery, Department of Surgery, McMaster University, Hamilton, ON, Canada
[2] Division of Orthopaedic Surgery, University of Toronto, Toronto, ON, Canada

Clinical scenario

- A 19-year-old male soccer goalkeeper hit on left anterior shin while jumping with knees flexed trying to catch a ball.
- Sudden onset pain in left knee joint and inability to play the rest of the game.
- On assessment, patient has an effusion in the left knee joint, lack of full extension, and 9 mm of anterior posterior laxity.
- No fractures on plain film radiographs.

Top three questions

1. In patients with a posterior cruciate ligament (PCL) injury, how accurate is the clinical examination in the diagnosis of PCL injury compared to magnetic resonance imaging (MRI)?
2. In patients with isolated PCL injury, does reconstruction surgery result in improved patient-

centered outcomes compared to nonoperative management?

3. In patients with isolated PCL injury, does a double-bundle (DB) reconstruction technique result in improved patient-centered outcomes compared to a single-bundle (SB) reconstruction technique?

Question 1: In patients with a posterior cruciate ligament (PCL) injury, how accurate is the clinical examination in the diagnosis of PCL injury compared to magnetic resonance imaging (MRI)?

Rationale

The ability to accurately diagnose a PCL tear in both the acute and the chronic setting is essential in guiding treatment by an orthopedic surgeon.

Clinical comment

PCL injury is often overlooked by both patients and clinicians, and for this reason it is important that sensitive and specific tools are used in the diagnostic process.[1] There is large variability in the reported rate of injury to the PCL with numbers ranging between 1 and 44% of all acute knee injuries depending on the population studied.[2–4] The sensitivity, specificity, and accuracy of MRI have been found to approach 100% in the diagnosis of PCL injuries.[5] However, accurate diagnosis via clinical exam would increase the ease and cost-effectiveness of diagnosis and could facilitate the earlier detection and treatment of PCL injuries.

Available literature and quality of the evidence

- Level I: 1 retrospective cohort examining accuracy of MRI[5] and 1 randomized controlled trial (RCT) examining physical exam versus MRI.[6]
- Level III: 1 systematic review examining physical exam versus reference standard: arthrotomy, arthroscopy, or MRI.[7]
- Level IV: 3 case series examining accuracy of MRI.[8–10]

Findings

The last double-blinded, RCT examining clinical tests for PCL insufficiency was performed in 1994 by Rubinstein et al.[6] Using direct comparison to MRI, the study found that there was a 96% overall clinical examination accuracy in diagnosing chronic PCL injuries amongst sports medicine fellowship-trained orthopedic surgeons, with a 90% sensitivity and 99% specificity in detecting a PCL tear. However, interobserver disagreement about the grade of injury existed in 19% of cases. The posterior drawer test was found to be the most sensitive and specific clinical test; however, for grade 1 laxity it was found to only have a sensitivity of 70%. A systematic review of level II and III studies by Kopkow et al. concluded that the diagnostic accuracy of physical exam tests for PCL injury was largely unknown due to poor quality evidence with high risk of bias.[7] Multiple level III[5] and IV[8,9] studies have suggested that the accuracy of MRI for the diagnosis of acute PCL injury approaches 100%. Its accuracy for chronic PCL injuries, on the other hand, has been shown to be as low as 57% in a level IV case series by Servant et al.[10]

Another method of diagnosis to consider for PCL injuries not included in the studies above is posterior stress

radiography, which can be superior to arthrometric evaluation in quantifying posterior tibial translation.[11] Its efficacy and comparison to MRI need to be studied further.

Resolution of clinical scenario

- One level I study suggests that the overall clinical examination accuracy in diagnosing chronic PCL injuries is excellent (96%).
- The majority of studies examining diagnostic accuracy of physical exam for PCL injury are old and contain high risk of bias.
- Level III and IV studies suggest the accuracy, specificity, and sensitivity of MRI in detecting acute PCL injury approaches 100% but is much less accurate for chronic PCL injury.
- Return to case: for the male goalkeeper with a mechanism of injury concerning for PCL injury, MRI would be helpful in the acute setting for diagnosis. Clinical examination is nearly as accurate as MRI if assessed in the chronic setting. However, MRI may still be helpful to rule out associated pathology, such as posterolateral corner (PLC) injury, or for preoperative planning.

Question 2: In patients with isolated PCL injury, does reconstruction surgery result in improved patient-centered outcomes compared to nonoperative management?

Rationale

All surgical procedures pose a risk to the patient. The orthopedic surgeon needs relevant evidence-based data on long-term outcomes and risks in order to determine whether the benefit of surgical reconstruction is greater than conservative treatment and whether the risk/benefit ratio is justifiable.

Clinical comment

PCL injuries can be classified based on grade. A grade 1 PCL injury has 1–5 mm of posterior translation of the tibia on the femur on posterior drawer test as compared to the contralateral knee, grade 2 has 6–10 mm of translation, and grade 3 has >10 mm.[12] Typically, nonsurgical management has been advocated for patients with isolated grade 1 or 2 PCL injuries or for those who have grade 3 injuries with mild symptoms or low activity demands.[13] Nonoperative treatment involves use of a dynamic anterior drawer brace and focused rehabilitation.

Available literature and quality of the evidence

- Level III: 2 retrospective cohort studies.[14],[15]
- Level IV: 3 case series on outcomes of nonoperative management of isolated PCL injury.[12],[16],[17]
- Level IV: 1 systematic review of level III and IV studies comparing long-term outcomes after operative and nonoperative management of isolated PCL injuries.[18]

Findings

In a retrospective comparative cohort study of 4169 patients, Wang et al. evaluated long-term results of PCL deficiency and found that patients with PCL reconstruction had a decreased cumulative incidence of meniscus tear (0.41%), osteoarthritis (OA) (2.30%), and subsequent total

knee replacement (TKR) (0.48%) compared with patients who were treated nonoperatively (2.44%, 3.46%, 1.69%; all $p < 0.05$).[14] After adjusting for covariates, PCL-injured patients who underwent reconstruction within one year after PCL injury showed a significantly lower risk of these aforementioned sequelae than those who never underwent reconstruction (within one month: adjusted hazard ratio [HR] = 0.390; 95% confidence interval [CI] = 0.284–0.535; one month to one year: adjusted HR = 0.546; 95% CI = 0.398–0.748). The study did not specify the initial grade of PCL injury. Another retrospective cohort, by Patel et al., followed 57 patients (58 knees) with isolated grade 1 or 2 PCL injuries treated nonoperatively with rehabilitation programs over a mean 6.9 years.[15] At latest follow-up, 66% of patients had no knee pain and 10% had moderate knee pain on exertion. Lysholm-II knee scores were excellent in 23 knees (40%), good in 30 knees (52%), fair in two knees (3%), and poor in three knees (5%). No statistically significant correlation ($p = 0.097$) was seen between the grade of PCL laxity and Lysholm-II knee score. Shelbourne et al. also found no correlation between knee laxity and subjective knee scores or radiographic changes in a 10-year follow-up case series of 68 patients who underwent nonsurgical treatment of acute, isolated grade 1 or 2 PCL injuries.[16] On the other hand, a case series by Keller et al. of patients with PCL tears treated nonoperatively reported that those with greater ligamentous laxity had more subjective complaints, lower overall knee scores, and were less likely to return to their preinjury activity level.[12] However, unlike the aforementioned studies, Keller et al. also included patients with grade 3 initial knee laxity. Jacobi et al. found the use of dynamic PCL bracing for four months after isolated acute PCL injury significantly reduced initial posterior sag from 7.1 mm to 2.3 mm at 12

months and restored continuity of PCL on MRI in 95% of patients at six months.[17]

Although no level I comparative studies between operative and nonoperative management for PCL injuries have been done, a systematic review of 12 level III and IV studies by Shelbourne et al. in 2017 reported that Tegner scores, International Knee Documentation Committee (IKDC) scores, and Lysholm scores were comparable between operative (n = 6) and non-operative (n = 66) studies (Table 136.1).[18] The authors concluded that, outside of laxity, nonoperative management of isolated PCL tears compared favorably with the long-term results of operative management.

Table 136.1 Summary of outcomes from a systematic review by Shelbourne et al.[18]

Outcomes at final follow-up	Nonoperative studies	Operative studies
Final follow-up times (years)	6.2–15	6.3–12
Tegner scores	6.6–7.7	5.7–7.4
IKDC scores	73.4, 82.7, 84	65, 87
Lysholm scores	85.2	81–92.1
Rates of osteoarthritis	17–88%	13.3–63.6%

Resolution of clinical scenario

- Level III evidence suggests PCL reconstruction may decrease the cumulative incidence of meniscal tears, OA, and subsequent TKR in the long term; however, grade of initial injury was not specified.
- Level III and IV evidence suggests that nonoperative management of grade 1 or 2 PCL tears results in

comparable functional outcome scores as operative management in the long term. It should be noted that these studies did not include bony avulsions of the PCL, for which surgical management is typically advocated.[13]

- Level III evidence suggests that treating grade 1 or 2 PCL injuries with bracing significantly reduces initial posterior sag and restores continuity of PCL on MRI in the majority of patients.
- Return to case: the goalkeeper is found to have an isolated PCL injury with 9 mm of anterior posterior laxity (grade 2). He is treated nonoperatively with a dynamic anterior drawer brace and sent for functional rehabilitation.

Question 3: In patients with isolated PCL injury, does a double-bundle (DB) reconstruction technique result in improved patient-centered outcomes compared to a single-bundle (SB) reconstruction technique?

Rationale

A number of different surgical techniques exist to reconstruct the PCL. Understanding the patient-important outcomes associated with these techniques and whether one is superior can help orthopedic surgeons choose the best operative technique.

Clinical comment

Surgical management of isolated PCL injuries is typically reserved for patients with symptomatic grade 3 injuries who continue to have pain or clinical instability despite nonoperative management.[13] One of the main controversies regarding surgical technique for posterior cruciate ligament reconstruction (PCLR) include use of an SB or DB technique. An SB technique reconstructs only the anterolateral bundle (ALB) of the PCL, while a DB technique aims to restore normal anatomy and native knee kinematics by reconstructing both the ALB and the posteromedial bundle (PMB).[19] These can be further modified by utilizing a transtibial technique or tibial inlay technique. Transtibial technique involves centering the femoral and tibial tunnels on the ALB footprint, for which concern has been reported regarding the sharp angle that the PCL graft forms at the proximal aperture of the tibial tunnel. Thus, the tibial inlay technique was developed, which involves securing a bone plug with a cannulated screw in a bone trough created in the tibial PCL attachment site.[20]

Available literature and quality of the evidence

- Level III: 1 systematic review and meta-analysis comparing SB PCLR to DB technique,[21] 1 systematic review,[22] 3 prospective RCTs, 8 case-control studies, 7 retrospective cohort studies.

Findings

A systematic review and meta-analysis of level II and III studies (n = 441 patients) by Chahla et al. compared SB and DB PCLR techniques at minimum two-year follow-up. The authors found significantly improved objective posterior tibial stability and objective IKDC scores in the DB cohort, but no significant differences in postoperative

Lysholm or Tegner scores.[21] Focusing on the randomized trials, Wang et al. found no difference in functional assessment, posterior tibial translation, knee scores, or radiographic changes between SB and DB PCLR.[23] However, both Yoon et al. and Li et al. reported significant decreases in posterior tibial translation with DB technique compared to SB.[24],[25] Whether this difference in posterior translation is clinically significant is unknown.

A limitation when comparing SB to DB PCLR in the aforementioned studies is the variation in use of transtibial and tibial inlay techniques. However, whether utilizing these different techniques will influence clinical outcomes is unclear. A systematic review of seven retrospective studies (n = 149 patients transtibial, 148 patients tibial inlay) found no clinically important differences between transtibial and tibial inlay techniques, including Tegner or Lysholm scores or residual laxity.[22]

Resolution of clinical scenario

- Currently, the literature is lacking any level I clinical studies to definitively determine the superiority of a specific PCLR technique, including SB versus DB and transtibial versus tibial inlay techniques.
- Level III evidence suggests the DB technique improves objective posterior tibial stability relative to SB technique, but the clinical relevance of this remains unclear. There is no significant difference found in Lysholm or Tegner scores.
- Return to case: after four months of intensive physiotherapy and bracing, the patient has not been able to fully return to sport at his previous level and returns to the clinic. Posterior laxity is now approximately 11 mm (grade 3) and a reconstruction is

planned. The surgeon decides to do an arthroscopic SB transtibial PCLR, as this is the surgeon's preferred technique and no one technique has been shown to be superior in the literature.

Summary of answers

- The overall clinical knee examination has a 96% accuracy in diagnosing chronic PCL injuries.
- Low-quality evidence suggests the accuracy, specificity, and sensitivity of MRI for diagnosis of acute PCL injuries approaches 100%, but is less accurate for chronic injuries.
- Grade 1 and 2 PCL injuries treated nonoperatively have comparable long-term knee function scores as those treated operatively.
- Low-quality evidence suggests PCL reconstruction could decrease the cumulative incidence of meniscal tears, OA, and subsequent TKR in the long term.
- DB PCLR may improve objective posterior tibial stability relative to SB PCLR, but there is no clinical difference in Lysholm or Tegner scores.
- Future high-quality studies are needed to determine the superiority of one PCLR technique over the others.

137 Combined Anterior Cruciate Ligament and Medial Collateral Ligament Injuries

Domiziano Tarantino MD[1], Rocco Aicale MD[1], and Nicola Maffulli MD MS PhD FRCS (Orth)[1,2]

[1] Department of Musculoskeletal Disorders, School of Medicine and Surgery, University of Salerno, Salerno, Italy

[2] Queen Mary University of London, Barts and the London School of Medicine and Dentistry, Centre for Sports and Exercise Medicine, Mile End Hospital, London, UK

Clinical scenario

- A 27-year-old woman presents to the outpatient clinic with pain and giving way in her left knee. The patient mentions having fallen while skiing two months before. At the time of the injury, she heard a “pop” followed by about four days of knee pain and swelling, forcing her to remain immobile.
- On examination, abnormal anterior laxity was detected in the injured left knee. In addition, there is a grade III positive valgus stress test.
- Two weeks after the trauma, feeling well, the patient resumed playing sports. While playing basketball, she experienced the first episode of her knee giving way.
- Magnetic resonance imaging (MRI) confirms the diagnosis of a combined anterior cruciate ligament and medial collateral ligament (ACL+MCL) injury.
- The patient undergoes surgical treatment with an arthroscopic reconstruction of the ACL, and open repair of the MCL.

Top three questions

1. In patients with ACL+MCL tears, are some clinical examination maneuvers more accurate in terms of diagnostic ability compared to others?
2. Are there any specific risk factors that predispose individuals to combined ACL+MCL injuries?
3. In patients with ACL+MCL tears, does a specific treatment result in better clinical outcomes compared to others?

Question 1: In patients with ACL+MCL tears, are some clinical examination maneuvers more accurate in terms of diagnostic ability compared to others?

Rationale

It is important to know how to accurately diagnose a combined ACL+MCL injury, since clinical examination plays a crucial role in the diagnosis. Advanced imaging (i.e. MRI) is appropriate, but should not replace a thorough history and physical examination.[1]

Clinical comment

Many clinical diagnostic tests are available to diagnose ligamentous injuries, and they require a thorough understanding of the anatomy and the biomechanics of the joint. The most commonly used are the valgus stress test (Table 137.1), Lachman test, and the anterior drawer test.

Table 137.1 Classical method of grading MCL injuries using the valgus stress test. Source: Adapted from Reider[2] and Bollier and Smith.[3]

Grade I	MCL is tender and swollen but exhibits no increased laxity; it signifies a partial injury to some fibers without elongation of ligament
Grade II	MCL is elongated but not completely disrupted; there is increased tenderness and laxity to the valgus stress test but with a firm endpoint
Grade III	MCL has lost all structural integrity so there is laxity without endpoint and instability • 1+ (3–5 mm) • 2+ (6–10 mm) • 3+ (>10 mm)

Available literature and quality of the evidence

Levels I–V evidence exists to answer this question.

Findings

A case series study by Kastelein et al. evaluated the reliability of pain valgus stress test (PVST) and laxity valgus stress test (LVST) comparing

them with MRI data.[4] The sensitivity and specificity were 0.78 (0.64–0.92) and 0.67 (0.57–0.76), respectively, for PVST and 0.91 (0.81–1.00) and 0.49 (0.39–0.59), respectively, for the LVST.

The valgus stress test is the best way to assess the competency of the MCL complex (superficial and deep MCL fibers). Pain or laxity with valgus stress applied through the knee indicates an MCL injury, and it allows the clinician to establish the degree of the lesion.[2]

The Lachman test and the anterior drawer tests are the most common tests for diagnosing anterior instability of the knee. A systematic review and meta-analysis by Huang et al. showed good reliability of these tests in diagnosing ACL injuries.[5] The Lachman test sensitivity ranges from 0.84 to 0.9 and the specificity from 0.89 to 0.93. The sensitivity of the anterior drawer test ranges from 0.69 to 0.76 and the specificity from 0.91 to 0.94.

The pivot shift test is a dynamic test that demonstrates the subluxation occurring when the ACL is nonfunctional.[3] The sensitivity of the pivot shift test ranges from 0.43 to 0.55, and the specificity from 0.95 to 0.99.[4]

Overall, many clinical diagnostic tests are available to diagnose ligamentous injuries. Level IV[4] and V[2] evidence suggests that PVSTs and LVSTs have a high sensitivity in detecting ACL+MCL tears, and can establish the degree of the lesion. Level I evidence suggests that the Lachman test have high sensitivity and specificity, while the anterior drawer test shows good sensitivity and high specificity.[5] Level I evidence also suggests that the pivot shift test shows a low sensitivity and a high specificity.[5]

Resolution of clinical scenario

- Level IV and V evidence demonstrates that suspected MCL lesions should be assessed by the valgus stress test for the MCL.
- Level I evidence demonstrates that suspected ACL lesions should be assessed by the Lachman test, the anterior drawer test, and the pivot shift test.

Question 2: Are there any specific risk factors that predispose individuals to combined ACL+MCL injuries?

Rationale

Sport is an important risk factor for ACL+MCL injuries, but many recent studies showed that sex and anatomical features can also predispose patients to ligament rupture.

Clinical comment

ACL tear is a multifactorial injury involving biomechanical, neuromuscular, hormonal, anatomical, and genetic mechanisms.[6] Risk factors can lead to poor control and high mechanical loads on both ACL and MCL during athletic movements like landing, cutting, pivoting, and twisting.[7] In particular, females, with maturity, experience worsening of their neuromuscular joint control.[8]

Available literature and quality of the evidence

Level I–V evidence exists to answer this question.

Findings

The ACL injury rate for female athletes is often reported as being 2–8 times higher than the rate for male athletes in the same sport at the same level of competition.[9–11]

Recent controlled laboratory studies focused on the influence of loading on the ACL and MCL,[12–15] and demonstrated that both ligaments experience strains during multiplanar simulated jump landing, with the ACL being loaded more and expressing larger peak strains than the MCL during physiologic athletic tasks.

Schilaty et al. performed two controlled laboratory studies on cadaveric specimens which confirmed that females experience a greater strain on the ACL when compared to males during simulated jump landing tasks, but that there were no differences in MCL loading between sexes, with only a minimal increase of MCL loading during the impact forces.[16,17]

Some studies have demonstrated that narrow intercondylar notch dimensions are associated with the risk of ACL injury, and that lower intercondylar notch width index (NWI) and intercondylar notch width (NW) stenosis predispose to ACL injury.[18,19]

Overall, level II evidence suggests that female athletes have the highest risk of ACL injury.[7,11]

Level V evidence suggests that both ACL and MCL experience strains during multiplanar simulated jump landing,[12–15] and that females experience a greater strain on the ACL when compared to males during simulated jump landing tasks, with no differences in MCL loading between sexes.[16,17] Level I[18] and level III[19] evidences suggest that

narrow intercondylar notch dimensions are associated with the risk of ACL injury.

Resolution of clinical scenario

- Level II, III, and V evidence demonstrates that a combined ACL–MCL lesion should be suspected in athletes (especially if female) with well-recognized risk factors playing sports that have a high risk for ligament injuries.
- Level I and III evidence demonstrates that a combined ACL–MCL lesion should be suspected in patients with a narrow femoral intercondylar notch or in whom diagnostic tools such as MRI show a smaller NWI.

Question 3: In patients with ACL+MCL tears, does a specific treatment result in better clinical outcomes compared to others?

Rationale

It is important to know the treatment options for combined ACL+MCL tears; the options vary depending on the grades of lesion in each ligament.

Clinical comment

Currently, the described options are as follows: full conservative MCL–ACL treatment, full surgical MCL–ACL treatment, combined surgical MCL and conservative ACL treatment, and combined conservative MCL and surgical ACL treatment. Table 137.2 summarizes the available literature.

Table 137.2 Relevant data of each study on ACL+MCL combined tears.

Author	n	MCL Grade diagnosis		Treatment MCL injury	ACL injury	Outcome
Blanke et al.[21]	**5**	**II**	**MVST and IKDC grading**	**Surgery**	**Surgery**	At final follow-up all patients had no problems in activities of daily living with normal ROM. All patients reached full range of motion in flexion and extension equivalent to grade A according to IKDC score
Dong et al.[24]	**69**	**III**	**MVST, radiographic stress-position imaging, and IKDC grading**	**Surgery**	**Surgery**	At follow-up, 89% of patients group had returned to a normal or nearly normal level of sports participation. Most patients showed no signs of trouble during their daily routine, with normal or nearly normal ROM

Author	n	MCL Grade diagnosis		Treatment MCL injury	ACL injury	Outcome
Ateschrang et al.[27]	**16**	**II–III**	**MVST at 0° and 30°, and valgus stress radiograph at 0° and 20°**	**Surgery**	**Surgery**	ROM improved gradually after 6 and 12 weeks postoperatively, resulting in good function after one year. Knee range of motion was reduced slightly after three months postoperatively and nearly normal at one-year follow-up
Blanke et al.[22]	**67**	**I–III**	**MVST at 0° and 30° and IKDC grading**	**Combined**	**Surgery**	At the final follow-up, all patients had no problems in activities of daily life with normal or nearly normal ROM. All the patients had returned to performing at a normal or nearly normal level of sports

Author	n	MCL Grade diagnosis		Treatment MCL injury	ACL injury	Outcome
Piątkowski et al.[30]	**27**	**III**	**MVST at 0° and flexion, and MRI**	**Surgery**	**Surgery**	Good and very good functional outcomes in the Lysholm scale were seen in 74% of the sample. Good and excellent outcomes were achieved by 63% of the patients in the IKDC scale. There were three cases of major ROM limitation

Author	n	MCL Grade diagnosis		Treatment MCL injury	ACL injury	Outcome
Zhang et al.[23]	**21**	**II–III**	**Valgus stress radiograph at 20°, MRI, and IKDC grading**	**Surgery**	**Surgery**	At follow-up, no patient exhibited anteromedial rotatory instability (AMRI), and 95% of patients had full ROM of the affected knee. The 90% of patients returned to their preinjury activity level postoperatively, whereas two patients were still participating at a lower activity level and complained of pain in the knee

Author	n	MCL Grade diagnosis		Treatment MCL injury	ACL injury	Outcome
Koga et al.[25]	**17**	**III**	**MVST at 0° and 30°**	**Surgery**	**Surgery**	Almost all patients recovered sufficient valgus stability in valgus stress radiograph, and the median Lysholm score was 91. Valgus laxity with concurrent residual laxity of reconstructed cruciate ligaments progressed in two patients postoperatively

Author	n	MCL Grade	diagnosis	Treatment MCL injury	ACL injury	Outcome
Liu et al.[26]	**7**	**—**	**Valgus stress radiograph at 20°, IKDC grading**	**Surgery**	**Surgery**	At the final follow-up, almost all patients had improved in terms of valgus laxity, and both the IKDC subjective scores and Lysholm scores significantly improved postoperatively. None of the patients had limitations of knee extension, and the patients did not complain of subjective functional knee problems

Author	n	MCL Grade diagnosis		Treatment MCL injury	ACL injury	Outcome
Kitamura et al.[32]	**16**	**III**	**Valgus stress radiograph at 20°, arthroscopy, and IKDC grading**	**Surgery**	**Surgery**	At the final follow-up, one patient showed a loss of knee extension of more than three. Lysholm scores averaged 94.8 points. In the IKDC evaluation, most patients were graded as A or B. The clinical outcome with a minimum two-year follow-up was favorable with satisfactory stability

Author	n	MCL Grade diagnosis		Treatment MCL injury	ACL injury	Outcome
Marx and Hetsroni[29]	**13**	**III**	**MVST, arthroscopy**	**Surgery**	**Surgery**	Knee motion was maintained in nearly all cases. Grade 0–1+ valgus stability was obtained in all cases. In cases of MCL with primary ACL reconstruction, IKDC subjective, Lysholm, and KOOS sports scores were 91 ± 6, 92 ± 6, and 93 ± 12, respectively, and return to preinjury activity levels was achieved

Author	n	MCL Grade diagnosis		Treatment MCL injury	ACL injury	Outcome
Dong et al.[28]	**29**	**—**	**MVST, radiographic stress-position imaging, and IKDC grading**	**Surgery**	**Surgery**	Most patients had normal or nearly normal range of motion of the knee joint. In 83.9% of patients the symptoms were graded as normal or nearly normal according to IKDC symptom scores. The 91.1% of patients had returned to performing at a normal or nearly normal level of sports

Author	n	MCL Grade diagnosis		Treatment MCL injury	ACL injury	Outcome
Westermann et al.[31]	**27**	**III**	**KOOS, IKDC, and Marx activity scores**	**Combined**	**Surgery**	At the baseline, lower KOOS and IKDC scores were seen in patients who underwent operative MCL treatment. At two years the nonoperative MCL cohort maintained significantly better KOOS Sports Rec (88.2 vs 74.4), KOOS QOL (81.3 vs 68.4), and IKDC (87.6 vs 76.0) scores compared to the MCL surgery group. Marx activity scores were equal between groups at the time of study enrollment; however, patients who underwent operative MCL management had lower activity scores at two years (6.5 vs 10.7)

IKDC, International Knee Documentation Committee score; MVST, manual valgus stress test; ROM, range of motion; KOOS, Knee injury and Osteoarthritis Outcome Score.

Available literature and quality of the evidence

Level I–IV evidence exists to answer this question.

Findings

Grade I MCL lesions

While surgical treatment of an ACL rupture is well established to allow individuals to return to demanding activities, the treatment of concomitant MCL lesions is controversial. Conservative treatment of concomitant grade I MCL injuries is generally advised, given the good healing potential of this ligament.[20–26]

Grade II MCL lesions

The optimal treatment regimen of concomitant grade II MCL lesions remains unclear, with a tendency toward surgical intervention.[20,21] However, a standard surgical technique for grade II MCL lesions does not exist. Blanke et al. suggested a surgical technique for grade II concomitant MCL lesions that improved both valgus and anterior stability, and led to excellent short-term results at final follow-up.[21]

One year later, Blanke et al. proposed a new treatment concept for concomitant lesions of the MCL and ACL: for grade II MCL lesion, they suggested conservative treatment in the absence of AMRI.[21] Surgical management was proposed in the presence of AMRI. The outcomes, at the final follow-up, were optimal for both nonoperative and operative procedures, with the former being more satisfactory. AMRI seems to be a crucial factor for the decision between the surgical and nonsurgical treatment of concomitant MCL lesions, and should be considered in the treatment decision, especially in grade II MCL lesions. The possibility of conservative treatment should be taken into account depending on patient preferences, since spontaneous healing and downgrading of the MCL lesion is possible.

Ateschrang et al. presented the first clinical results grade II and III MCL reconstruction by a novel minimally invasive ligament bracing technique in combination with a single-bundle ACL reconstruction within 14 days of injury.[27] They reported good clinical results and objectively restored knee stability without cases of knee stiffness or arthrofibrosis.

Grade III MCL lesions

In 2012, Dong et al. presented a novel triangular shape, double-bundle allograft technique with a reconstruction of chronic MCL injury in patients with medial instability of the knee, and investigated its clinical

outcomes and with a follow-up of 33 months on average.[28] They reported improved valgus and rotational stability in the short term, with patients being able to return to a normal or nearly normal levels of sports. The authors of that study also cautioned against using this technique in acute cases due to risk of scarring and stiffness.

Koga et al. treated acute cases of medial knee injury (MCL and posterior oblique ligament) combined with cruciate ligament injuries initially conservatively, followed by subsequent operative treatment for residual grade III valgus instability combined with ACL reconstructions.[25] The clinical outcomes of their surgical management strategy were reasonable in terms of restoring medial knee stability, although valgus laxity with concurrent residual laxity of reconstructed cruciate ligaments progressed in some patients.

Marx and Hetsroni evaluated 12 patients who had ACL and MCL reconstructions, with the latter being performed using Achilles allograft, small incisions, and anatomic insertions to reconstruct the MCL.[29] Patients were first treated nonoperatively for 10 weeks using braces, then underwent surgery in case of increased valgus laxity. With this combined procedure, return to preinjury activity level in recreational athletes was achieved.

The treatment approach suggested by Zhang et al. for patients with chronic combined ACL-grade III MCL tears was nonoperative treatment for the MCL and late ACL reconstruction, using bracing for six weeks to allow the MCL to heal.[23] If nonoperative treatment of the MCL failed after appropriate nonoperative management, they performed simultaneous reconstruction of both the ACL and MCL. The outcomes were improved anterior, valgus, and rotatory stability of the knee, along with good functional result at a minimum follow-up of two years.

While all the previous studies advocated nonoperative treatment as the first choice for acute MCL injury, Piątkowski et al. and Dong et al. performed their surgical treatment in the acute setting.[24],[30] They performed a two-stage operative treatment (MCL repair first, and delayed ACL repair) in patients with acute anteromedial instability of the knee. Good or very good clinical outcomes were achieved according to the International Knee Documentation Committee (IKDC) scale and the Lysholm scale. Unsatisfactory functional outcomes and risk of complications were seen more often in older patients, suggesting that this technique is currently recommended in younger individuals.

Dong et al. compared the clinical results of two techniques – the triangular ligament reconstruction (TLR, described above[28]) and the anatomic ligament repair (ALR) – in the treatment of acute grade III MCL

injury combined with an ACL tear.[24] Clinical outcomes showed no major difference in the ALR and TLR groups based on IKDC scores and medial opening evaluations in the short-term. However, TLR offered better rotatory stability than ALR at final follow-up.

Finally, Westermann et al. showed that both operative and nonoperative management of MCL tears demonstrated clinical improvements between study enrollment and two-year follow-up, but that MCL surgery during ACL reconstruction was associated with more frequent stiffness, worse patient-reported outcomes and lower activity at two years, with a higher reoperation rate for arthrofibrosis after operative repair of the MCL (19%) versus nonoperative treatment (9%).[31]

Overall, the management of combined ACL+MCL injuries is widely debated and should be tailored based on injury grade and individual goals for each patient. In combined ACL grade I MCL tears, level I[24] and level IV evidence[20–23,25,26] suggests that while the ACL is treated surgically the MCL can be treated conservatively.

In combined ACL grade II MCL tears, level II[23] and IV[19–21] evidence suggests that a clearly preferred option for grade II MCL lesions does not exist, and that the MCL can be treated both surgically or conservatively, with a recent tendency toward surgical intervention.

In combined ACL grade III MCL tears, level II[24,31] and IV[23,25,28–30] evidence suggests that grade III MCL tears can be treated nonoperatively at first (with surgery being performed later in case of failed conservative management) or surgically in the acute setting.

Given the lack of standardization in the selection process of patients, timing of surgery, surgical technique (combined or two-stage), outcome criteria, and outcome assessment, this question still remains largely unanswered.

Resolution of clinical scenario

- Level I and IV evidence demonstrates that in patients with suspected ACL–MCL injury, isolated partial and grade I injuries of the MCL can be managed nonoperatively.
- Level II and IV evidence demonstrates that there are no differences in outcomes when an ACL injury associated with grade II MCL injury is addressed by surgical reconstruction of ACL and conservative measures or surgical repair of MCL.
- Level II and IV evidence demonstrates that surgical repair for combined ACL grade III MCL injury is advocated. Early versus late ACL reconstruction is still controversial.

Summary of answers

- Suspected MCL lesions should be examined by the valgus stress test.
- Suspected ACL lesions should be examined by the Lachman test, the anterior drawer test, and the pivot shift test.
- An ACL+MCL lesion should be suspected in patients (especially if female) playing sports that have a high risk for ligament injuries, and in patients with a previous diagnosis of narrow femoral intercondylar notch or in whom diagnostic tools such as MRI show a smaller NWI.
- Isolated partial and grade I MCL injuries can be managed nonoperatively.
- There are no differences in outcomes when an ACL injury associated with grade II valgus laxity is addressed by surgical reconstruction of ACL and conservative measures or surgical repair of MCL.
- Surgical repair for combined ACL grade III MCL injury is advocated. Early versus late ACL reconstruction is still controversial.

138 Multiligamentous Knee Injuries

James P. Stannard MD and Hee Young Lee MD
University of Missouri Department of Orthopaedic Surgery, Columbia, MO, USA

Clinical scenario

- A 32-year-old male construction worker is involved in a motor vehicle collision on the way home from work. He sustains a right femur fracture and is noted to have mild swelling around the right knee as well.
- After intramedullary nailing of the femur the next day, it is noted that the patient has gross knee instability in all directions.
- He has a normal vascular exam with 2+ pulses bilaterally for both the dorsalis pedis and posterior tibial arteries.

Top three questions

1. In patients undergoing surgical treatment for knee dislocation, does collateral ligament reconstruction result in better clinical outcome compared to repair?
2. In patients diagnosed with knee dislocation, does acute reconstruction within three weeks after the injury result in improved results compared to delayed reconstruction?
3. In patients undergoing knee surgery, does restricted blood flow therapy yield better clinical outcomes, muscle strength, and size compared to conventional rehabilitation?

Question 1: In patients undergoing surgical treatment for knee dislocation, does collateral ligament reconstruction result in better clinical outcome compared to repair?

Rationale

Traditional instruction has been that medial and lateral corners should be repaired if good quality tissue is present and the repair is accomplished within three weeks. However, the current opinion is that the failure rate is lower for both the posteromedial corners (PMCs) and posterolateral corners (PLCs) with reconstruction of the ligaments when compared with repair. Thus, it is important to understand if, and by how much, reconstruction improves clinical outcomes.

Clinical comment

Dislocation of the knee refers to a multiligamentous knee injury that frequently includes a bi-cruciate injury.[1] Commonly, knee dislocation results in disruption of at least three of the four major ligaments of the knee and leads to significant functional instability. Vascular and neurologic damage, as well as associated fractures, can complicate the treatment of the multiligament-injured knee.[2]

Early versus delayed surgery, repair versus reconstruction, and autograft versus allograft tissue for reconstruction remain topics of debate. High-quality research efforts to investigate these controversies are hampered by the heterogeneous nature of the injuries themselves, the relatively infrequent occurrence of knee dislocations, and the many treatment strategies available.[3]

Available literature and quality of the evidence

Posteromedial corner (PMC)

Stannard et al. reported a significant difference between the failure rate of PMC repairs and PMC reconstructions treated within four weeks of the injury. This study compared the outcomes in knee dislocation patients whose injury included a torn PMC. A total of 71 knee dislocation patients with 73 PMC tears qualified for the study and were followed for a mean of 43 months. A total of 25 patients had a repair, with five failures (20%), compared with 48 patients who had a reconstruction (with auto- or allograft) with only two failures (4%). Reconstruction of the PMC using a technique that re-establishes the critical triangle of the medial collateral ligament, the posterior oblique ligament, and the semitendinosus yielded better stability than repair in patients with a knee dislocation that included PMC instability.[4]

Posterolateral corner (PLC)

In direct comparisons of repair versus reconstruction, there are two publications regarding high-grade lateral/posterolateral injuries. Stannard et al. reported a significant difference in favor of reconstruction when evaluating stability and return to sport.[5] They did not detect a statistically significant difference in Lysholm, International Knee Documentation Committee (IKDC) scores, or return to work rates between the two groups of 57 knees. Levy et al. initially repaired lateral injuries before reconstruction. The 40% (4 of 10) failure rate in the repair group was reduced to a 6% (1 of 18) failure rate in the reconstruction group.[6] Due to the higher failure rate of repair compared to reconstruction (40% vs 6% in one cohort and 37% vs 9% in another cohort), repair is not currently recommended.[2],[6] However, avulsed ligaments,

particularly off the fibular head (lateral collateral ligament, LCL; popliteofibular ligament PFL, and the biceps tendon) should be repaired. Additionally, it is recommended that capsular tissue and the lateral meniscocapsular ligaments should be reattached to the bone.[7]

- Level II: 3[1],[4],[5]
- Level III: 3[2],[3],[6]
- Level V: 1.[7]

Findings

Level II evidence indicated a significant difference in objective stability with reconstruction but did not indicate a significant difference in Lysholm, IKDC scores, or return to work rates.

Resolution of clinical scenario

- Reconstruction of the PMC and PLC is recommended to avoid treatment failure.

Question 2: In patients diagnosed with knee dislocation, does acute reconstruction within three weeks after the injury result in improved results compared to delayed reconstruction?

Rationale

The timing of surgical reconstruction remains controversial. Reconstruction during the acute phase after the injury allows patients to recover from fractures and

knee reconstruction simultaneously. However, the risk of skin breakdown and arthrofibrosis may be higher during the acute inflammatory phase immediately following the injury. Early surgical reconstruction has been reported to yield better functional and clinical outcomes, and reduction of the risk of additional chondral and meniscal injuries as a result of instability.[8]

Clinical comment

Some authors have reported that early surgery resulted in arthrofibrosis, and a low rate of return to work. In contrast, delayed surgery has been reported to show restoration of preoperative knee range of motion (ROM) and reduced wound complications after resolution of swelling postoperatively.[9]

Available literature and quality of the evidence

The heterogeneous nature of knee dislocations involving more than two ligament injury combinations makes it difficult to generalize the findings of surgical outcome studies and to design and conduct prospective randomized treatment studies.

Harner et al. reported 33 patients on subjective and objective outcomes with use of four different knee rating scales at a minimum of 24 months after the operation including 19 patients treated within three weeks after injury and 12 patients treated three weeks after injury. Patients group treated within three weeks had a higher mean Knee Outcome Survey Sports Activity Score (89 vs 69, $p = 0.04$) less positive Lachman test (2+) (3 vs 6, $p = 0.04$). The mean Lysholm score (91 vs 80, $p = 0.07$) was also better in the acutely treated group. Final knee ROM was similar although four patients in the acute group

required manipulation under anesthesia for arthrofibrosis (21%).[10]

A study by Tzurbakis et al. reported statistically better clinical outcomes in terms of IKDC knee form subjective (86% vs 44%, p = 0.008) and symptom (85% vs 56%, p = 0.04) subgroups in the acute treatment group (within three weeks of injury, 35 patients) compared with the chronic group (>3 weeks following injury, nine patients) with a minimum of 24 months' follow-up. However, overall IKDC normal or near-normal rating (77% vs 55%), mean Lysholm score (88 vs 82), and final knee ROM were not significantly different.[11]

In a systematic review of 24 retrospective studies involving 396 knees, Mook et al. suggested that delayed reconstructions of severe multiligament knee injuries have equivalent outcomes in terms of stability when compared with acute surgery. However, acute surgery was associated with flexion deficits (odds ratio = 5.18; 95% confidence interval [CI]: 1.5–17.5; p = 0.004). Additional treatment for joint stiffness was significantly more likely in association with acute treatment (17%; 95% CI: 13.0–22.4%; p <0.001) when compared with chronic treatment (0% [0 of 71]; 95% CI 0.0–5.1%).[12]

- Level II: 3[8],[10],[11]
- Level III: 1[12]
- Level IV: 1.[9]

Findings

Overall, in comparative studies that have directly compared acute to chronic management of knee dislocations, there were mixed results in Lysholm, Meyers, IKDC, and Knee Outcome Survey scores.

In a systematic review, a higher portion of patients in the acutely treated group showed more flexion deficits that required additional treatment for joint stiffness.

Resolution of clinical scenario

- It is recommended that knee reconstruction should be started acutely if the patient's condition allows.

Question 3: In patients undergoing knee surgery, does restricted blood flow therapy yield better clinical outcomes, muscle strength, and size compared to conventional rehabilitation?

Rationale

Blood flow restriction (BFR) with low resistance loads is becoming popular in musculoskeletal rehabilitation, especially in the postoperative setting, in order to mitigate disuse atrophy and to promote hypertrophy following immobilization for earlier return to activities. Thus, it is clinically important to understand the application of BFR to multiligament injury of the knee that generally requires a longer time for rehabilitation.

Clinical comment

Postoperative rehabilitation of the multiligament reconstructed/repaired knee begins with restoration of motion and is followed by a gradual, progressive strengthening program.[2]

Since these patients cannot tolerate high-intensity exercise postoperatively, low-intensity exercise with BFR should be adopted while protecting reconstructed structures in an earlier phase of healing.

A low-intensity resistive load (20–50% of one-repetition maximum) with hypoxic metabolic stress induced by externally applied tourniquet around the proximal portion of the exercising limb promotes muscle hypertrophy by various physiological synergistic pathways.

Available literature and quality of the evidence

There is a lack of direct, comparative analysis in regard to the effectiveness of BFR in terms of preserving muscle mass and strength.

However, there are two level I randomized controlled trials (RCT) and one level II controlled trial that analyzed BFR rehabilitation following ACL reconstruction using hamstring tendons.

In 2000, Takarada et al. reported diminished disuse atrophy of quadriceps muscle after ACL reconstruction in cross-sectional images on magnetic resonance imaging (MRI) on postoperative day 3 and day 14. They compared two matched groups, five minutes of occlusive stimuli using a pneumatic cuff that was given to one group twice a day from day 3 to 14.[13] These stimuli were applied without the addition of a load.

Ohta et al. compared two randomized groups of ACL reconstruction patients. Occlusion stimuli were applied to one group of patients with pneumatic tourniquets and both groups followed the same training protocol. They found a statistically significant difference in quadriceps cross-sectional area on MRI scans after 16 weeks.[14]

In contrast, in 2016, Iversen et al. compared two randomized groups of athletes who underwent ACL reconstruction. Occlusive stimuli with pneumatic cuff twice a day and low-load resistance quadriceps exercises were performed from postoperative day 2 to 14. They did not find a difference regarding the reduction of quadriceps atrophy measured by MRI.[15]

In 2019, Hughes et al. compared two groups of hamstring autograft ACL reconstruction patients pre- and postoperatively during an eight-week rehabilitation program. In this randomized trial, significant and comparable increases in muscle thickness (5.8 ± 0.2% and 6.7 ± 0.3%) and pennation angle (4.1 ± 0.3% and 3.4 ± 0.1%) were observed with no difference in the BFR group (n = 14, 30% of one repetition maximum) and high load resistance exercise group. However, significantly greater increases in several measures of self-reported function (50–218 ± 48% vs 35–152 ± 56%), Y-balance performance (18–59 ± 22% vs 18–33 ± 19%), ROM (78 ± 22% vs 48 ± 13%), and reductions in knee joint pain (67 ± 15% vs 39 ± 12%) and effusion (6 ± 2% vs 2 ± 2%) were observed in the BFR group compared to high load resistance exercise group. From these observations, they suggested blood flow restricted resistance training BFR-RT may be more appropriate for early rehabilitation in ACL reconstruction patients due to the similar effect on skeletal muscle hypertrophy and strength and favorable effect on knee joint pain and effusion.[16]

A meta-analysis of 20 studies performed by Hughes et al. included an analysis of ACL reconstruction (n = 3), knee osteoarthritis (n = 3), older adults at risk of sarcopenia (n = 13), and sporadic inclusion body myositis (n = 1). Analysis of pooled data indicated low-load BFR training had a moderate effect on increasing strength (Hedges' g = 0.523; 95% CI 0.263–0.784, p <0.001), but was less

effective than heavy-load training (Hedges' g = 0.674; 95% CI: 0.296–1.052, p <0.001).[17]

- Level I: 3[13],[14],[16]
- Level II: 1[15]
- Level III: 2.[2],[17]

Findings

Overall, the literature shows that BFR with low load training rehabilitation can be effective in reducing muscle atrophy following knee surgery. And it can be hypothesized that accelerated rehabilitation with BFR can result in effective clinical outcome in the short-term follow-up. However, long-term results have yet to be published. In addition, further research is needed to establish specific protocols for postoperative rehabilitation using BFR technique including its frequency, duration, and intensity.

Resolution of clinical scenario

- Level I RCTs suggest that BFR can reduce disuse hypotrophy of quadriceps after ACL reconstruction.
- Level I RCTs suggest that BFR can be beneficial for early rehabilitation considering its favorable effect on pain and effusion.

Summary of answers

- Reconstruction of PMC and PLC is recommended to avoid treatment failure, but it does not show significantly better results in Lysholm, IKDC scores, or return to work rates.

- It is recommended that knee reconstruction should be started acutely if the patient's condition allows, but the quality of the data is low. There is a current multicenter trial that seeks to answer this question.
- BFR can be considered a promising rehabilitation method in order to preserve quadriceps muscle mass after knee surgery.

139 Posterolateral Corner Injuries

Nolan S. Horner MD[1], Chetan Gohal MD[1], Olufemi R. Ayeni MD PhD[1], and Daniel B. Whelan MD MSc[2]
[1] Division of Orthopaedic Surgery, Department of Surgery, McMaster University, Hamilton, ON, Canada
[2] Division of Orthopaedic Surgery, University of Toronto, Toronto, ON, Canada

Clinical scenario

- A 32-year-old hockey player injured his knee after suffering a pivoting injury playing hockey one month ago.
- He now complains of posterolateral knee pain and is unable to play hockey. His knee hyperextends when going up and down stairs and gives way with twisting and pivoting activities.
- His physical exam reveals 10 mm of lateral opening on varus stress with no endpoint, a positive posterolateral drawer test, and a positive dial test at 30° of flexion.
- The patient's magnetic resonance imaging (MRI) shows complete tears of the lateral collateral ligament (LCL), popliteus tendon (PLT), and popliteofibular ligament (PFL).

Top three questions

1. In patients undergoing surgical treatment for an isolated posterolateral corner (PLC) injury, does PLC reconstruction result in superior functional outcome

scores and reduced re-rupture rates compared to PLC repair?

2. How do the functional outcomes and rupture rates in patients with isolated PLC injuries compare between surgical management and nonoperative management?
3. In patients undergoing surgical treatment for a PLC injury, do anatomic PLC reconstructions improve functional outcomes and rupture rates compared to other reconstruction techniques?

Question 1: In patients undergoing surgical treatment for an isolated posterolateral corner (PLC) injury, does PLC reconstruction result in superior functional outcome scores and reduced re-rupture rates compared to PLC repair?

Rationale

There are compelling data on acute repair versus reconstruction that will help surgeons perform procedures which yield better results.

Clinical comment

There has been much debate in the literature regarding the decision to repair or reconstruct the PLC in patients with high-grade injuries. In general, repair of the PLC involves repair of the LCL and other anatomic structures of the PLC to their anatomic locations. Multiple reconstruction techniques have been described using autogenous or allograft tendons to reconstruct the PLC.[1],[2] It should be

noted that repair of the PLC may not always be possible if surgery is performed in a delayed fashion or if the patient presents with a chronic PLC injury. Furthermore, some authors have advocated for augmenting acute repairs with reconstruction techniques.[3]

Available literature and quality of the evidence

- Level II: 1 prospective comparative cohort study.[4]
- Level III: 1 retrospective comparative cohort study.[5]

Findings

In 2005, Stannard et al. reported their prospective cohort study in which there were 57 cases of PLC injury. Of the 35 patients treated with acute (<3 weeks) repair and 22 patients treated with primary reconstruction, there were 13 (37%) and 2 (9%) failures, respectively. There was no significant difference in Lysholm scores between the two groups after revision reconstruction of the failures. However, 44 of these patients had sustained high-energy trauma resulting in multiligament knee injury. A total of 13 patients had an isolated PLC injury. Of these 13 patients, seven underwent acute repair within three weeks of injury; the remaining six underwent reconstruction. None of the six reconstructions failed, but two of the seven repairs failed.[4]

Levy et al., in 2010, reported their results on patients with multiligament knee injuries who underwent either repair (n = 10) or reconstruction (n = 18) of the posterolateral structures.[5] There were four failures in the repair group and only one failure in the reconstruction group. The difference in failure rates was found to be significant (p = 0.04). After revision reconstruction for failures there was no statistical difference found between the two groups in

terms of International Knee Documentation Committee (IKDC) or Lysholm scores. Multivariate regression analysis found that patient demographics, time to surgery, interval between stages (for the repair group), number of ligaments involved, and location of LCL/PLC tears did not affect final outcome.

Resolution of clinical scenario

- Level II and III evidence suggests that repair of the PLC results in a higher failure rate than reconstruction.
- Level II and III evidence suggests that there is no difference in functional outcomes between repair and reconstruction after revision reconstruction of failures.
- Current best evidence is limited by sample sizes and the fact that isolated high-grade PLC injuries are rare and often treated in conjunction with other knee injuries.

Question 2: How do the functional outcomes and rupture rates in patients with isolated PLC injuries compare between surgical management and nonoperative management?

Rationale

If comparable outcomes can be achieved between surgical and nonoperative management for patients with PLC injury then avoiding the risks associated with surgery would be beneficial for patients.

Clinical comment

PLC injuries are generally classified as grade I+ through 3+.[6] A grade I+ injury has 0–5 mm opening on varus stress with a definitive endpoint, grade II+ injuries have 5–10 mm opening on varus stress with a definitive endpoint, and grade III+ injuries have >10 mm opening on varus stress with no or a soft endpoint. Although surgical management of high-grade PLC injuries has generally been reported to have good outcomes, nonsurgical management may be a good option in patients with low-grade injuries or who are not suitable for surgery. Nonoperative management of PLC injuries includes extension bracing and physiotherapy.

Available literature and quality of the evidence

- Level IV: 2 retrospective case series.

Findings

Kannus reported nonoperative management for 11 grade II and 12 grade III injuries of the PLC.[7] Patients were immobilized for a variable period of time (grade II, 2–5 weeks, grade III, 2–7 weeks), followed by early rehabilitation which continued for at least six months. At follow-up (average 8.3 years) the grade II patients had generally good Lysholm scores; however, residual laxity was common (Table 139.1). Patients with grade III injuries fared more poorly and at follow-up had high rates of gross lateral laxity, post-traumatic osteoarthritis (OA), and less favorable Lysholm scores. However, it should be noted that there may have been confounding factors contributing to the poor outcomes in the patients with grade III injuries, as these patients are more likely to have concomitant injuries to other ligaments, the articular cartilage, and the meniscus.

Table 139.1 Results reported by Kannus after nonoperative management of PLC injuries. Source: Adapted from Kannus.[7]

Injury grade	Lysholm score	Return to preinjury activity	Post-traumatic OA
Grade II (n = 11)	88 (good)	9 (82%)	0 (0%)
Grade III (n = 12)	65 (fair)	2 (17%)	6 (50%)

Krukhaug et al. reported on the nonoperative management of seven patients with primary lateral instability of 1+.[8] Six patients were managed with early range of motion and one with a cylinder cast for six weeks. At follow-up (average 7.5 years), six patients had a completely stable knee on varus stressing, and one patient treated in a cylinder cast had residual laxity of 1+. Median Lysholm score for the stable patients was excellent, at 95.

Resolution of clinical scenario

- Level IV evidence suggests that grade I+ and II+ isolated PLC injuries can be treated nonoperatively.
- Level IV evidence suggests that grade III+ PLC injuries treated nonoperatively will have high rates of post-traumatic OA and gross lateral laxity and therefore operative management should be strongly considered in most patients.
- There is currently insufficient literature comparing nonoperative management to operative management of isolated grade I+ and II+ PLC injuries to make any conclusions about the superiority of one management strategy.

Question 3: In patients undergoing surgical treatment for a PLC injury, do anatomic PLC reconstructions improve functional outcomes and rupture rates compared to other reconstruction techniques?

Rationale

Strong evidence to establish the optimal technique for reconstruction of PLC injuries will allow for improved outcomes for patients.

Clinical comment

Many anatomic and nonanatomic PLC reconstruction techniques are described in the literature. Biomechanical studies have shown the LCL, the PFL, and the PLT to represent the most important structures to the stability of the PLC.[9] Anatomic posterolateral reconstructions reproduce all three of these key structures, whereas nonanatomic PLC reconstructions only aim to reproduce one or two of these structures.[10]

Available literature and quality of the evidence

- Level IV: multiple case series.
- Level III: 3 retrospective comparative cohort studies.

Findings

Various case series exist showing significant improvement in postoperative functional outcome scores using a variety of different anatomic and nonanatomic reconstruction techniques.[11–14] In all studies the number of patients was

small and the injuries sustained were varied in terms of the other associated ligamentous injuries.

Three studies have retrospectively compared clinical outcomes for different types of reconstruction techniques. Jung and coworkers reported a retrospective cohort study of patients with PCL and grade II PLC injuries.[15] In this study 19 patients underwent PLC reconstruction via a transtibial sling procedure and 20 patients via a transfibular sling procedure. The fibular head tunnel technique led to a significantly better improvement in rotational stability ($p = 0.007$), although no significant difference was found for varus stability and clinical outcome scores. Yoon et al. retrospectively compared anatomic reconstruction (n = 21) with a PLC sling procedure (n = 25).[16] They found a significantly better improvement in external rotation laxity and varus laxity with anatomic reconstruction ($p < 0.05$). The Lysholm Knee Score improved significantly in both groups ($p < 0.05$) and no significant difference was found between the two groups. Another retrospective comparative cohort compared treatment of grade III PLC injuries with either LCL and PFL reconstruction (n = 5) versus an anatomic LCL, PFL, and PLT reconstruction (n = 17). The anatomic reconstruction resulted in significantly improved side-to-side difference in lateral joint opening ($p < 0.001$); however, there was no significant difference in IKDC forms.

Resolution of clinical scenario

- Level IV evidence suggests that a number of different anatomic and nonanatomic reconstruction techniques result in significantly improved functional outcome scores and posterolateral stability postoperatively.
- Level III evidence has shown no significant difference in functional outcomes between reconstruction

techniques.

Summary of answers

- Early evidence suggests that acute (<3 weeks) PLC repair may have higher rates of failure than reconstruction; however, the same evidence suggests there is no difference in functional outcome scores after revision reconstruction of failures.
- Low-quality evidence suggests that patients have good functional outcomes and low rates of post-traumatic OA after nonoperative management of grade I+ and II+ PLC injuries.
- Grade III+ PLC injuries should generally be treated operatively as those treated nonoperatively have high rates of gross laxity and post-traumatic OA.
- There are many reconstruction techniques that have been described in the literature that result in good outcomes for the treatment of high-grade PLC injuries. There is no literature to suggest the clear superiority of one PLC reconstruction technique.
- The PLC literature as a whole is made up of low-level evidence. Interpreting the PLC literature is further complicated by the fact that isolated high-grade PLC injuries are rare and often occur in conjunction with other ligamentous knee injuries. For this reason, there is both high intra- and interstudy heterogeneity in terms of the associated injuries in patients treated for PLC injuries.

140 Lateral Extra-Articular Tenodesis Procedures and the Anterolateral Ligament

Felipe Moreira MD, Merce Reverté MD PhD, Enric Castellet MD, and Joan Minguell MD PhD
Vall d'Hebron University Hospital, Barcelona, Spain

Clinical scenario

- A 15-year-old woman comes to your office for pain and effusion in her right knee after sustaining an injury while playing basketball (landing from a jump) four days ago.
- History and physical reveals a Lachman 2+, grade II/III pivot shift, knee hyperextension, and joint effusion. MRI confirms rupture of the ACL at the level of its femoral insertion. There is no associated meniscal injury.
- The patient is a passionate basketball player (semiprofessional) and wants to continue practicing this sport.

Top three questions

1. In patients undergoing anterior cruciate ligament reconstruction (ACLR), does the addition of lateral extra-articular tenodesis (LET), compared to ACLR alone, improve function, and return to sport results while diminishing failure rate?
2. In patients undergoing ACLR, does the addition of LET, compared to ACLR alone, reduce rotational laxity, thus

preventing osteoarthritis (OA) and meniscal lesions?

3. In patients undergoing ACLR, is there a surgical technique of LET, as an augmentation to ACLR, that has proven to have superior biomechanical and clinical results compared to other techniques?

Question 1: In patients undergoing anterior cruciate ligament reconstruction (ACLR), does the addition of lateral extra-articular tenodesis (LET), compared to ACLR alone, improve function, and return to sport results while diminishing failure rate?

Rationale

Intra-articular reconstruction has become the technique of choice to address ACL deficiency. However, intra-articular reconstruction does not restore normal knee kinematics and failure rate also remains a factor to consider in many cases, especially in high-demand young athletes.[1],[2] In the past two decades, many surgeons have recommended extra-articular reconstruction in conjunction with an intra-articular technique in order to address normal kinematics and reduce failure rate.

Clinical comment

It is our impression that the use of additional extra-articular procedures is increasing in number, especially in challenging primary cases and revisions. By attempting to control rotation laterally, further away from the pivot point

of the knee, extra-articular reconstruction may be better suited to control rotational motion by having a better lever arm.[3] A simple intra-articular procedure combined with an extra-articular augmentation may achieve better clinical results, while also diminishing failure rates.

Available literature and quality of the evidence

The quality of literature addressing results of lateral extra-articular procedures associated with ACLR is highly variable, with levels I–IV evidence. Studies lack standardization of protocols and outcomes. The majority of the outcome papers are case series or cohort studies. There are seven randomized controlled trials (RCTs),[4–10] five recent systematic reviews,[11–15] and one large trial currently underway.[16]

Findings

Randomized controlled trials

A growing number of RCTs examine the effect of extra-articular augmentation. The trials differ in the type of LET and intra-articular reconstruction, outcome measures, and definitions of failure. Drawing firm and reliable conclusions is difficult based on this current highly heterogeneous data set. In total, seven RCTs were found.[4–10] Only one study demonstrated improved patient-reported outcomes for patients undergoing ACLR associated with LET over controls(6).[6] In this study, 75 patients were randomized evenly to three treatment groups. These consisted of: (i) the Marcacci technique (ACLR+LET), (ii) a four-strand, single-bundle hamstring ACLR, or (iii) a bone–patella–bone ACLR. At five-year follow-up the LET group had higher subjective International Knee Documentation Committee (IKDC) scores and also a quicker return to sport. Later on,

some of the same authors in a different study found that, when compared to a double-bundle group, the Marcacci technique performed worse in terms of IKDC scoring and pivot shift grading.[8] Higher return to sport rates were seen in the double-bundle group, with the Marcacci cohort returning to sport more quickly.

Current trials

The Standard ACL Reconstruction versus ACL and Lateral Extra-Articular Tenodesis (STAbiLiTY) study is a recently-completed RCT of 600 divided in two groups (ACLR + modified Lemaire LET vs ACLR), focusing on high-risk patients, coordinated by the University of Western Ontario.[16] The trial includes patients 14 to 25 years old with an ACL deficient knee who play competitive pivoting sports, and have a grade 2 pivot shift or generalized ligamentous laxity. Participants are randomized to hamstring ACLR or ACLR with an iliotibial band-based LET (modified Lemaire). The primary outcome measure is graft failure at two years, with secondary outcomes being patient-reported outcome scores, objective functional outcomes, biomechanical assessment, imaging, return to activity, adverse events, and cost outcomes. Preliminary results of the trial have been presente,[17] and while the interim results should be interpreted with caution, they appear favorable for LET. Failure rates and the rate of asymmetric pivot shift are significantly lower in favor of the LET procedure. However, this appears to come at the cost of increased early morbidity, with increased pain and reduced lower limb function at three months.[17]

Resolution of clinical scenario

- Extra-articular anterolateral procedures have undergone a renaissance in combination with ACLR in

selected cases.

- Preliminary results from an ongoing clinical trials are supportive for LET when used as an augmented intra-articular ACL reconstruction in a targeted group of high-risk patients.
- Based on these findings, one can only hypothesize some potential indications for high-risk patients (professional athletes, revision cases, etc.).

Question 2: In patients undergoing ACLR, does the addition of LET, compared to ACLR alone, reduce rotational laxity, thus preventing osteoarthritis (OA) and meniscal lesions?

Rationale

Rotational stability may not be restored by intra-articular reconstruction alone. Subjectively measured as a positive pivot shift, this instability may be negatively associated with subjective and objective outcomes.[18],[19] Renewed interest in LET is based on its important role in biomechanical stability. Nevertheless, over-constraint has also been linked to OA.

Clinical comment

Despite the reported risk of joint over-constraint, consideration should be given to reconstructing the anterolateral structures and the ACL concurrently to maximally restore both anterior tibial translation and rotatory stability. However, the role of LET in improving

rotational knee stability remains a controversial subject.[12] To reduce rotational laxity might mean reducing residual pivot shift, and increasing patient satisfaction and functional stability, though it may also risk over-constraint.

Available literature and quality of the evidence

Most of the studies discussed in Question 1 also report on rotational laxity and OA, with level I–IV evidence. The same seven RCTs are available,[4–10] one meta-analysis,[14] as well as the STAbiLiTY trial.[16] Level IV evidence has been found in relation to meniscal lesions.[13,20]

Findings

Randomized controlled trials

The same seven RCT mentioned above also look into biomechanics.[4–10] Only one of those studies found statistically significant results. Vadalà et al. prospectively evaluated the role of Coker–Arnold's extra-articular procedure in reducing the incidence of a residual postoperative rotational knee laxity in female patients with ACL deficient knees who had a preoperative grade 2 or 3+ pivot shift.[9] They randomized 60 patients to four-strand hamstring ACLR with or without an extra-articular Coker–Arnold procedure. At mean follow-up of 44.4 months, a residual positive pivot shift was found in 57.1% of patients with an isolated ACLR and in 18.6% of patients with a combined ACLR and LET, thus significantly reducing the rotational instability of the knee.[9]

Meta-analysis

A meta-analysis published by Devitt et al. investigated the effect of LET augmentation in early (≤12 months) and delayed ACLR.[14] Interestingly, LET augmentation was not

effective in reducing residual pivot shift in the early ACLR group; however, there was statistically significant reduction in residual pivot shift in delayed ACLR.

Current trials

The STAbiLiTY study discussed above, includes radiographic markers of OA as a secondary outcome.[16] Preliminary results report significantly lower rates of pivot shift in favor of the LET procedure.[17] No meniscal lesions or OA markers have yet shown preliminary significant results.

Resolution of clinical scenario

- Biomechanical studies suggest that traditional lateral tenodeses are most efficient in restoring native knee kinematics in combined ACL and anterolateral injured knees.
- Reduction in pivot shift favors LET augmentation.
- In one study, ACLR + LET was not associated with an increased rate of OA of the knee in the first 11 years, but the authors found rates increased thereafter.[13]

Question 3: In patients undergoing ACLR, is there a surgical technique of LET, as an augmentation to ACLR, that has proven to have superior biomechanical and clinical results compared to other techniques?

Rationale

At least 12 procedures have been described in order to address the rotational instability that is left when performing an ACL reconstruction. Therefore, if LET as an augmentation process can be recommended in certain cases, there should also be an *ideal* LET technique. Choosing and becoming proficient in one procedure would simplify and refine a surgeon's learning curve.

Clinical comment

LET techniques have evolved by mainly altering graft choice and tibiofemoral positioning. Despite that, a significant degree of uniformity can be observed, with the extra-articular graft generally attaching distally at the Gerdy's tubercle and traveling proximally and posterolaterally toward the lateral femoral condyle.[21–31] A recent article consulting global experts on the field saw agreement that LET procedures do have a place in current ACL surgery. Lemaire tenodesis was reported as being the most used technique.[32]

Available literature and quality of the evidence

One systematic review has been done comparing biomechanical outcomes of various LET procedures.[20] Most of the evidence recorded in this review was level III–IV. No level I–II study has been done in order to compare clinical results among different LET techniques.

Findings

Among LET procedures there is no single best *evidence-based* approach, and most surgeons regularly undertake extra-articular reconstructions following a technique that is most familiar to them.[32]

Anatomical and biomechanical studies documenting LET procedures recommend fixing the graft with the tibia maintained in an externally rotated position.[21–30] However, non-neutral positioning of the tibia interferes with the *screw home* mechanism because the externally fixed graft effectively inhibits physiological rotation of the tibia about its central axis.[33] A common theme among the aforementioned studies was the nonanatomic nature of their graft placement.

Slette et al. performed a systematic review of the various LET techniques.[20] From the eight studies that analyzed rotatory movement, seven showed joint over-constraint, indicated by a significant reduction in internal rotatory movement relative to that of the native knee joint.[33–39] After a period of initial stability, LET reconstructions have often shown a tendency to elongate, with return of anterolateral rotatory instability in the ACL-deficient knee. This could theoretically be avoided by isometric placement of graft. Sidles et al. asserted that an entirely isometric LET procedure does not exist.[40] It has been reported that an increase in separation distance between the insertion points of a ligament reconstruction of 6% could lead to permanent graft elongation; therefore, appropriate graft positioning and tensioning of LET procedures are paramount in order to at least minimize its risk of elongation.[41] In a recent study, Kittl et al. reported that any tibiofemoral reconstruction combination that inserted proximal to the lateral epicondyle and coursed deep to the lateral collateral ligament was nearly isometric between 0 and 90. As the knee extended, only a slight increase in length was shown, implying an ability to inhibit anterior subluxation of the lateral tibial plateau. Among the LET procedures analyzed, the MacIntosh procedure was

reported to display the most isometric pattern from 0 to 90 of flexion.[42]

Resolution of clinical scenario

- No one technique appears to be superior from the others.
- The MacIntosh procedure was reported to display the most isometric pattern.
- Investigation on the anatomy and biomechanics might prove to be extremely helpful in the future guiding possible new procedures.

Summary of answers

- RCT evidence supports the use of LET to augment ACL reconstruction in high-risk patients (e.g. high-level athletes, revision cases, etc.).
- Biomechanical studies suggest LET augmentation leads to a reduction in positive pivot shift tests, and is not associated with increased rates of osteoarthritis.
- No one LET technique has been definitively shown to be superior to others.

141 Cartilage Lesions of the Knee

Mario Hevesi MD[1], Aaron J. Krych MD[1] and Daniël B. F. Saris MD PhD[1,2]

[1] Department of Orthopedic Surgery, Mayo Clinic, Rochester, MN, USA

[2] Department of Orthopaedics, University Medical Center Utrecht, Utrecht, The Netherlands

Clinical scenario

- A 25-year-old patient presents following a low-energy torsional trauma sustained to his left knee while playing recreational sports.
- He has persistent pain, occasional catching, and locking preventing him from returning to his preinjury sports participation.
- On physical exam, a mild left knee effusion is present. Ligaments are intact; however, provocative tests indicate medial meniscus pathology, and clinically, coincident articular cartilage injury is suspected.

Top three questions

1. In patients with suspected chondral knee injury, how accurate is magnetic resonance imaging (MRI) compared to subsequent arthroscopic findings in the diagnosis of focal cartilage lesions of the knee?
2. In patients with full-thickness cartilage lesions undergoing knee preservation surgery, what is the difference in clinical outcomes between common surgical options for treating focal cartilage pathology?

3. For patients undergoing articular cartilage surgery, do certain patient-specific, prognostic factors predict improved or inferior clinical outcomes following surgical intervention compared to others?

Question 1: In patients with suspected chondral knee injury, how accurate is magnetic resonance imaging (MRI) compared to subsequent arthroscopic findings in the diagnosis of focal cartilage lesions of the knee?

Rationale

The prevalence of trauma-related cartilage lesions ranges from 23 to 54%, with meniscal tears often accompanied by focal chondral pathology.[1] Most lesions are not detected at the time of initial evaluation and place patients at risk to develop early-onset osteoarthritis with subsequent, accompanying decreases in quality of life as well as high associated medical costs.

Clinical comment

Evaluation of cartilage pathology on MRI is important to inform both the patient and the surgeon regarding potential treatment and management approaches to focal traumatic defects in the absence of generalized degenerative changes. The clinical suspicion of an articular cartilage defect and related surgical strategy is mainly based on clinical examination and MRI.

Available literature and quality of the evidence

Level I evidence consisting of three validating cohort studies with a good reference standard (arthroscopy) is available.[2–4] All included studies were prospective and compared a pre-arthroscopic MRI to findings during arthroscopy, considering Outerbridge grade 0–I changes as disease-negative status and grade II–IV changes as disease positive status.

Table 141.1 Treatment options for focal articular cartilage lesions.

Microfracture (MF): a 12 mm diameter awl is used to penetrate the subchondral plate, creating access to the bone marrow, filling the cartilage lesion with a clot populated with bone-marrow-derived stem cells, growth factors, and platelets and generating a fibrocartilage scar.[5]
Autologous chondrocyte implantation/matrix-induced chondrocyte implantation (ACI/MACI): Chondrocytes are taken by biopsy, expanded in vitro, and reinjected under a periosteal flap that covers the defect.[6] Newer generations of ACI use collagen covers (second generation), characterize the chondrogenic potential of the product (CCI), or seed chondrocytes onto matrices (MACI).[7] Resulting repair tissue is hyaline-like cartilage.
Osteochondral autologous transplantation (OATs): osteochondral autografts are harvested from less-weight bearing areas of the knee and transferred to the defect, providing a hyaline cartilage surface.[8]

Findings

Overall, MRI sensitivity ranged from 57 to 91%, specificity from 71 to 95%, negative predictive value from 74 to 95%, and positive predictive value from 59 to 87%.[2–4] In a sub-analysis provided by von Engelhardt et al., sensitivity and

specificity improved with increasing lesion grade, with 29% sensitivity and 95 % specificity for subtle grade I structural changes and 74% sensitivity and 95% specificity for full-thickness grade IV changes.[3]

In summary, MRI shows a moderate detection of clinically relevant (grade II–IV) articular cartilage defects (sensitivity: 57–91%) (overall quality: moderate). MRI is the best available noninvasive diagnostic tool to detect high-grade focal articular cartilage lesions.

Resolution of clinical scenario

- We recommend routine MRI in the workup of patients with suspected cartilage pathology to inform management including surgical plan and approach.

Question 2: In patients with full-thickness cartilage lesions undergoing knee preservation surgery, what is the difference in clinical outcomes between common surgical options for treating focal cartilage pathology?

Case clarification

The MRI showed a 4 cm^2 grade IV articular cartilage lesion of the medial femoral condyle (MFC).

Rationale

Advances in cartilage preservation and restoration procedures have led to an increasing number of therapies available to the treating physician. The nature of

regenerated tissue and the theoretical basis of different cartilage surgeries vary.

Clinical comment

Adequate treatment is important for young patients presenting with focal cartilage lesions of the knee to prevent progression to early osteoarthritis. Surgical success relies on selecting the optimal treatment to address the corresponding pathology (Table 141.1).

Available literature and quality of the evidence

Multiple level I systematic reviews of randomized controlled trials (RCTs)[9,10] as well as 15 clinically relevant level I randomized trials[11–25] are available in comparing and contrasting outcomes for treatment options for focal articular cartilage lesions. All included studies were of high quality with Coleman scores ranging from 68 to 94.[9,10] The average defect size ranged from 2.4 to 6.1 cm^2 and all but two defects were graded ≥III. A pooled analysis of clinical outcomes was not possible due to the heterogeneity of clinical outcome measures.

Findings

After one-year follow-up, MF demonstrated inferior clinical outcomes compared to OATs in both Hospital for Special Surgery ($p < 0.05$) and International Cartilage Repair Society (ICRS) scores ($p < 0.03$).[12] Following 2–3 years of follow-up, MF demonstrated inferior clinical results when compared to ACI ($p = 0.048$), MACI ($p = 0.001$), and OATs ($p < 0.001$).[12,16,18] MF outcomes remained inferior to OATs when follow-up was extended to 10 years, with significantly decreased ICRS and Tegner activity scores ($p < 0.005$).[21] Lesions >4 cm^2 or >2 cm^2 performed clinically worse ($p < 0.05$) after MF treatment, while the influence of lesion

size on clinical outcome was not present after ACI or OATs.[12,15,21] An increase in clinical outcome after ACI or a decrease in MF was generally observed after 12 years of follow-up, suggesting MF generates a less stable regenerative product.[12,16] However, a randomized study of chronic articular cartilage lesions did not show any difference in clinical outcome between ACI and MF at five-year follow-up and later at 15 years.[13–15]

In terms of comparisons between advanced regenerative techniques, at one year OATs and MACI did not differ in terms of Cincinnati score ($p = 0.32$) and after 19 months of follow-up, OAT and ACI did not differ ($p = 0.227$) on the same scale; however, failure rates and clinical outcomes were superior in the ACI group as compared to OATs at 10-year follow-up.[11,19,25] In summary, treatment of focal articular cartilage lesions by ACI/MACI or OATs provides better medium-term clinical results compared to MF (overall quality: high). ACI/MACI and OAT are both good treatment options for grade III and IV focal articular cartilage lesions with similar clinical results.

Resolution of clinical scenario

We recommend addressing the patient's defect with ACI/MACI or OATs preferentially over MF given his young age and the desirability of durable preservation outcomes.

Question 3: For patients undergoing articular cartilage surgery, do certain patient-specific, prognostic factors predict improved or inferior clinical outcomes following surgical intervention compared to others?

Rationale

Identification of prognostic factors for clinical outcomes following joint preservation surgery will lead to optimal patient selection and subsequent benefit from cartilage surgery.

Clinical comment

The overall benefit from cartilage surgery is 70–95%. Cartilage preservation success hinges on selecting patients with prognostic factors favorable for regenerative therapies.

Available literature and quality of the evidence

Multiple level I randomized trials are available which have demonstrated data linking age,[18,19,21,25] symptom duration,[23,25] and defect location[19,21] to patient outcomes.

Findings

Patient age

Studies showed a statistically significant influence ($p < 0.05$) of patient age on MF, ACI, and OATs treatment outcome, where increasing age is associated with inferior clinical results out to 10-year follow-up.[18,19,21,25]

Duration of symptoms

Treatment of focal cartilage defects in patients with symptom duration shorter than three years in CCI and shorter than one year as well as 50 months in ACI and MACI were clinically more successful ($p < 0.05$) than patients undergoing treatment for prolonged symptomatology.[23,25]

Defect location

Initial reports on ACI safety and efficacy suggested inferior outcomes when used in the patella, with two of seven patients reporting good to excellent results.[6] However, at the time, patellar maltracking and instability were not well recognized and not addressed intraoperatively. In modern series, clinically and statistically similar results have been reported for OATs and MF for medial and lateral femoral condyle (LFC) defects at up to 10-year follow-up.[21] Similarly, at 10-year minimum follow-up, Bentley et al. reported no difference in failure rate between LFC, MFC, and patellar lesion location for ACI or MF.[19] However, level I RCTs investigating the safety and efficacy of regenerative therapies for focal cartilage injuries were not powered for a primary outcome of detecting differences in outcomes between anatomic locations.

Resolution of clinical scenario

- The patient's young age and short duration of symptoms are positive prognostic factors, favoring the efficacy of cartilage preservation surgery in this scenario.
- The nonpatellar location of his defect may also be of positive prognostic value; however, results regarding lesion location are conflicting.

Summary of answers

- The increasing number of young patients presenting with knee trauma and related cartilage injury requires detailed evaluation of articular cartilage damage followed by customized treatment plans to prevent the development of early osteoarthritis.

- MRI is the best available noninvasive diagnostic tool to detect high-grade focal articular cartilage lesions, providing moderate detection of clinically relevant (grade II–IV) articular cartilage defects.
- Several surgical treatment options for focal cartilage lesions are available.
- Medium-term clinical outcomes favor cell-therapy and transplantation-based procedures (ACI/MACI, OATs) over other treatment strategies.
- The location of cartilage defects may influence clinical outcomes, but more recent results demonstrate equally good outcomes in the patellofemoral joint when underlying maltracking and instability are addressed at the time of surgery.
- Increasing age negatively influences clinical outcomes after cartilage surgery, while a shorter duration of symptoms is favorable for prognosis.

142 Patellofemoral Pain Syndrome (Runner's Knee)

Carlos Prada MD MHSc[1] and Sebastián Irarrázaval MD[2]
[1] Division of Orthopaedic Surgery, Department of Surgery, McMaster University, Hamilton, ON, Canada
[2] Department of Orthopaedic Surgery, Pontificia Universidad Católica de Chile, Santiago, Chile

The term *patellofemoral pain* is the preferred term, and is a synonym for other terms including: *PFP syndrome*, *chondromalacia patellae*, *anterior knee pain* and/or *syndrome*, and *runner's knee*.[1]

Clinical scenario

- An overweight 25-year-old female patient presents with bilateral anterior knee pain which is exacerbated by running.
- The pain started three months ago, and there is no medical history of trauma, infection, or surgery.
- Pain is predominantly anterior, and activities such as going up and down stairs exacerbate her pain. Radiographs and magnetic resonance imaging (MRI) show no abnormality.

Top four questions

1. In patients with a diagnosis of runner's knee, are there specific imaging findings that are different compared with patients without runner's knee?

2. In patients with a diagnosis of runner's knee, does neuromuscular electrical stimulation (NMES) associated with conservative treatment result in better patient-reported outcome measures (PROMs), compared with conservative treatment without NMES?
3. In patients with a diagnosis of runner's knee, are combined hip and knee exercises associated with better clinical outcomes, compared with knee exercises alone?
4. In patients with a diagnosis of runner's knee, does being overweight predict worse PROMs, compared with being normal weight?

Question 1: In patients with a diagnosis of runner's knee, are there specific imaging findings that are different compared with patients without runner's knee?

Rationale

Diagnostic imaging tools represent an important cost for the healthcare system and/or patients. Given the high prevalence and clear clinical presentation of this condition, it is reasonable to analyze if imaging is necessary in the diagnosis and treatment process of these patients. In addition, potential association between this disorder and patellofemoral osteoarthritis has been reported.

Clinical comment

Runner's knee, also known as *patellofemoral pain* (PFP) is a common syndrome. Usually, when patients decide to pursue medical attention, they expect to be referred for diagnostic imaging tests. Nevertheless, these tests

represent an economic burden to patients and/or the healthcare system, without necessarily changing treatment or prognosis. In addition, some studies had shown an association between PFP and patellofemoral osteoarthritis, which have increased the awareness of this condition.[2]

Available literature and quality of the evidence

This search produced the following level I studies: one systematic review and meta-analysis[3] and three randomized controlled trials (RCTs). Whenever possible, these level I studies will be used to answer the question. Lower level of evidence studies will be used to address the role of other imaging modalities that lack high-quality evidence.

Findings

Diagnostic modalities findings in runner's knee patients compared to the normal population

Magnetic resonance imaging (MRI)

Drew et al. found that an increased MRI bisect offset at 0° flexion angle under load was associated with PFP, and that there was a large standardized mean difference (SMD = 0.99; 95% confidence interval [CI]: 0.49–1.49) as determined from moderate level evidence.[3] MRI bisect offset has been shown as the most significant feature related to patellofemoral joint (PFJ) space narrowing in adults between 70 and 79 years with knee pain.[4] There is also a moderate SMD for the association between PFP, patellar tilt (0.63; 95% CI: 0.37–0.90) and patellofemoral contact area (−0.53; 95% CI: −1.01 to −0.06).

Computed tomography (CT)

CT-derived congruence angles at 15° flexion angle, with and without load, have shown a large SMD from moderate evidence level (1.40; 95% CI: 0.04–2.76) and (1.24; 95% CI: 0.37–2.12), respectively. There is limited evidence to support a difference between PFP patients and the normal population regarding tibial tubercle rotation angle at 0° without load[5,6] and trochlear depth at 15° without load.[7] In addition, there is controversial evidence for patellar tilt at 15° under load.[8,9]

Ultrasound (US)

Different studies comparing US findings between patients with PFP and healthy individuals have been conducted. Limited evidence supports a difference between PFP patients and healthy controls in terms of: vastus medialis oblique (VMO) fiber angle, VMO insertion, and volume;[10] VMO contraction ratio and capacity reduction;[11] and an increase in VMO electrical mechanical delay and vastus lateralis delay.[12] In addition, evidence suggests that the atrophy is not specific for VMO, but for the quadriceps as a whole muscular group.[13]

X-rays

There is controversial evidence regarding a difference in congruence angle, support sulcus angle, and Insall–Salvati index at 30° without load, between patients with PFP and healthy individuals. Limited evidence support a difference in congruence angle at 45° with load,[14,15] but not at 35°.[16] Similarly, limited evidence supports sulcus angle difference at 45° without load,[14,15] but no evidence shows a difference at 35°[16] or 30°.[17]

Changes observed during intervention through imaging modalities

Two studies have revealed that, after quadriceps strengthening exercises, there was a significant increase in PFJ contact area which might reduce mechanical stress, improving PFJ function. These studies also exhibited that the patellofemoral bisect offset and patellar tilt changed with bracing.[18],[19]

Resolution of clinical scenario

The patient's imaging did not show any specific abnormalities, which is the case in the majority of cases of PFP. Eventually, some dynamic imaging exam measurements can be performed to identify certain features associated with PFP, but this will probably not change the patient's initial management (overall quality: moderate).

Question 2: In patients with a diagnosis of runner's knee, does neuromuscular electrical stimulation (NMES) associated with conservative treatment result in better patient-reported outcome measures (PROMs), compared with conservative treatment without NMES?

Rationale

- Even when NMES is widely used as a therapeutic tool in patients with PFP, there is controversy concerning its utility as concurrent treatment with other nonsurgical interventions.

Clinical comment

Patients with PFP are frequently sent to physiotherapy. NMES has been extensively used during physiotherapy sessions despite the lack of consensus in its benefit.

Available literature and quality of the evidence

This search produced the following level I studies: one systematic review[20] and eight RCTs. Whenever possible, these level I studies were used to answer the question.

Findings

NMES

A recent systematic review included eight RCTs (n = 345) where PFP patients were treated with different NMES protocols and associated co-interventions.[20] Four trials compared NMES plus exercise versus exercise alone. Different NMES protocols were used as well as co-interventions associated with exercise (one study added patellar taping[21] and another added patellar taping and ice in both groups).[22] On average, studies showed pain reduction with a mean difference in Visual Analog Scale (VAS) score of −1.63 (95% CI: −2.23 to −1.02). However, this difference may not be relevant given that the minimal clinically important difference (MCID) in VAS has been determined to be between 1.5 to 2.0 points[23] and lies within the CI range.

Two RCTs compared NMES protocols.[24],[25] They did not find any differences at six weeks between the protocols in overall knee pain, knee function, or quadriceps fatigue.

A recent RCT, not included in the systematic review, showed knee extensors strengthening, muscle hypertrophic response, and increased fascicle length with an eccentric

training program, but no difference when NMES was added.[26]

Resolution of clinical scenario

Current evidence demonstrates no benefit of adding NMES as an intervention in patients with PFP. Physicians and physiotherapists should encourage patients to focus on other conservative measures while working at rehabilitation sessions (overall quality: low).

Question 3: In patients with a diagnosis of runner's knee, are combined hip and knee exercises associated with better clinical outcomes, compared with knee exercises alone?

Rationale

- Controversy exists for the utility of hip training to treat patients with PFP and its effectiveness compared to knee strengthening alone.
- Physiotherapy is probably the most commonly used therapeutic tool in PFP patients, but there is a lack of standardized rehabilitation protocols. Therefore, most patients are treated with different rehabilitation methods depending on physiotherapists' preferences.

Clinical comment

Patients with PFP are frequently sent to physiotherapy. The high diversity of rehabilitation protocols can lead to

unpredictable results. Reviewing the evidence could help clinicians to make better decisions in patients with PFP.

Available literature and quality of the evidence

This search produced the following level I studies: two systematic reviews addressing this research question were included. Whenever possible, these level I studies were used to answer the question.

Findings

Hip plus knee exercises versus knee exercises

A recent systematic review and meta-analysis included six studies (n = 359) comparing the effect of hip and knee strengthening with a knee-only strengthening program on strength, and found no differences (SMD = 0.2; 95% CI: −0.1 to 0.4).[27] Nevertheless, this study found that hip and knee strengthening significantly reduced pain by 1.5 points (95% CI: −2.3 to −0.8) out of 10 points, compared with knee strengthening alone, during the intervention (10 trials, n = 517). This reduction was held beyond the intervention for 12.0 ± 5.7 weeks with a decrease in intensity of 1.9 points (95% CI: −3.1 to −0.7) out of 10. In addition, the effect of both intervention programs on self-reported activity levels was examined (eight trials, n = 471) showing a significantly improved activity level with an effect size of 0.7 (95% CI: 0.2–1.3) for the hip and knee strengthening group. This was also held beyond the intervention (five trials, n = 188) with an effect size of 1.2 (95% CI: 0.4–2.0) at 12.0 ± 5.7 weeks.[27]

A meta-analysis evaluating exercise as a treatment for PFP pooled data from three studies (n = 104) which assessed pain during activity in the short-term (≤3 months).[28] Hip

and knee exercises were associated with better results than knee exercises alone (SMD = −2.02; 95% CI: −3.8 to −0.6).

Similar results, with data gathered from two studies (n = 46), were observed favoring hip plus knee exercises for usual pain at short-term (SMD = −1.77; 95% CI: −2.78 to −0.76). Moreover, one study including 49 participants exhibited a clinically important reduction in pain during activity at long-term (≥3 months) for the hip plus knee exercise group (SMD = −3.9; 95% CI: −4.46 to −3.34).[29]

Resolution of clinical scenario

Adding hip exercises to knee exercises helps patients with PFP in diminishing both their short- and long-term pain at rest and during activity. Therefore, adding hip exercises to knee exercises for patients with PFP should be routine (overall quality: high).

Question 4: In patients with a diagnosis of runner's knee, does being overweight predict worse PROMs, compared with being normal weight?

Rationale

- An increasing proportion of the population is overweight and obese, with an estimated 39% of adults being at least overweight based on body mass index (BMI).
- Many patients with PFP are overweight and are actively attempting to lose weight through exercise, thus

appropriate recommendations regarding BMI and safe exercises are necessary.

Clinical comment

PROMs used to compare clinical results are increasing in popularity because they incorporate patients views on clinical outcomes. Treating physicians frequently advise overweight PFP patients to lose weight as part of their treatment, but frequently do so without considering evidence to support this recommendation.

Available literature and quality of the evidence

This search produced the following level I studies: one systematic review concerning BMI and PFP[30] and one systematic review about PROMs in PFP.[31] We could not find specific evidence concerning overweight patients and PROMs compared to healthy individuals in PFP.

Findings

Overweight patients with runner's knee syndrome

Hart et al. assessed whether BMI was a risk factor for PFP development, whether BMI was higher in individuals with PFP, and whether there was any link between BMI and intervention outcomes.[30] Data from 33 studies provided moderate evidence of higher BMI in patients with PFP compared to healthy individuals (equivalent to mean difference 0.84; 95% CI: 0.43–1.26). There was not a significant relationship between BMI and interventions outcomes. On the other hand, a clinical trial in adolescents revealed that BMI did not increase the risk of developing PFP (−0.66; 95% CI: −1.98 to 0.66).[32]

PFP PROMs

Green et al. evaluated PFP disease-specific PROMs, finding moderate level evidence supporting the use of the following six measures:[31]

- Flandry Questionnaire
- AKPS (Kujala Anterior Knee Pain Scale)
- MFIQ (Modified Functional Index Questionnaire)
- EPQ (Eng and Pierrynowski Questionnaire)
- VAS-U (Visual Analog Pain Scale: usual pain)
- VAS-W (Visual Analog Pain Scale: worst pain).

Resolution of clinical scenario

It is challenging to give recommendations regarding BMI and its influence on knee pain due to PFP. Best current evidence suggests that being overweight is associated with an increased prevalence of PFP, but it is not clear whether losing weight will improve outcomes. Nevertheless, even when healthcare professionals cannot guarantee that losing weight will improve symptoms in these patients, increased physical activity is likely to help patients in many other health domains (overall quality: moderate).

Summary of answers

- Diagnostic imaging is rarely specific for PFP. Only a few characteristics, like an increased MRI bisect offset at 0° knee flexion under load and a CT-derived congruence angle at 15° with and without load, were associated with PFP.
- Adding NMES to traditional nonsurgical treatment does not seem to confer any additional benefit in patients with PFP.

- Physiotherapy for PFP patients should include not only knee exercises but also hip strengthening exercises, to help patients reduce their short- and long-term pain at rest and during activity.
- An elevated BMI is associated with increased prevalence of PFP in adults, but it is not clear that losing weight will improve symptoms.

[4] Orthopaedics and Traumatology Sports Center (CETE), Department of Orthopaedics and Traumatology, Paulista School of Medicine (EPM), Federal University of São Paulo, São Paulo, Brazil

Clinical scenario

- A 49-year-old male runner with a history of bilateral partial medial meniscectomies (six years prior), and worsening medial-sided right knee pain of several months' duration, refractory to cortisone injection, and conservative treatment.
- Body mass index (BMI) 27.3. Bilateral varus alignment, normal range of motion (ROM) (0–130), right knee medial joint line tenderness and pain with McMurray maneuvers.
- Radiographs demonstrate medial joint space narrowing and moderate Fairbank's changes. Long cassette radiograph reveals bilateral varus (8°).

Top three questions

1. In middle-aged patients with varus malalignment and medial osteoarthritis (OA), does high tibial osteotomy (HTO) result in superior outcomes (i.e. survivorship, function, complications) compared to unicompartmental knee arthroplasty (UKA)?
2. In middle-aged patients with lower limb varus malalignment, concomitant meniscal deficiency, and OA, does medial open-wedge high tibial osteotomy (OWHTO) result in improved outcomes (i.e. limb length alignment, function, time-dependent improvement) compared to lateral closed-wedge high tibial osteotomy (CWHTO)?
3. In middle-aged patients undergoing HTO, does bone graft supplementation improve bone healing and patient outcomes compared to no bone graft supplementation?

Question 1: In middle-aged patients with varus malalignment and medial osteoarthritis (OA), does high tibial osteotomy (HTO) result in superior outcomes (i.e. survivorship, function, complications) compared to unicompartmental knee arthroplasty (UKA)?

Rationale

HTO and UKA are both indicated for the active, middle-aged patient suffering medial-sided knee OA. However, the superiority of one technique over the other with regards to function, survivorship, and complication profiles is

controversial. Currently, a paucity of high-level evidence exists to suggest a clear benefit of one procedure over the other.

Clinical comment

It is unclear whether HTO or UKA is superior for treatment of varus-associated medial knee OA.

Available literature and quality of the evidence

To date, only three prospective, randomized controlled trials (RCTs),[1–3] performed in 1991, 2001, and 2004, have compared risks and benefits of HTO versus UKA – all specifically using CWHTO. Two nonrandomized prospective studies,[4,5] one utilizing CWHTO and one OWHTO, were published in 1989 and 2008, respectively. More recently, numerous retrospective analyses have also been included for systematic review.[6]

Findings

The highest-quality evidence comparing HTO and UKA for medial-sided OA rests with three RCTs, all using CWHTO, and published many years ago.[1–3] There was no statistical significance in 10-year survival for patients with a mean age of 67 years (77% UKA; 60% HTO).[3] Both groups had similar mean knee scores, functional Knee Society Scores, and British Orthopaedic Association scores at one, five,[2] and seven, 10 years.[3] Range of motion did not differ significantly between cohorts.[1,2] In terms of muscle torque, maximal gait velocity, and duration of single support, UKA patients demonstrated superior results at six months postoperatively compared to HTO patients at 12 months.[1] However, while UKA patients showed significantly greater free walking speed, step frequency, and step length at three months postoperatively, these differences

disappeared at one and five years.[2] Lastly, only one of three studies investigated intraoperative and postoperative complication rates, revealing higher complication rates in HTO (28.1%) versus UKA (7.1%), including deep vein thrombosis, superficial wound infection, pseudarthrosis, hardware failure, and fracture in the HTO cohort versus arthrofibrosis with UKA.[3] In summary, comparable outcomes with regard to survivorship, patient-reported outcomes, ROM, and gait were found, with possible increased complication rates in HTO over UKA.[1–3] From these studies alone, however, superiority cannot be established. Furthermore, with increasing prevalence of OWHTO versus CWHTO, RCTs comparing OWHTO and UKA are required.

A systematic review and meta-analysis of pooled results was conducted on studies of all levels of evidence: nine retrospective, three prospective randomized, and two prospective non-RCTs (total 1041 knees undergoing HTO and 5497 knees undergoing UKA). The meta-analysis demonstrated superior ROM following HTO, but less pain, higher rates of self-perceived outcome as *excellent/good*, and fewer perioperative complications after UKA. However, the procedural indications and patient characteristics vary among studies. Indeed, both procedures yield satisfactory outcomes, though it appears that valgus HTO may be more appropriate for younger active patients and UKA more appropriate for older patients.[6]

Resolution of clinical scenario

- HTO and UKA are reasonable options for this middle-aged, active individual.
- Older, high-quality trials show similar results between CWHTO and UKA.

- With the advent of OWHTO and improved technology, consideration may be given to recent, lower-level studies.
- Pooled meta-analyses showed HTO patients had better ROM, but UKA patients reported less pain, better patient scores, and fewer perioperative complications.
- As this patient is young, nonobese, and possesses full ROM, and a desire to return to activity, a joint preserving procedure may be more appropriate.

Question 2: In middle-aged patients with lower limb varus malalignment, concomitant meniscal deficiency, and OA, does medial open-wedge high tibial osteotomy (OWHTO) result in improved outcomes (i.e. limb length alignment, function, time-dependent improvement) compared to lateral closed-wedge high tibial osteotomy (CWHTO)?

Rationale

HTO is a well-established procedure for the treatment of patients with varus malalignment and OA of the medial knee. The most commonly performed techniques of HTO are lateral CWHTO and the medial OWHTO. Both techniques have their advantages and disadvantages. Still, no consensus has been reached in the literature regarding the optimal approach.

Clinical comment

As lateral-closing and medial-opening HTO are both frequently performed procedures in this aforementioned patient population, elucidating the optimal technique is critical for a more individualized and appropriate treatment plan.

Available literature and quality of the evidence

To date, several RCTs have been published comparing lateral-closing wedge and medial-opening wedge HTOs. Additionally, prospective and retrospective cohort studies have been performed.

Findings

Several differences have been reported between OWHTO and CWHTO. For example, OWHTO has been shown to lead to greater incidences of patella baja,[7,8] the effects of which may alter knee kinematics, decrease ROM, increase patellofemoral contact pressures, and lead to anterior knee pain.[7] Conflicting and variable data exists regarding accuracy of correction between the two approaches.[8–10] Higher complication rates after OWHTO have been described,[9,11] with reported six-year complication rates 38% (9% after CWHTO).[11] Conversely, in a one-year follow-up study, a greater number of complications and longer surgery times were reported following CWHTO.[8] Interestingly, more patients undergoing CWHTO required early conversion to total knee arthroplasty (TKA).[11] Additional conflicting data exists regarding limb length changes following surgery. At one-year follow-up, OWHTO significantly increased lower limb length (mean 7.6 mm), while CWHTO did not have a significant effect.[12] Additionally, radiologic outcomes at six months reported an increase in limb length after OWHTO (3.1 mm), but

observed a mean leg length decrease after CWHTO (5.7 mm).[13] Cruciate ligament stability is critical for choosing between CWHTO and OWHTO, as the technique can be employed to additionally alter tibial slope, and confer stability in the ligament-deficient state.[7,14–17] Perhaps most importantly, many studies reliably show comparable improvements in clinical outcomes between techniques regarding reduced pain and improved function comparably at one-year,[11] two-year,[18] and six-year follow-up.[11]

Resolution of clinical scenario

- CWHTO and OWHTO are both appropriate options for this selected patient, given the lack of concomitant cruciate deficiency.
- Despite conflicting data, both techniques reliably achieve alignment correction and improve clinical outcomes.
- Differences in complication rates between techniques is controversial.
- OWHTO can lead to patella baja and altered limb length.
- Earlier conversion to TKA may be expected in patients undergoing CWHTO.

Question 3: In middle-aged patients undergoing HTO, does bone graft supplementation improve bone healing and patient outcomes compared to no bone graft supplementation?

Rationale

Healing of the osteotomy site is influenced by a multitude of factors, including patient co-morbidities, surgical technique, implant stability, and biologic factors. To enhance the success of HTO procedures, there is increasing interest in developing and applying a variety of biologic and complementary therapies to accelerate new bone formation and maturation at the osteotomy site. Currently, several potential augmentation techniques exist, and efforts to define their application, efficacy, and safety are ongoing.

Clinical comment

It is unclear whether healing at the osteotomy site post-HTO can be influenced by factors (i.e. biologics, low-intensity pulsed ultrasound [LIPUS]) outside of surgical technique, implant stability, and patient characteristics.

Available literature and quality of the evidence

To date, several randomized studies exist; however, they are limited by small sample sizes, short follow-up periods, and biases from their individual randomization techniques, allocation of concealment (or lack thereof), blinding, losses to follow-up, and application of intention-to-treat analyses.

Findings

The effectiveness of mesenchymal stem cell (MSC) augmentation for improved healing in HTO patients has yet to be determined. In a prospective study comparing platelet-rich plasma (PRP) and MSC augmentation of HTO, though improved cartilage healing and acceptable improvements in Knee injury and Osteoarthritis Outcome Score (KOOS), Lysholm, and Visual Analog Scale (VAS) scores were observed in both techniques, there was no

indication of either technique contributing to enhanced healing at the osteotomy site.[19] The same holds true in another prospective RCT examining intra-articular administration of autologous bone-marrow-derived MSCs.[20]

Data regarding the effectiveness of PRP for osteotomy site healing are conflicting. Computed tomography (CT) evaluation of bone healing at the osteotomy site yielded no significant differences six weeks postoperatively when bone chips were supplemented with or without PRP.[21] In fact, marked, statistically significant reductions in bone density below the wedge were observed in PRP-supplemented patients, suggesting no benefit and even potential harm with PRP supplementation.[21] This finding contrasts the beneficial effects reported in a study comparing rates of and time for bone healing in patients with PRP and bone marrow aspirate versus patients in whom autologous iliac crest graft was used.[22] Bone-healing rates were achieved in 100% of patients grafted with autologous iliac crest, and in 91% of patients with PRP supplementation – with no difference in time required for bone healing.[22] This latter study is further supported by an RCT, which compared three groups of osteotomy site fillings: (i) osteotomy site filled with lyophilized bone chips with platelet gel (PG), (ii) lyophilized bone chips with PG and bone marrow stromal cells, and (iii) lyophilized bone chips in isolation.[23] Histology of CT-guided biopsies of the osteotomy site, and serial clinical and radiographic assessments, demonstrated complete clinical and functional healing one year postoperatively in all three groups, though both noncontrol groups demonstrated more enhanced osteointegration.[23] In an RCT of patients undergoing HTO for genu varum, comparing lyophilized bone chips with PG to those without PG, CT-guided biopsies, clinical data, and radiographic evidence demonstrated new vessel formation and

deposition of new bone 45 days postoperatively after PG supplementation, suggesting accelerated healing.[24]

Bone substitute materials have been investigated to enhance post-HTO healing. Supplementation of heterologous bone graft (HBG) with nonhydroxyapatite (NHA) been shown to improve osteointegration one year postoperatively.[25],[26] Use of hydroxyapatite or lyophilized bone chips demonstrated comparable efficacy at one year.[27] Lastly, both cadaveric and clinical studies demonstrate improved stability, complete gap healing, and no issues with wound healing, loss of correction, infection, or complications from injectable calcium phosphate into the osteotomy void.[28–30]

Lastly, of increasing interest is the application of LIPUS. Though extensively studied in the fracture population, data are sparse concerning HTO.[31] The addition of LIPUS in patients undergoing OWHTO demonstrated accelerated radiographic bone healing over the short term.[32] The clinical significance of this, however, remains unknown, and is likely influenced by the phase of bone healing that the technology is applied, as well as its duration at individual applications.[33]

Resolution of clinical scenario

- Optimizing patient characteristics and surgical technique remains the mainstay to ensuring optimal osteotomy site healing.
- There is a paucity of data surrounding the use of PRP, MSCs, hyaluronic acid, or LIPUS in the HTO population; larger studies with longer-term follow-up are needed to assess efficacy and complication profile.

Summary of answers

- High-quality evidence demonstrates similar patient-reported outcomes, gait measurements, and ROM when comparing CWHTO and UKA. A recent meta-analysis, which incorporates studies utilizing both CWHTO and OWHTO, however, demonstrates superior ROM following HTO, but less pain, better patient scores, and fewer perioperative complications after UKA. There is a paucity of high-level clinical evidence comparing OWHTO and UKA.
- In varus OA, CWHTO and OWHTO are appropriate with concomitant ACL and PCL deficiency, respectively. Controversy exists regarding the accuracy of alignment correction and complication profiles between techniques. Many studies reliably show comparable improvements in clinical outcomes between techniques regarding reduced pain and improved function comparably at one-,[11] two-,[18] and six-year follow-up.[11]
- Augmentation of osteotomy site healing with biologics or LIPUS has shown promise in short-term studies; however, larger studies with longer-term follow-up are needed to assess efficacy and complication profile.

[4] Department of Orthopaedic Surgery, Flevoziekenhuis, Almere, The Netherlands

Clinical scenario

- During a soccer match, a 23-year-old male athlete suffers an inversion injury during a cutting movement while trying to pass an opponent. The ankle immediately feels swollen and painful. He has limited ability to bear weight, and is transferred to the Emergency Department.
- According to standard protocol, the Ottawa Ankle Rules (OAR) are applied and are found positive due to pain over the lateral malleolus, and an x-ray is taken, which is negative for a fracture.
- Apart from visible swelling of the lateral ankle and pain on palpation, no further physical tests can be tolerated by the patient.

Relevant anatomy

Of all ankle sprains, 85% involve the lateral ankle ligaments.[1] This ligament complex consists of three ligaments: the anterior talofibular ligament (ATFL), the calcaneofibular ligament (CFL), and the posterior talofibular ligament (PTFL).[2] The most common mechanism leading to lateral ligament damage is an inversion–plantarflexion–internal rotation injury of the foot. Ligament damage occurs when tension on any of the three ligaments in the ankle exceeds the extensile strength in the tissue. The maximal load to failure is lowest for the ATFL followed by the CFL. The PTFL has the highest load to failure.[3] The deltoid is the primary ligament on the medial side of the ankle. Damage on the medial side of the ankle occurs less frequently and is often associated with ankle fractures. The focus of this chapter is on the lateral ankle sprains (LAS), and deltoid damage will therefore not be further discussed in this chapter.

Overall, the term *ankle sprain* is used to describe a variety of pathologies of the ligaments of the ankle. To classify the severity of damage to the ankle ligaments, a grading system has been developed (Table 144.1).[4] As the microscopic ligament severity often does not completely capture a patient's overall pathology, a system based on clinical symptoms only has also been introduced.[5]

Table 144.1 Classification system for ankle sprains and injury to lateral ligaments. Source: Adapted from Konradsen et al.[4]

	Injury severity[4]	**Clinical symptoms[5]**
Grade I	Microscopic injury without stretching of the ligament on macroscopic level	Little swelling and tenderness, minimal or no functional loss, and no mechanical joint instability
Grade II	Macroscopic stretching, but the ligament remains intact	Moderate pain, swelling, and tenderness, some joint motion loss, and mild to moderate joint instability
Grade III	Complete rupture of the ligament	Complete ligament rupture with marked swelling, hemorrhage, and tenderness, function loss, and joint motion and instability are markedly abnormal

Top three questions

1. In patients with acute lateral ankle injuries, does advanced imaging result in better diagnosis compared to radiographs only?
2. In patients with lateral ankle ligament injuries, does functional support result in better outcomes compared to cast immobilization?
3. In patients with acute injury of the lateral ligament complex, does surgical treatment lead to better outcomes compared to conservative treatment?

Question 1: In patients with acute lateral ankle injuries, does advanced imaging result in better diagnosis compared to radiographs only?

Rationale

Many patients who present to the Emergency Department after sustaining an LAS mainly suffer from pain and are unable to bear weight on the affected ankle. This in combination with pain of the lateral ankle usually leads to positive OAR, and thus x-rays are typically performed. For most patients, a fracture is then excluded. Are these rules reliable enough and are there other types of imaging that may provide more accurate diagnosis, especially in those who suffer from so much pain that it prevents full physical examination?

Clinical comment

In many patients, the pain is so severe that a thorough initial physical assessment is impossible. Reliable initial imaging techniques may help diagnose the injured tissue and decide whether early treatment is required to enable quick return to play.

Available literature and quality of the evidence

The best available evidence for this research question was mainly extracted from cohort studies and systematic reviews based on cohort studies (level II). Only two included studies had a randomized controlled trial (RCT) design (level I).

Findings

The OAR are widely used to diagnose fractures in patients who have suffered from acute ankle trauma. However, a large proportion of the radiographs are negative in patients who sustained an LAS. This raises the question whether the OAR are sufficient in patients with LAS. To compensate for the low reported specificity, the use of OAR only by an experienced nurse or physician has been proposed.[6] Other clinical decision rules, such as the Bernese decision rules, have also been suggested.[7] The sensitivity of these clinical decision rules, however, was too low to promote clinical use.[6] Ultrasound (sensitivity 92%; specificity 64%)[8],[9] in the acute setting may actually do a better job of determining which patients require a radiograph,[6] as it may both diagnose small foot and ankle fractures and ligament and other soft tissue injury (level III).[10],[11]

Additional diagnostics that may provide further insights include magnetic resonance imaging (MRI) and computed tomography (CT). Despite the role of MRI in patients who require further treatment, it is costlier than other imaging modalities, its availability is limited in the acute setting,[12] and it does not have an additional role in those who can be discharged without further follow-up.[13] Therefore, just as with CT scans, MRIs do not have any additional value in the acute setting (level II).[7]

Resolution of clinical scenario

- If a fracture is suspected, other clinical decision rules may be used in addition to the OAR to increase specificity.
- If available, ultrasonography can be used to provide a more reliable assessment of the extent of the injury and may be used to determine who requires a radiograph.

- MRI and CT imaging, especially in the acute setting, are generally not indicated.

Question 2: In patients with lateral ankle ligament injuries, does functional support result in better outcomes compared to cast immobilization?

Rationale

Patients that present to the Emergency Department are often unable to bear weight on their affected ankle. To provide some stability, immobilization by means of a cast may be chosen as an acute treatment method. However, this prevents early exercise, whereas taping and braces may be applied and removed by patients as needed.

Clinical comment

Lateral ankle ligament injury can be treated with plaster cast immobilization or functional supports, such as tape, elastic bandage, or brace. All options are widely used in clinical practice, which suggests either a lack of available evidence or a lack of familiarity with the evidence.

Available literature and quality of the evidence

A total of 10 RCTs have compared functional support with plaster cast immobilization in patients who sustained lateral ankle ligament injuries (level I).[14–23]

Findings

Functional support by means of tape, elastic bandage, or brace is widely used in the treatment of LAS. This type of

treatment provides support without immobilizing the ankle joint. Patients who were treated with a lower leg plaster cast for at least four weeks experienced more pain at short-, intermediate-, and long-term follow-up compared to patients who were treated with functional support (risk ratio [RR] = 1.50; 95% confidence interval [CI]: 1.14–1.91) (level III).[14–23] At follow-up, patients who received a plaster cast also experienced more swelling compared to patients who received functional support (RR = 1.75; 95% CI: 1.21–2.43) (level III).[14,15,17,18,21,24,25] For subjective stability, no difference was found between the different types of treatment (RR = 1.10; 95% CI: 0.81–1.45) (level III).[14–18,21,26,27]

Resolution of clinical scenario

- In case of lateral ankle ligament injury, functional support is superior to immobilization in terms of pain and swelling.
- The athlete from the clinical scenario should primarily be treated by means of functional support of choice.

Question 3: In patients with acute injury of the lateral ligament complex, does surgical treatment lead to better outcomes compared to conservative treatment?

Rationale

In patients that suffer from a severe lateral ligament injury, only elite athletes generally qualify for surgical treatment to enable quick recovery. Direct comparisons, however, are required to define the superiority of one treatment over

another and to define which patients require which type of treatment.

Clinical comment

To minimize costs and optimize decision-making, treatment modalities (e.g. conservative and surgical) need to be compared and indications need to be well defined.

Available literature and quality of the evidence

A total of 20 RCTs were found that included some form of comparison between conservative treatment and surgery in patients with lateral ligament damage after sustaining an ankle sprain (level I). Table 144.2 summarizes recommendations from available RCTs, and prospective and retrospective cohort studies (level III).

Table 144.2 Treatment per grade of severity of the ankle sprain. Source: Adapted from Lynch and Renstrom.[28]

Grade	Treatment
Grade I	"Non-operative management: functional treatment including RICE, short period of immobilization if indicated, functional support, early ROM exercises; weight-bearing, neuromuscular training exercises including proprioceptive training."[28]
Grade II	
Grade III	Early functional treatment provides the fastest recovery. Secondary surgical repair provides results comparable results to primary repair, even years after the initial injury. However, for individuals with chronic instability not responding to conservative treatment, surgery may be required.

*RICE: rest ice compression elevation; ROM: range of motion

Findings

The selected treatment may depend on the severity of the initial injury and the timing of treatment (Table 144.2). Initially, conservative treatment may be preferred as it is less invasive and provides good early functional outcomes and reasonable return to work and sport timelines. Additionally, in contrast to surgical treatment, conservative treatment is without any direct complications (other than perhaps stiffness). If surgery is found to be indicated in the subacute or chronic setting, secondary repair still provides outcomes equal to primary repair. Unfortunately, after both conservative and surgical treatment, 10–30% of patients may still suffer from chronic symptoms (level II).[28]

In terms of pain, there is a significant difference in favor of surgery only while weightbearing (RR = 0.67; 95% CI: 0.54–0.82), whereas there was no difference for pain at rest or on palpation (level II).[18,19,29–38] This effect diminishes at long-term follow-up. For swelling, no difference has been demonstrated (RR = 0.84; 95% CI: 0.64–1.10) (level II).[18,19,29–38] ROM was evidently better in the conservative treatment group (RR = 1.95; 95% CI: 1.16–3.28) (grade III).[18,27,32,34,37–39] Subjective instability is less frequent in surgical treatment patients compared to the conservative treatment patients (RR = 0.69; 95% CI: 0.57–0.83) (level II).[18,19,29–38] More patients returned to their pre-injury sports levels after surgical treatment (RR = 0.75; 95% CI: 0.39–0.83) (grade III).[27,34,37–39] Of these, there was no difference in number of patients that quit their sporting activities (RR = 0.68; 95% CI: 0.35–1.35).[34,37–39] Despite an initial reduction in level of sporting activity among patients that underwent surgical treatment, more patients returned to a higher level of activity compared to the conservative treatment group (RR = 0.53; 95% CI: 0.33–0.86) (level III).[27,34,37–39] Concerning reinjury, surgery only showed a minimal advantage (RR = 0.80; 95% CI: 0.65–

0.98) (level II).[18,27,29,31,32,34–37,40] Finally, complications reported for surgery included deep venous thrombosis (DVT), tenderness of the scar, sensory loss, wound infection, and/or necrosis, atrophy, and arthrosis, of which DVT and arthrosis were also reported for conservative treatment.[18,27,32,34,37–39]

Resolution of clinical scenario

- Both conservative treatment and surgery provide quick recovery in the acute setting, but conservative treatment provides superior results concerning joint; range of motion ROM.
- For this athlete, conservative treatment should be first-line, with secondary surgical stabilization as an option in case of failure.
- If complaints persist, and at delayed physical examination the injury is diagnosed as a grade III injury or becomes chronic, surgery should be considered.
- In individual cases of professional athletes and in cases of concomitant injuries, surgical treatment can be considered.

Summary of answers

- Imaging is of value after LAS, especially if a fracture is suspected. If available, ultrasonography should also be considered to assess who requires further assessment.
- In case of lateral ankle ligament injury, functional support is preferred over immobilization because of superior results regarding pain and swelling.
- In the less severe cases, conservative treatment is preferred.

- Secondary surgery provides similar long-term results as primary surgery, thus in case of uncertainty, a surgeon may choose to await normal recovery based on conservative treatment.
- In individual cases of professional athletes and in cases of concomitant injuries, acute surgical treatment can be considered.

145 Achilles Tendinopathy

Domiziano Tarantino MD[1], Rocco Aicale MD[1] and Nicola Maffulli MD MS PhD FRCS (Orth)[1,2]

[1] Department of Musculoskeletal Disorders, School of Medicine and Surgery, University of Salerno, Salerno, Italy

[2] Queen Mary University of London, Barts and the London School of Medicine and Dentistry, Centre for Sports and Exercise Medicine, Mile End Hospital, London, UK

Clinical scenario

- A 41-year-old male runner presents with swelling 2.5 cm in diameter, 4 cm proximal to the insertion of the Achilles tendon. For three months, he has felt pain at the beginning and at the end of training sessions, with diminished discomfort in between.
- There is tenderness of the Achilles tendon. He has no neurovascular deficits. The physician makes a diagnosis of Achilles tendinopathy (AT).
- Eccentric exercise is presented as an option for this patient. However, the patient would like to apply a wait-and-see policy or undertake a program of concentric exercises.
- After failed management with eccentric exercises alone, the physician proposes to the patient that he should undertake extracorporeal shockwave therapy (ESWT).
- After searching the internet, the patient asks the doctor to give him information about platelet-rich plasma

(PRP) injections.

Top three questions

1. In patients with AT, does a program of eccentric exercises result in better clinical outcomes compared to control?
2. In patients with AT, does a program of eccentric exercises result in better clinical outcomes compared to shockwave therapy?
3. In patients with AT, does a program of eccentric exercises result in better clinical outcomes compared to PRP injections plus eccentric exercises?

Question 1: In patients with AT, does a program of eccentric exercises result in better clinical outcomes compared to control?

Rationale

Current opinion suggests that the majority of health professionals consider eccentric exercises as an appropriate management tool for AT. Eccentric exercises have been proposed to promote collagen fiber cross-link formation within the tendon, thereby facilitating tendon remodelling.[1]

Clinical comment

Several management options have been proposed to allow recovery of patients with AT. However, outcomes with long-term follow-up of the different options are not well defined.

Available literature and quality of the evidence

A range of randomized controlled trials (RCTs) and case control studies are available to answer this question.

Findings

Comparison of eccentric exercise versus wait-and-see strategy

Horstmann et al. conducted an RCT comparing the effectiveness of whole-body vibration versus eccentric training or a wait-and-see approach for chronic AT.[2] After a 12-week intervention phase, pain improvements at the midsection of the tendon were greater in the vibration and eccentric training groups than in the wait-and-see group, but only the eccentric training intervention reduced pain at the musculotendinous junction. Improvements in sonographic parameters and changes in muscle strength were similar for the vibration training and the eccentric training groups.

Comparison of eccentric exercises versus concentric exercises

Rowe et al. performed a systematic review on the conservative management of midportion AT.[3] They pointed out that eccentric loading exercises have the strongest supporting evidence of all the conservative treatment modalities. There is moderate evidence to suggest that concentric calf muscle training is not as effective as an eccentric training regimen. Two studies randomized participants to either eccentric or concentric calf muscle training for 12 weeks.[4,5] The results from both studies showed significantly greater reductions in pain for the eccentric training group compared with the concentric training group. However, in both studies, patients reported

some improvement with concentric exercises and, in practice, combined concentric/eccentric exercises were frequently prescribed initially where eccentric exercises were intolerable because of pain or because the patient was too weak to start with eccentric exercises right away.

In a case control study, Yu et al. assessed the effect of eccentric strengthening on pain, muscle strength, endurance, and functional fitness factors in male patients with AT.[6] Eccentric strengthening, in comparison with concentric strengthening, showed significant improvement in pain, ankle dorsiflexion endurance, total balance index, and agility after the intervention.

One year later, in a single-blind, cross-sectional study, Yu et al. aimed to identify changes in muscle activation by comparing muscle activities of the affected side (AS) and nonaffected side (NAS) during eccentric and concentric exercise in runners with unilateral AT.[7] Concentric exercise induces higher maximum muscle activation in every muscle studied, except the medial gastrocnemius of the AS, where eccentric exercise induced higher maximum muscle activation when compared with concentric exercise. Relatively high levels of statistical significance were found for the rectus femoris, tibialis anterior, peroneus longus, and lateral gastrocnemius.

Beyer et al., in an RCT comprising 58 recreational athletes, evaluated the effectiveness of eccentric training (ECC) and heavy slow resistance (HSR) training among patients with midportion AT.[8] HSR training three times per week was equally effective in reducing symptoms compared to ECC performed seven days per week in patients with AT, with the former being associated with greater patient satisfaction at short-term follow-up.

Overall, there is a consensus about the positive effects of eccentric exercises protocols for patients with AT. Level I

evidence suggests that eccentric exercises are better than wait-and-see treatment in terms of pain reduction at both tendon midsection and musculotendinous junction.[2]

Regarding the comparison between eccentric and concentric exercises, in level I studies the eccentric exercises were found to be superior to concentric exercises in reducing symptoms.[3–5,8]

Level III studies have demonstrated that eccentric exercises demonstrate significant improvements in pain, ankle dorsiflexion endurance, total balance index, and agility after the intervention, and that concentric exercises are useful for muscle activation on the AS, with the exception of the medial gastrocnemius, where eccentric exercises were found to be superior.[6,7]

The available evidence provides little support for the superiority of eccentric exercises used as the only management modality; therefore, future work should compare isolated eccentric and concentric action under equal load at various exercise dosages in individuals with tendinopathy.

Resolution of clinical scenario

- Level I evidence demonstrates that eccentric exercises are superior to wait-and-see treatment.
- Level III evidence demonstrates that both eccentric and concentric exercises could be considered as equally good for patients with AT.

Question 2: In patients with AT, does a program of eccentric exercises result in better clinical outcomes compared to shockwave therapy?

Rationale

Unfortunately, not all patients with AT respond well to a program of eccentric exercises, and often other management modalities are required.

Clinical comment

ESWT may be a good option in these patients, and offers a potential alternative to other more invasive management modalities.

Available literature and quality of the evidence

Two systematic reviews[9],[10] and one current concepts review[11] are available to answer this question.

Findings

Conservative treatment with ESWT is proving successful, and moderate evidence indicates that ESWT is more effective than eccentric loading for insertional AT[12] and equal to eccentric loading for midportion AT in the short term. Additionally, there is moderate evidence that combining ESWT and eccentric loading in midportion AT may produce superior outcomes to eccentric loading alone, as reported by Rompe et al.[13]

Overall, level I evidence suggests that, even if ESWT is proving successful for AT, it is not more effective than eccentric exercises, and both ESWT and eccentric

exercises can be used together in a more efficient rehabilitative protocol for patients with AT.[9–11]

Resolution of clinical scenario

- Level I evidence demonstrates comparable results with eccentric loading or low-energy ESWT.
- Level I evidence demonstrates that eccentric loading alone is less effective when compared with a combination of eccentric loading and repetitive low-energy ESWT.

Question 3: In patients with AT, does a program of eccentric exercises result in better clinical outcomes compared to PRP injections plus eccentric exercises?

Rationale

The rationale for the use of PRP to promote tendon healing is the high content of cytokines and cells in hyperphysiologic doses of PRP.

Clinical comment

PRP is a bioactive component of whole blood, which is now being widely used in different fields of medicine for its perceived effect of aiding the regeneration of tissues with poor healing potential.[14]

Available literature and quality of the evidence

Maffulli et al.[15] evaluated the role of PRP injections for AT through the outcomes of several studies.[16–18]

Findings

De Jonge et al. did not find superiority of PRP injections over a placebo (saline) injection combined with the typical eccentric loading exercise program in terms of clinical outcomes and healing of the tendon, with no significant intergroup differences over a one-year follow-up.[16] In agreement with these findings, a follow-up study to this RCT confirmed that injection therapy using PRP does not produce a significant improvement in patients with AT compared with saline.[17] Patients were randomized to eccentric exercises with either a PRP injection or saline injection; the Victorian Institute of Sports Assessment-Achilles (VISA-A) scores over 24 weeks follow-up showed no significant differences between the two groups.

Kearney et al. published a pilot study for a larger RCT to evaluate the feasibility of conducting a larger trial to evaluate the difference in VISA-A scores at six months between patients with AT treated with a PRP injection compared with an eccentric loading programme.[18] They explicitly noted that, as a pilot study, the study was underpowered to detect clinical differences, and, in 20 patients, they failed to find a statistically significant difference between the outcome scores (VISA-A) recorded for both groups at final follow-up. The results of the definitive trial will be of great interest.

Overall, level I studies suggest that PRP injections are not superior to both placebo treatments and eccentric exercises for patients with AT.[15–18] Currently, there is no evidence that PRP injections provide statistically significant relief versus placebo in multiple randomized trials. Therefore, routine use for midsubstance AT cannot be recommended at this time.[19]

Resolution of clinical scenario

- Level I evidence demonstrates that there is no evidence to justify a PRP injection in patients with AT even when associated with appropriate physical therapy.

Summary of answers

- Eccentric exercises are superior to wait-and-see treatment, and both eccentric and concentric exercises could be considered as equally good for patients with AT.
- Comparable results can be obtained with eccentric loading or low-energy ESWT.
- Eccentric loading alone or low-energy ESWT are each less effective than a combination of eccentric loading and repetitive low-energy ESWT.
- There is no evidence to justify a PRP injection in patients with AT, even when associated with appropriate physical therapy.

VII Wrist

146 Distal Radius Malunions

Muhanned Ali MD[1], Roberto S. Rosales MD PhD[2], and Isam Atroshi MD PhD[3]

[1] Department of Orthopedics Hässleholm and Kristianstad Hospitals, Hässleholm, Sweden

[2] Unit for Hand & Microsurgery GECOT, La Laguna, Tenerife, Spain

[3] Department of Clinical Sciences – Orthopedics, Lund University, Lund, Sweden

Clinical scenario

- A 59-year-old healthy woman injures her dominant wrist after a fall at home. Her wrist radiographs show a displaced extra-articular distal radius fracture with a dorsal angulation of 15° (from 0°) and an ulnar variance of 3 mm.
- The treating surgeon has a discussion with the patient about surgical and nonsurgical treatment options and the expected outcomes in case the fracture heals with malunion or in a near anatomical position. They also discuss which treatment method would be most effective in restoring near normal anatomy.
- The patient asks, in case of symptomatic malunion, whether future surgical treatment would improve her symptoms.

Top three questions

1. In patients with distal radius fracture, does malunion increase the risk of greater patient-reported disability

and poor functional outcomes compared to those that heal in a near anatomical position?

2. In patients with displaced distal radius fracture, does treatment with open reduction and volar locking-plate fixation reduce the incidence of malunion compared to closed reduction and cast or percutaneous pin fixation?
3. In patients with a malunited distal radius fracture, is corrective osteotomy effective in improving patient-reported disability and function?

Question 1: In patients with distal radius fracture, does malunion increase the risk of greater patient-reported disability and poor functional outcomes compared to those that heal in a near anatomical position?

Rationale

Displaced distal radius fractures, if not reduced and the reduction effectively maintained by some type of fixation, heal with malunion. There is controversy regarding whether, and to what extent, distal radius fracture malunion increases the risk of disability and poor functional outcomes such as weak grip strength and limited wrist and forearm range of motion. This issue is important because it directly impacts the choice of treatment.

Clinical comment

If there is evidence that patients with malunited distal radius fracture are more likely to have worse patient-

reported outcomes and functional outcomes than those without malunion, the goal of treatment should be to ensure fracture healing in a near anatomical position. Consequently, treatment methods that have a higher likelihood of achieving this goal should be used (provided that the complication rate does not outweigh the treatment benefit). There are no established criteria for the definition of malunion but dorsal angulation of 10° or greater and positive ulnar variance of 3 mm or greater have been commonly used.[1–3]

Available literature and quality of the evidence

With regard to patient-reported disability our search identified two prognostic studies that directly address the question (one level I study and one level II study) and one therapeutic randomized controlled trial (RCT) (level I) that indirectly relates to the question. Only the level I prognostic study reported longitudinal outcomes (including baseline disability). Both prognostic studies reported relative risks (RRs). With regard to functional outcomes, our search identified three therapeutic RCTs (level I) that have addressed these outcomes in relation to malunion, but the analyses of this relationship were cross-sectional and no odds ratios or RRs were reported, decreasing their level of evidence.

Findings

In a level I prognostic longitudinal study Brogren et al. reported one-year outcomes in adult patients with displaced extra-articular or intra-articular distal radius fractures, treated with closed reduction and cast or external or percutaneous pin fixation.[4] The study found that malunion (defined as dorsal tilt >10° and/or ulnar variance ≥1 mm) is associated with higher disability, measured with the Disabilities of the Arm, Shoulder, and Hand (DASH)

questionnaire, regardless of patient age. The RR for persistent disability at one year (defined as a DASH score of ≥15) was 2.5 (95% confidence interval [CI]: 1.1–5.8) in malunion involving either dorsal tilt or ulnar variance and 3.7 (95% CI: 1.5–9.1) in malunion involving both dorsal tilt and ulnar variance. The number needed to harm (NNH) was 2.5 (95% CI: 1.8–5.4). In a longer follow-up of the cohort, Brogren et al. reported that arm-related disability, measured with the DASH, is more likely to persist at least two years in patients with fractures that healed with malunion than in patients without malunion.[5] In a level II study Grewal and MacDermid estimated that RR for persistent disability (defined as DASH score >20 or Patient-rated Wrist Evaluation [PRWE] score >20) associated with malunion (defined as dorsal angulation >10°, radial inclination <15°, or ulnar variance ≥ 3 mm) one year after distal radius fracture was 5.8 in patients of <65 years and 1.5 in older patients (DASH) and 2.9 and 1.6, respectively (PRWE); the authors concluded that patients at all ages have a higher risk of a poor outcome with malalignment of the distal radius when compared with those with acceptable alignment, but the risk is mitigated in patients over the age of 65 years.[1] In a therapeutic RCT among patients aged >65 years with distal radius fracture Arora et al. reported that in the group treated with closed reduction and cast, all patients who attended one-year follow-up (80% of those randomized) had malunion (defined as dorsal tilt ≥10°, radial shortening >2 mm, and articular incongruity ≥2 mm), but still had mean DASH and the PRWE scores indicating no or low disability.[6] The study, however, did not analyze whether the outcomes differed according to severity of malunion.

With regard to functional outcomes, Wakefield and McQueen reported that malunion, defined as dorsal angulation of ≥10° or radial shortening of ≥3 mm, was a

predictor of poor outcome.[7] Sanchez-Sotelo et al. reported that at one-year follow-up volar angle, radial angle, and ulnar variance showed a significant relationship with grip strength and range of movement.[8] McQueen et al. reported that at one-year follow-up, carpal malalignment had significant correlation with diminished grip strength and range of rotation and radial shortening had significant correlation with diminished grip strength (only p values reported, not the actual correlation coefficients).[9]

Resolution of clinical scenario

There is evidence that patients with malunion of distal radius fractures are more likely to have higher patient-reported disability and worse functional outcomes than patients without malunion.

Question 2: In patients with displaced distal radius fracture, does treatment with open reduction and volar locking-plate fixation reduce the incidence of malunion compared to closed reduction and cast or percutaneous pin fixation?

Rationale

Treatment of displaced distal radius fractures has shifted toward increasing use of open reduction and fixation with volar locking-plate. This has been based (besides the advantage of allowing early wrist motion) on the assumption that volar locking-plate fixation is more effective than closed reduction and cast or percutaneous pin fixation (common treatment methods) in restoring

normal anatomy. However, treatment with open reduction and volar plate fixation is associated with greater costs and complications.

Clinical comment

If treatment of distal radius fracture with open reduction and volar locking-plate fixation reduces the incidence of malunion, and if there is evidence that malunion is associated with a higher risk of worse patient-reported disability and functional outcomes, then the use of this treatment method is justified (provided that the complication rate does not outweigh this benefit).

Available literature and quality of the evidence

We identified six RCTs (level I therapeutic) that reported adequate radiological outcomes data comparing open reduction and fixation with volar locking-plate with closed reduction and cast or percutaneous pin fixation (with none or only a minor proportion of the patients receiving other supplemental treatment, such as external fixation).

Findings

Arora et al. compared volar locking-plate fixation with closed reduction and cast in 73 patients aged ≥65 years and reported that at one-year mean standard deviation (SD) palmar tilt was 3° (7), radial inclination 21° (3), and ulnar variance 0.7 (1.8) mm in the plate group versus −10° (19), 16° (9), and 3.2 (2.9) mm, respectively, in the cast group (all between-group differences were statistically significant).[6] Costa et al. conducted a multicenter trial with 461 adult patients and found that at one-year mean (SD) dorsal angulation was −5° (8) and ulnar variance 1.3 (2.0) mm in the plate group versus −0.5° (12) and 2.4 (2.3) mm, respectively, in the Kirschner wire (K-wire) fixation group;

adjusted mean differences (95% CI) −4.6 (−6.8 to −2.5) and −1.1 (−1.5 to −0.6), respectively.[10] Bartl et al. compared volar locking-plate fixation with closed reduction and cast in 155 patients aged ≥65 years and reported that at three months mean (SD) palmar tilt was 5° (7), radial inclination 20° (5), and ulnar variance 0.4 (1.6) mm in the plate group versus −4° (13), 18° (6), and 1.6 (2.3) mm in the cast group; mean difference (95% CI) 8.8 (5.5–12.1), 2.6 (0.9–4.3), and −1.2 (−1.8 to −0.6), respectively.[11] Marcheix et al. compared volar locking-plate with mixed pinning in 103 patients aged >50 years and reported that at six months mean (SD) palmar tilt was 1° (7), radial inclination 22° (4), and ulnar variance 2 (2) mm in the plate group versus 4° (11), 23° (5), and 2 (2) mm, respectively, in the pinning group (no statistically significant between-group differences).[12] Rozental et al. compared volar locking-plate fixation with percutaneous pin fixation in 45 patients aged 19–79 years and found that at one-year mean (SD) volar tilt was 5° (5), radial inclination 21° (4), and radial height 11 (2) mm in the plate group versus 3° (4), 21° (3), and 11 (2) mm, respectively, in the pin-fixation group (no statistically significant between-group differences); 9% of the pin-fixation group had supplemental external fixation.[13] Karantana et al. compared volar locking-plate with percutaneous pin fixation in 130 patients aged 18–73 years and found that at one-year mean (SD) volar tilt was 8° (6), radial inclination 24° (4), and radial height 11 (2) mm in the plate group, versus 2° (10), 23° (4), and 9 (3) mm, respectively, in the pin-fixation group (between-group difference in volar tilt was statistically significant); 17% of the pin-fixation group had supplemental external fixation.[14]

Resolution of clinical scenario

Treatment of displaced distal radius fracture with volar locking-plate fixation reduces the incidence of malunion compared to closed reduction and cast or percutaneous pin fixation. This benefit would need to be judged in relation to evidence regarding complications associated with these treatment methods.

Question 3: In patients with a malunited distal radius fracture, is corrective osteotomy effective in improving patient-reported disability and function?

Rationale

Patients with distal radius fracture malunion presenting with persistent disability and pain, hand weakness, and reduced wrist and/or forearm range of movement are often treated surgically with osteotomy. Distal radius osteotomy (sometimes combined with ulnar osteotomy) is a major surgical procedure that requires substantial postoperative rehabilitation.

Clinical comment

Patients with malunion of distal radius fracture often consult surgeons about the benefits of reconstructive surgery. Therefore, it is important to determine the evidence supporting the efficacy of corrective osteotomy of the malunited distal radius fracture in reducing disability and pain and improving function.

Available literature and quality of the evidence

The most appropriate study design to answer this research question would be an RCT, but no RCTs could be found. The search found three level II therapeutic studies reporting preoperative and postoperative data, enabling calculation of effect size (ES), as well as several level III studies.

Findings

Abramo et al. studied 25 patients (age 25–74, mean 52 years) with mean (SD) dorsal angulation 17° (10), radial inclination 20° (10), and ulnar variance 4.0 (2.2) mm.[15] The authors reported that at one year after osteotomy mean DASH score had improved from 36 to 23 (ES 0.81), Visual Analog Scale (VAS) pain score from 6.3 to 3.8 (ES 1.2), grip strength from 62 to 82% of uninjured side (ES 1.05), forearm rotation from 137° to 156° (ES 0.58), and flexion/extension from 102° to 120° (ES 0.85). Tarallo et al. studied 20 patients (age 17–64, mean 40 years) with mean (SD) dorsal angulation 23° (7), radial inclination 29° (7), and ulnar variance 3.6 (0.3) mm.[16] The authors reported that at 1.7–6 (mean 4) years after osteotomy, mean DASH score improved from 54 to 25 (ES 2.1), VAS pain score from 1.1 to 0.3 (ES 0.62), grip strength from 11 to 27 (ES 5.5), forearm supination from 16° to 80° (ES 8.5), forearm pronation from 75° to 84° (ES 0.62), wrist flexion from 45° to 60° (ES 0.9), and wrist extension from 39° to 70° (ES 2.8). Kiliç et al. studied 17 patients (age 18–67, mean 41 years) with mean (SD) dorsal angulation 27° (10), radial inclination 18° (6), and ulnar variance 12.1 (3.8) mm.[17] The authors reported that at 1–3.2 (mean 1.7) years after osteotomy mean Quick-DASH score improved from 27 to 6 (ES 2.3), grip strength from 18 to 24 (ES 1.0), wrist flexion from 42° to 51° (ES 0.75), forearm supination from 58° to 78° (ES 1.9), and forearm pronation from 61° to 79° (ES 5.1), whereas mean extension decreased from 59° to 56°.

The complications reported in these three studies were transient nerve lesions (radial sensory nerve in six and median nerve in two), one re-operation because of plate breakage and one flexor pollicis longus tendinitis; seven patients underwent implant removal.

The majority of the level III studies reported results in the same direction as the level II studies but the complications also included nonunions and complex regional pain syndrome.

Resolution of clinical scenario

Based on level II evidence (no RCTs) corrective osteotomy of the malunited distal radius improves patient-reported disability and pain, range of motion, and grip strength.

Summary of answers

- Patients with malunion after distal radius fracture are more likely than patients without malunion to have worse patient-reported outcomes and functional outcomes.
- Distal radius fractures are less likely to heal with malunion if treated with open reduction and fixation with volar locking-plate than with closed reduction and cast or percutaneous pin fixation.
- In patients with distal radius malunion corrective osteotomy is effective in improving patient-reported disability and pain, grip strength, and range of motion.

147 Distal Radial–Ulnar Joint

Nina Suh MD
Division of Orthopaedic Surgery, Roth McFarlane Hand and Upper Limb Centre, St. Joseph's Hospital, London, UK

Clinical scenario

- A 70-year-old female complains of persistent ulnar-sided right wrist pain with pain and clunking particularly with wrist supination and pronation.
- She has tried activity modification, bracing, and nonsteroidal anti-inflammatories with no relief of symptoms.
- She has no medical co-morbidities but she does have a remote history of a right distal radius fracture with an ulnar styloid base fracture that was treated with locked volar plating of the distal radius.

Top three questions

1. Should patients with concomitant ulnar styloid base fracture be treated with open reduction and internal fixation (ORIF) or conservatively at the time of distal radius locked plating to preserve distal radial–ulnar joint (DRUJ) stability and wrist function?
2. In patients with DRUJ instability, how successful are anatomical reconstructions of the volar and dorsal radioulnar ligaments in restoring DRUJ stability and improving clinical symptoms?

3. In patients with DRUJ instability that lead to DRUJ arthritis, does semi-constrained total DRUJ arthroplasty provide greater function, pain relief, and implant longevity compared to total ulnar head replacement?

Question 1: Should patients with concomitant ulnar styloid base fracture be treated with open reduction and internal fixation (ORIF) or conservatively at the time of distal radius locked plating to preserve distal radial–ulnar joint (DRUJ) stability and wrist function?

Rationale

Distal radius fractures are one of the most common injuries of the upper extremity and ulnar styloid fractures can be present in nearly 60% of cases.[1,2] However, the impact of an ulnar styloid fracture on DRUJ instability and wrist function in the setting of a concomitant distal radius fracture is as yet unclear and there remains contradictory evidence reported in the literature.[2–4] In particular, the impact of the location of ulnar styloid fracture, base versus nonbase, is important to understand: the attachment of the superficial limb of the triangular fibrocartilage complex (TFCC) gives the theoretical risk of increased DRUJ instability with ulnar styloid base fractures. DRUJ instability is an independent risk factor for poorer clinical outcomes and so must be avoided at all costs.[5]

Clinical comment

Understanding the radiographic parameters associated with DRUJ instability after locked volar plating will help guide clinicians to predict those injury patterns requiring early intervention.

Available literature and quality of the evidence

Literature remains sparse on this topic, and although prospective studies have been reported in the literature, none was randomized.[2,4,6,7] The majority of studies are retrospective case series.[8]

Findings

The majority of clinical studies found that the presence and/or nonunion of an ulnar styloid fracture did not affect DRUJ stability,[2,4,6–8] wrist range of motion (ROM),[2,9] grip strength,[2] and clinical outcome measures such as the Modified Mayo Wrist Score (MMWS),[2,9] Michigan Hand Outcomes Questionnaire (MHQ),[7] and/or the Disabilities of the Arm, Shoulder, and Hand Questionnaire (DASH).[2,9] Moreover, in those patients who received volar locked plating, Souer et al. found that untreated ulnar styloid base fractures that were initially displaced $\geq$2 mm did not demonstrate negative sequelae with respect to function or outcome.[6] Furthermore, although untreated ulnar styloid fractures trended toward decreased grip strength, flexion, and ulnar deviation in their patient cohort, the insignificance of ulnar styloid fracture location and displacement on DRUJ instability was confirmed by Kim et al.[2] These findings were also consistent with Lindau et al.'s study that reported no negative outcomes associated with ulnar styloid fractures despite an association between complete peripheral TFCC tears and DRUJ instability.[10] Potential bias may be present in the literature, however, as Kazemian et al. and Sammer et al. excluded patients that

were identified with ulnar styloid fractures and intraoperative DRUJ instability after volar plating of the distal radius.[4,7]

Contrary studies include a biomechanical study that found ulnar styloid fractures into the fovea caused DRUJ instability and reported only partial recovery of stability with anatomic fixation.[11] Additionally, in a mixed cohort of conservatively and operatively managed distal radius fractures, Kramer et al., May et al., and Stoffelen et al. found higher pain scores, DRUJ instability, and decreased ROM with ulnar styloid fractures.[1,12,13]

Resolution of clinical scenario

- The radiographic presence of an ulnar styloid fracture irrespective of size and displacement is not necessarily associated with DRUJ instability or worsened clinical outcomes in the setting of a distal radius fracture that has undergone open reduction internal fixation.[2,4,6–9]
- Intraoperative assessment of the DRUJ after distal radius volar plating should be undertaken to assess for residual DRUJ instability and, if present, instability should be addressed at that time.[4,7]

Question 2: In patients with DRUJ instability, how successful are anatomical reconstructions of the volar and dorsal radioulnar ligaments in restoring DRUJ stability and improving clinical symptoms?

Rationale

The DRUJ requires strong soft tissue support for stability as the bony architecture confers minimal inherent structural support.[14] The TFCC is the primary soft tissue support agreed upon in the literature and is composed of various components of which the volar and dorsal radioulnar ligaments are of particular importance.[15] Persistent DRUJ instability leads to incongruent contact on the cartilaginous surfaces and subsequently post-traumatic arthritic wear may ensue causing pain, weakness, and decreased ROM. Although other nonarticular DRUJ reconstructions are reported in the literature, they have been limited by their poor biomechanical restoration of DRUJ kinematics and stability.[16] Consequently, reconstruction of both the volar and dorsal radioulnar ligaments is favored to restore the primary restraints and kinematics of the DRUJ.

Clinical comment

Understanding the effectiveness of reconstructing both volar and dorsal radioulnar ligaments in restoring DRUJ stability and symptom relief will help guide patients to make an informed decision about postoperative surgical expectations.

Available literature and quality of the evidence

Literature remains sparse on outcomes from anatomical volar and dorsal radioulnar ligament repairs, and all reported studies are retrospective case series with varied outcome measures and inconsistent follow-up.[17–23] The largest series reported 48 patients,[20] while the longest follow-up averaged approximately nine years.[21] Although the original reconstruction proposed by Adams and Berger was the basis for most volar and dorsal radioulnar ligament reconstructions,[17] modifications were performed by many authors making true procedural comparisons

difficult.[19,20,22] In addition, some patients required concurrent procedures, making delineation of the effect of the ligamentous reconstruction alone difficult.[17,23]

Findings

All studies reported that the vast majority of patients improved DRUJ stability after the procedure with greater than 78% of patients having objective clinical resolution of DRUJ instability (range: 55–100%).[18,21,23] Mayo Wrist Scores also improved,[19,21,22] as did DASH[18,19] and Patient-Rated Wrist Evaluation (PRWE) scores.[19,23] Pain typically decreased[17,22] allowing the majority of patients to return to pre-injury work or recreational activities.[18]

Recovery of postoperative motion was less predictable with some authors reporting loss of the pronation–supination arc,[17,20,21] no change,[18,19] or an improvement.[22] Grip strength recovery was also variable with some authors reporting no significant change,[18,20] while others reported an improvement.[19,22,23] The most common postoperative complications were residual instability,[17,19–23] residual pain,[17,23] and irritation from the graft knot.[19,22] Otherwise, the procedure was not associated with complications causing significant morbidity. Lastly, no radiographic arthritic changes were noted at long-term follow-up (mean follow-up: 85.53 months).[22]

Arthroscopic-assisted TFCC ligament reconstruction is reported by some authors in the literature due to the theoretical advantage of soft tissue preservation while allowing greater exposure to debride the TFCC prior to reconstruction.[19,22] Based on the published reports in the literature, no conclusive superiority of arthroscopic versus open methods can be recommended yet.

Resolution of clinical scenario

- Reconstruction of the volar and dorsal radioulnar ligaments for irreparable TFCC tears can be recommended to provide symptom relief, improved patient satisfaction scores, increased grip strength, and equivocal pronation–supination ROM recovery with minimal complications.[17,23]
- Further investigation is required to assess whether arthroscopic methods are superior to open methods. Consequently, in the interim, the surgeon should choose the approach they are most proficient in executing.[17,19,22]

Question 3: In patients with DRUJ instability that lead to DRUJ arthritis, does semi-constrained total DRUJ arthroplasty provide greater function, pain relief, and implant longevity compared to total ulnar head replacement?

Rationale

DRUJ arthritis results in diminished wrist ROM as well as grip strength. Traditional reconstructive options for an arthritic DRUJ include partial or total distal ulna resections. However, complications such as residual stump instability and/or radioulnar convergence have compelled clinicians to seek out solutions that recreate more normal DRUJ kinematics.[24] As a result, partial or complete DRUJ arthroplasties have increasingly been utilized to provide

pain-free, stable wrists for patients; however, the evidence for clinical superiority remains unclear.

Clinical comment

Understanding the clinical outcome differences between partial versus total DRUJ arthroplasties may help guide clinicians attempting to decide between different prostheses for symptomatic DRUJ arthritis.

Available literature and quality of the evidence

The literature remains sparse with the majority of studies being retrospective, nonstandardized case series with variable long-term follow-up and inconsistent clinical outcome reporting.[25–52] The patient population investigated was also heterogeneous with variable indications for surgery, and no randomized controlled study comparing implants has yet been published.[25–52]

Findings

The two major ulnar head replacements reported in the literature are the Herbert-type prosthesis (KLS Martin, Tuttlingen, Germany)[25–33] and the Avanta Uhead (Small Bones Innovations, Morrisville, PA, USA).[30,34–37] Lesser-known implants such as the First Choice ulnar head replacement (Ascension Orthopedics Inc, Austin, TX, USA) also exist. Data interpretation is difficult as multiple implants are pooled for data comparison.[32,33] A biomechanical study comparing the Herbert and Avanta ulnar implants found them comparable in maintaining near-normal DRUJ kinematics as compared to the significantly abnormal kinematics found with distal ulna resection.[38]

For all studies related to ulnar head replacements, reported postoperative pain scores were improved[25,26,29–

[32],[36],[37],[39] and the postoperative supination to pronation arc ranged from 107° to 164°[25],[28] Furthermore, implant longevity was 99% for the Herbert-type prosthesis at a mean follow-up of 6.5 years and 90% for the Uhead at a mean follow-up of four years.[40]

Nearly all studies related to total DRUJ arthroplasty reported on the Aptis implant (Aptis Medical, Glenview, KY, USA) with the majority of published clinical outcomes originating from the institution of the original surgeon developer.[41–52] However, all studies reported postoperative pain relief with good patient satisfaction and the reported postoperative supination to pronation arc was 115° to 167°.[41–52] Implant longevity was also reported to be 98% at a mean of five years.[40]

Resolution of clinical scenario

- Implant arthroplasty would be reasonable to consider for DRUJ osteoarthritis (OA) to maintain normal DRUJ kinematics and to provide improved ROM and pain relief to patients.
- No significant difference in pain relief, ROM recovery, or implant longevity is observed between ulnar head replacement versus total DRUJ replacement; however, no comparative studies have been performed.
- Further prospective, randomized controlled, long-term trials are required to delineate implant longevity and the extent of postoperative motion recovery for partial and total DRUJ replacements.

Summary of answers

- The radiographic presence of an ulnar styloid fracture irrespective of size and displacement is not associated

with DRUJ instability or worsened clinical outcomes in the setting of a distal radius fracture that has undergone ORIF.[2,4,6–9]

- Intraoperative assessment of the DRUJ after distal radius volar plating should be undertaken to assess for residual DRUJ instability and, if present, instability should be addressed at that time.[4,7]
- Reconstruction of the volar and dorsal radioulnar ligaments for irreparable TFCC tears can be recommended to provide symptom relief, improved patient satisfaction scores, increased grip strength, and equivocal pronation–supination ROM recovery with minimal complications.[17–23]
- Further investigation is required to assess whether arthroscopic methods are superior to open methods. Consequently, in the interim, the surgeon should choose the approach they are most proficient in executing.[17,19–22]
- Implant arthroplasty would be reasonable to consider for DRUJ OA to maintain normal DRUJ kinematics and to provide improved ROM and pain relief to patients.
- No significant difference in pain relief, ROM recovery, or implant longevity is observed between ulnar head replacement versus total DRUJ replacement; however, no comparative studies have been performed.
- Further prospective, randomized controlled, long-term trials are required to delineate implant longevity and the extent of postoperative motion recovery for partial and total DRUJ replacements.

148 Wrist Osteoarthritis

Randy Bindra MD
Gold Coast Private Hospital, Southport, Queensland, Australia

Clinical scenario

- A 50-year-old accountant complains of right wrist and left thumb pain. He recalls a wrist sprain occurring over 10 years ago. Over the past two years, his pain has been gradually worsening. He describes a dull, aching pain worse with activity in the right wrist. In addition, he complains of insidious onset of left thumb pain, worse with pinching and gripping activities.
- Radiographs show evidence of radioscaphoid arthritis and scapholunate advanced collapse (SLAC) wrist on the right and scaphotrapeziotrapezoidal (STT) arthritis on the left.

Top three questions

1. In patients with wrist osteoarthritis with involvement of the radiocarpal and midcarpal joint, is arthroplasty more appropriate than total wrist fusion?
2. In patients with radioscaphoid arthritis, and preservation of the radiolunate joint, does proximal row carpectomy (PRC) result in better wrist motion than four-corner arthrodesis (4CA)?
3. In patients with STT joint arthritis is excisional arthroplasty (either distal scaphoid excision or

trapeziectomy with ligament reconstruction) more effective than STT joint arthrodesis?

Question 1: In patients with wrist osteoarthritis with involvement of the radiocarpal and midcarpal joint, is arthroplasty more appropriate than total wrist fusion?

Rationale

Total wrist arthroplasty (TWA) is a newer treatment option for the management of wrist osteoarthritis in low-demand individuals. Earlier ball-and-socket designs were associated with high loosening and dislocation rates. Current implants are better designed to be more stable with lesser range of motion (ROM) and better bony fixation.

Clinical comments

Wrist arthroplasty is indicated when other options such as PRC and partial fusion are not viable and the patient desires to retain wrist mobility. Examples of this situation would be bilateral wrist arthritis or occupation-specific situations, such as in musicians.

Available literature and quality of the evidence

Most of the literature available currently comprises case series and retrospective analyses. There is only one level III retrospective review which compares the outcomes of arthroplasty and arthrodesis of the wrist. Additionally, other literature on TWA is focused on patients with rheumatoid arthritis, which is outside the scope of this chapter.

Findings

Nydick and colleagues' study compared patient outcomes between two groups patients of whom 15 underwent wrist arthrodesis and seven had arthroplasty.[1] Mean Disabilities of the Arm, Shoulder, and Hand (DASH) Visual Analog Scale (VAS) scores were not statistically different between groups. However, mean Patient-Rated Wrist Evaluation (PRWE) was statistically significant: 31 versus 73 for TWA and arthrodesis, respectively. These questions from the PRWE were statistically significant and supportive of TWA: cut meat using a knife, fasten buttons, pushing up from a chair, personal care activities, and household work ($p = 0.01$). There was one complication of fixed wrist contracture in the arthroplasty group, two patients in the arthrodesis group had delayed union, and one required symptomatic screw removal.

In a retrospective review of 56 patients with a mean age of 52 years, who had undergone uncemented Motec wrist arthroplasty, Reigstad and colleagues found that the patients had greater ROM and grip strength at a mean of eight years following surgery.[2] Compared to preoperative values grip strength had increased by 3 kg ($p < 0.05$) and ROM had increased from 97 to 126° ($p < 0.05$). At final follow-up, 27 of 56 patients were working. The 10-year Kaplan–Meier survival of the implants was 86%.

In retrospective review of 23 wrists in 22 patients with the Maestro TWA, Nydick et al. noted that patients had a statistically significant reduction in pain from 8 to 2 ($p < 0.05$) at mean follow-up of 28 months.[3] Complications occurred in seven of the 23 patients: four wrist contractures, one implant failure, one deep infection, and one instability.

In a multicenter registry of the Remotion TWA implant, Boeckstyns reported a significant reduction in pain scores by 42 points at a mean two-year follow-up ($p < 0.01$).[4] The revision rate in this series was 3.7% with an estimated survival rate of 90% at four years.

Total wrist fusion (TWF) of the wrist has been used effectively for pain relief in the past. Weiss et al. reported being able to achieve pain relief in all of their 28 patients who underwent TWF for post-traumatic arthritis and enabled 13 of patients to return to full-time work, without restriction.[5] Four patients required re-operation due to discomfort of the extensor tendons following the surgery. In another study of 23 patients with TWF by Weiss and colleagues, 15 were able to return to full-time work at the average follow-up of 54 months.[6]

Results are not universally favorable. De Smet et al. found that many patients continued to have ongoing pain following fusions. Only six of 36 patients were pain free with activity at the time of follow-up of four years.[7] Many complications were seen in this study; 21 patients required re-operation following TWF where 18 required removal of metalwork and three required revision.

Resolution of clinical scenario

In this patient with post-traumatic wrist osteoarthritis, with pan-carpal changes, either arthroplasty or total fusion may be considered. The procedure selected will be dependent on the patient's activity level and desire to retain wrist mobility and their understanding of the limitations imposed by TWA and possibility of conversion of arthroplasty to fusion in the long term.

Question 2: In patients with radioscaphoid arthritis, and preservation of the radiolunate joint, does proximal row carpectomy (PRC) result in better wrist motion than four-corner arthrodesis (4CA)?

Rationale

Early stages of wrist arthritis with isolated involvement of the radioscaphoid joint are amenable to either PRC or 4CA. If the radiolunate and midcarpal joints are preserved, both procedures can provide pain relief while preserving wrist motion, but have different recovery periods and complications.

Clinical comment

Two usual patterns of wrist osteoarthritis include SLAC and scaphoid nonunion advanced collapse (SNAC). As long as the degenerative changes are confined to the radioscaphoid joint, both procedures (PRC and 4CA) can be offered to patients for pain relief and preservation of motion. However, once the arthritis has progressed to involve the midcarpal joint and the capitate articular surface, PRC becomes less viable and surgeons generally prefer 4CA.

Available literature and quality of the evidence

Authors have compared the outcomes of 4CA versus PRC with randomized controlled trials, and others have reported on case series. Clinical outcomes measured include: grip strength, wrist motion, rates of complication, and re-operations.

Findings

Both procedures have yielded good results with regard to pain relief. In a prospective randomized study Bisneto et al. reported on 23 patients with SLAC wrist not involving the midcarpal joint who underwent either PRC or 4CA performed by a single surgeon.[8] Pain reduction in the PRC group was significantly higher at 41% compared to preoperative scores ($p \leq 0.05$). The 4CA group experienced a 33% reduction in pain, but this was not statistically significant. Comparative postoperative pain scores between the two groups were not statistically significant. When measured 12 months postoperatively, ROM was significantly reduced in the operated wrists compared to preoperative values ($p \leq 0.05$). The average arc of flexion/extension was reduced by 25 and 17% in the 4CA and PRC groups, respectively. The average radial deviation was 0.3 and 10% less in the 4CA and PRC groups, respectively. Both procedures resulted in improved DASH scores when compared to preoperative values; the 4CA group saw a 30% reduction, while the PRC group saw a similar reduction of 28%.

Complications, particularly relating to hardware and union of the arthrodesis, are exclusive to 4CA. Traditional fixation involved stabilization of the construct with multiple Kirschner wires. Infection and discomfort from the wires prompted the use of specialized plates and similar implants. The use of circular plate fixations has been associated with delayed or non-union and dorsal impingement of the plate.[9] In this series, complications of the implant resulted in worsened grip strength, motion and a patient dissatisfaction rate of 40%. Furthermore, DASH scores were significantly different between the two groups: plate fixation scored 27, while traditional methods scored 8 ($p < 0.01$).[9]

Clinical improvement following PRC appears to be sustained in the long term. At an average of 24 years' follow-up, Wall and co-workers reported that 65% of patients were still satisfied with the outcome of the surgery.[10] Other authors have reported sustained improvement in grip and maintenance of satisfactory movement after more than a decade.[10],[11]

In a retrospective review by DiDonna and co-workers, where 21 patients treated with PRC, four patients required wrist fusion for painful radiocapitate arthritis. All these patients were below 35 years of age ($p = 0.03$), and this finding was presumably due to their higher activity levels and demands placed on the wrist.[12]

Resolution of clinical scenario

In our patient with wrist osteoarthritis involving the radioscaphoid joint following a chronic scapholunate disruption, it is appropriate to consider either 4CA or PRC. The reported higher complication rates of nonunion with 4CA and relatively similar outcomes with PRC, favor undertaking a PRC in patients over the age of 35.

Question 3: In patients with STT joint arthritis is excisional arthroplasty (either distal scaphoid excision or trapeziectomy with ligament reconstruction) more effective than STT joint arthrodesis?

Rationale

Scaphotrapeziotrapezoidal (STT) joint arthritis can be managed operatively by arthrodesis or arthroplasty using

an implant or interposed tendon. Arthroplasty has the advantage of retaining movement and avoids the risk of nonunion associated with arthrodesis.

Clinical comment

Degeneration of the STT joint is a natural part of aging. Arthritis in the STT joint can be disabling due to involvement of the wrist and the thumb. Once conservative management fails, operative treatment can be considered in the form of arthrodesis or excision arthroplasty of the STT articulation.

Available literature and quality of the evidence

While there is no study comparing outcomes of excision arthroplasty versus fusion, there are several case series of each treatment option that can help guide management. Among the options for excision arthroplasty, there are no studies comparing trapeziectomy with distal scaphoid excision for the management of isolated STT osteoarthritis.

Findings

When considering distal scaphoid excision arthroplasty or arthrodesis for this patient, it is important to consider the requirements of the patient. Garcia-Elias et al. reviewed 21 patients who were treated with a partial distal scaphoid excision, with or without tendon interposition.[13] The authors found that grip and pinch strength had increased by 26% and 40%, respectively, when compared to their preoperative measurements ($p = 0.001$). Nine patients had insertion of a flexor carpi radialis (FCR) *anchovy* or a capsular flap following resection. Patients with soft tissue interposition had significantly reduced motion at 113° compared to no interposition at 127° ($p = 0.04$) and there

was no difference in the grip strength between the two groups.

Pyrocarbon interposition arthroplasty for STT arthritis is generally considered for patients with dorsal intercalated segment instability (DISI) collapse of the wrist where excision is contraindicated. Scaphotrapezium pyrocarbon implants were employed for interpositional arthroplasty in a series of nine patients by Low and Edmunds.[14] Patients experienced pain relief following the procedure with VAS pain scores decreasing at rest and heavy activity by 4.9 and 6.7, respectively. In addition, wrist flexion and extension on average was above 90%, while grip and pinch strength were above 80% when compared to the contralateral side. The mean DASH score was 21 postoperatively and there were no complications at the mean follow-up time of 16.4 months. Pegoli and colleagues examined ten patients at an average of 19 months after pyrocarbon arthroplasty.[15] All patients returned to their daily activities three months postoperatively and pain scores reduced by four at both rest and activity. Additionally, both grip and pinch strength improved postoperatively by 25 and 29%, respectively. The authors had two (20%) dislocations requiring re-operation in their study.

In patients who have isolated STT arthritis, a trapeziectomy and excision of the proximal 2 mm of the trapezoid with ligamental reconstruction and tendon interposition has been recommended as an alternative treatment option.[16,17]

Andrachuk and Yang in 2012 examined cases of isolated STT arthritis in 12 wrists in 10 patients with an average age of 59 years and mean follow up 18 months.[18] The authors performed a complete excision of trapezium and resected approximately one-quarter of the proximal trapezoid. The authors noted a significant postoperative increase in the mean wrist flexion and extension from 48°

and 53° to 52° and 55°, respectively ($p < 0.05$). While these results are statistically significant, they are not, however, clinically relevant. Mean grip and pinch strengths improved from 15.6 to 19.2 kg and from 3.5 to 4.5 kg, respectively. Postoperative pain scores improved from 8.5 to 1.8 ($p < 0.001$). The Modified Mayo Wrist Score graded six patients as excellent, three as good, and a single patient as fair.

Reporting similar clinical outcome, Lagenhan and associates have recommended trapeziectomy with soft tissue reconstruction without partial trapezoid resection for the treatment of isolated STT arthritis.[19] In their series of 14 consecutive patients with a mean age of 65 and mean follow-up of 54 months, the authors reported a mean VAS score of 0, average grip strength of 24 kg, pinch strength 5 kg, DASH score of 16, and Modified Mayo Wrist Score of 84. The authors noted two patients complained of wrist pain at the time of final follow-up.

Watson et al. found that arthrodesis of the scaphotrapezial joint for arthritis provides pain relief and satisfactory wrist motion with 86% of patients, reporting improved function following operation. After an average of 14.7 weeks, 88% of patients returned to work.[16] Furthermore, the authors noted a low complication rate of 4%. However, other authors have had higher failure rates following STT fusion. Five of 19 patients had nonunion of STT fusion in the series reported by Frykman and coworkers.[17]

Resolution of clinical scenario

In this patient is appropriate to offer a distal scaphoid excision arthroplasty for treatment of his painful wrist; however, the existence of a DISI deformity must be excluded preoperatively. Alternatively, this patient may be offered a trapeziectomy with ligament reconstruction and

tendon interposition (LRTI), with similar clinical outcomes. Excision of the proximal part of the trapezoid does not seem to be imperative.

Summary of answers

- Wrist arthroplasty provides higher satisfaction rates than wrist arthrodesis. TWA does place restrictions on patients' activity level, and careful patient selection is necessary.
- For early stages of SLAC wrist, PRC provides outcomes similar to 4CA with a lower complication rate.
- When treating symptomatic isolated STT arthritis in the absence of wrist instability, excision arthroplasty, either of the distal scaphoid or the trapezium, is a more favorable option as it avoids the risk of nonunion while providing pain relief and maintaining mobility. There is no evidence that the interposition of soft tissue or implants provides any additional benefit.

149 Rheumatoid Wrist Reconstruction

Warren Hammert DDS MD
University of Rochester Medical Center, Rochester, NY, USA

Clinical scenario

- A 55-year-old woman with a history of rheumatoid arthritis (RA) is seen with progressive deformity in her wrists and hands.
- Radiographs demonstrate distal radioulnar joint (DRUJ) incongruity with dorsal prominence of her distal ulna, flexion of the scaphoid, radiocarpal degenerative changes, and ulnar deviation of her fingers.

Top three questions

1. In RA patients with DRUJ arthritis, does prosthetic arthroplasty provide better outcomes and stability compared to distal ulnar resection arthroplasty (Darrach)?
2. In RA patients with radiocarpal deformities (arthritis or carpal subluxation), does limited arthrodesis provide acceptable long-term results compared to total wrist arthrodesis?
3. In RA patients with advanced radiocarpal and midcarpal arthritis, do total wrist arthroplasty outcomes justify the expense when compared to wrist arthrodesis?

Question 1: In RA patients with DRUJ arthritis, does prosthetic arthroplasty provide better outcomes and stability compared to distal ulnar resection arthroplasty (Darrach)?

Rationale

The distal ulna is commonly dorsally prominent in RA due to incompetent ligamentous stabilizers of the DRUJ and volar extensor carpi ulnaris (ECU) subluxation, causing carpal supination and a caput ulna deformity. This deformity can cause attritional ruptures of extensor tendons, pain, and limitation in forearm pronation and supination.[1] Surgical treatment initially focused upon resection arthroplasty, as described by Darrach;[2] however, this treatment can lead to painful complications and newer surgical treatments have been developed, including a semi-constrained total DRUJ arthroplasty.[1],[3]

Clinical comment

Treatment of DRUJ pathology with resection arthroplasty relies upon local tissue stabilization to prevent symptomatic radioulnar impingement. Semi-constrained prostheses, which include an ulnar stem and link to the radius at the sigmoid notch, as described by Scheker,[3] do not rely upon soft tissue stabilization in patients that have demonstrated incompetent tissue quality, and may help prevent complications in the RA patient.

Available literature and quality of the evidence

No studies have directly compared prosthetic arthroplasty to resection arthroplasty. Level IV studies have evaluated

patient outcomes both with total DRUJ arthroplasty and distal ulna resection arthroplasty in RA patients.

Findings

With regards to distal ulna resection, Fraser et al. in 1999 evaluated the outcomes in RA patients and in post-traumatic patients and found that RA patients had improved pain, with 34 of 37 wrists pain free, and an increase in grip strength (average of 0.8 kg).[4] Additionally, Rana and Taylor evaluated 86 wrists in 70 RA patients treated with distal ulnar resection, reporting 95% pain-free wrists after surgery, improvement in forearm pronation and supination in all, and improvement in grip strength in 88%.[5] Within these case series, the authors did not find substantial pain or functional limitations from the previously described complications of distal ulna resection, including ulnar drift of the carpus, radioulnar impingement and ulnar instability. They reported ulnar clicking, without significant pain, and progressive ulnar drift of the carpus, without an influence on the patient's overall result.[4],[5]

When evaluating the semi-constrained DRUJ arthroplasty, Galvis and colleagues in 2014 evaluated a case series of RA patients who underwent 19 total DRUJ arthroplasties. At an average of 39-month follow-up, these patients demonstrated decreased pain from Visual Analog Scale (VAS) of 7.4 to 2.2, improvement in pronation from 56° to 78°, and improved supination of from 56° to 72°. No progression of ulnar carpal drift or tendon ruptures occurred; however, tendon irritation was seen in one patient.[6] Additional studies have evaluated patient outcomes after DRUJ arthroplasty; however, these studies were not specific to RA patients.

Resolution of clinical scenario

- There is incomplete evidence to conclusively support DRUJ arthroplasty over resection arthroplasty.
- Technical rationale including decreased reliance on incompetent soft tissue structures and decreased risk of radioulnar impingement support DRUJ arthroplasty as a reasonable alternative to DRUJ resection arthroplasty, specifically in the younger and less debilitated RA patient.
- Additionally, total DRUJ arthroplasty could be considered as a salvage option for a symptomatic resection arthroplasty if adequate ulnar length is maintained.
- Longer follow-up studies will be helpful in supporting DRUJ arthroplasty as a primary procedure for DRUJ deformity in RA.

Question 2: In RA patients with radiocarpal deformities (arthritis or carpal subluxation), does limited arthrodesis provide acceptable long-term results compared to total wrist arthrodesis?

Rationale

As commonly seen in RA patients, limited arthrodesis at the radiolunate or radioscapholunate joints allows for maintenance of wrist motion at the capitolunate articulation, or in the dart-throwing motion plane,[7] in patients with advanced degenerative changes of the radiocarpal articulation or carpal subluxation and preservation of the midcarpal joint.

Clinical comment

Degenerative changes within the midcarpal joint are commonly delayed in RA patients, as synovitis occurs later in the midcarpal joint as a result of the sparse ligamentous attachments.[1] In patients with subluxation of the carpus or advanced radiocarpal arthritis without degenerative changes to the midcarpal joint, partial wrist fusions allow for maintenance of some wrist motion. However, it is unclear whether partial wrist fusions demonstrate acceptable long-term outcomes versus total wrist arthrodesis in RA patients.

Available literature and quality of the evidence

No studies have directly compared limited versus total wrist arthrodesis. Level IV studies have evaluated patient outcomes with partial wrist arthrodesis.

Findings

Raven et al. performed the most recent long-term follow-up of RA patients after partial wrist arthrodeses and demonstrated improved wrist range of motion (ROM) and less pain, in spite of radiographic progression of midcarpal arthritis over time.[8] The authors reviewed studies on a total of 395 partial wrist arthrodeses and demonstrated consistent improvement in pain, patient satisfaction, wrist ROM, and grip strength.[8] Honkanen et al. showed maintenance of fusion in a mixed group of radioscapholunate and radiolunate arthrodesis RA patients who demonstrated a functional arc of wrist motion and improved grip strength. Two wrists progressed to midcarpal arthritis and underwent total wrist arthrodesis within the group of 23 wrists.[9] Ishikawa and colleagues evaluated long-term results in 25 patients who underwent partial wrist arthrodeses, demonstrating decreased pain,

improved forearm rotation, and increased grip strength at 10-year follow-up. They noted progression of carpal collapse in many of the patients over the follow-up period; however, all but one wrist remained stable.[10] The primary limitation of these studies is the lack of a control group, as all are case series.

Cavaliere and Chung's systematic review comparing arthrodesis and arthroplasty reported improved pain and patient satisfaction with consistent surgical outcomes after wrist arthrodesis.[11] Overall, total wrist arthrodesis does provide consistent outcomes but with loss of all wrist motion compared to a partial wrist arthrodesis.

Resolution of clinical scenario

- In the RA patient with radiocarpal deformity, without advanced degenerative changes in the midcarpal joint, a partial wrist arthrodesis provides a reliable rate of union, pain relief, and patient satisfaction.
- Even with progression of midcarpal arthritis after limited arthrodesis, the majority of patients demonstrate acceptable long-term outcomes to recommend partial wrist arthrodesis.

Question 3: In RA patients with advanced radiocarpal and midcarpal arthritis, do total wrist arthroplasty outcomes justify the expense when compared to wrist arthrodesis?

Rationale

In patients with RA at both the radiocarpal and midcarpal joints, total wrist arthrodesis and wrist arthroplasty are viable surgical options to alleviate pain.[1] While total wrist arthroplasty theoretically maintains wrist ROM, it is unclear whether patient outcomes after arthroplasty are sufficiently improved to justify the increased cost of arthroplasty when compared to arthrodesis.

Clinical comment

When wrist arthritis involves the midcarpal joint and there is loss of wrist motion, both wrist arthroplasty and total wrist arthroplasty provide reliable outcomes in the RA patient population.

Available literature and quality of the evidence

Systematic reviews of case series and cohort studies comparing the outcomes of arthroplasty and arthrodesis are present within the literature. A single level III prospective cohort study comparing patients is identified. A decision analysis level II study is also present to assist in answering this clinical question.

Findings

Murphy et al. evaluated arthroplasty and arthrodesis in 51 RA wrists in a prospective cohort study. Patients had similar outcomes, but improved ability for personal hygiene and buttoning in the arthroplasty group.[12] Cavaliere and Chung have contributed several studies to the management of advanced wrist arthritis in the RA patient. In 2008, they performed a systematic review on 18 arthroplasty and 20 arthrodesis studies. They concluded that arthrodesis provides more reliable outcomes and improved pain relief when compared to arthroplasty. Both groups demonstrated high patient satisfaction with increased complication and

revision rates following arthroplasty. While a theoretical benefit of arthroplasty is maintenance of motion, only three of the 14 studies demonstrated a functional ROM after arthroplasty.[11] In 2015, Yeoh and Tourret performed a systematic review of total wrist arthroplasty studies in the preceding five years and reported complication rates. Similarly, complications following wrist arthroplasty were higher than for arthrodesis and the preserved ROM did not always reach the full functional range. Additionally, survival rates vary between prosthetic design, and the authors recommend being selective in patients receiving this procedure.[13]

A survey of the American Society for Surgery of the Hand members and RA patients in 2010[14] reported that arthroplasty was preferred over nonsurgical treatment. An incremental cost of $2328/QALY gained for arthroplasty over arthrodesis was well below the $50 000 benchmark used to set the preferred treatment. This decision analysis study demonstrates that, despite the risk of revision surgery and increased costs of arthroplasty, RA patients may prefer this option and it should be considered a viable alternative.[15]

Resolution of clinical scenario

- Total wrist arthroplasty appears to be a cost-effective surgical option if the patient desires wrist motion, understands that functional wrist ROM cannot be guaranteed, and accepts the increased risks of revision and complications.
- If a patient with a contralateral wrist arthrodesis presents with advanced wrist arthritis, wrist arthroplasty should be considered to optimize function and the patient's ability to perform activities of daily living.

Summary of answers

- No comparative studies exist between prosthetic or resection arthroplasty of the DRUJ. In younger patients primary semi-constrained prosthetic DRUJ arthroplasty may decrease potential complications; however, resection of the distal ulna in lower demand patients may provide good outcomes.
- In patients without midcarpal arthritis, partial wrist arthrodesis provides reliable long-term outcomes with improved pain and patient satisfaction while maintaining wrist ROM and improving grip strength.
- Outcomes and cost analysis of wrist arthroplasty demonstrate that it is a reasonable surgical option for patients; however, preoperative patient counseling about the unpredictable outcomes and increased risk of revisions is critical to patient expectations.

150 Acute Scaphoid Fractures

Joseph J. Dias MD (Research) FRCS MBBS
AToMS, University Hospitals of Leicester NHS Trust, Leicester, UK

Clinical scenario

- A 26-year-old man presents after a fall onto outstretched hand with pain on the radial side of the wrist.
- He has five radiographic views of the wrist which demonstrate a clear bicortical fracture of the waist of the scaphoid.

Background

One in every 50 fractures is a scaphoid fracture,[1] and it occurs in young men, especially aged between 15 and 24.[2] Only 12% of scaphoid fractures occur in women, and the highest incidence is in girls between 10 and 14 years of age. The waist of the scaphoid is fractured in 77%, the tuberosity in 18%, and the proximal pole in around 5%. No scaphoid fracture classification clearly predicts union or indicates treatment but classifications help describe reported cases.[3–6]

Once a clear bicortical fracture is identified, the treatment objective is to get the fracture to unite and restore function without pain. The clinician needs to decide how to immobilize the fracture so that it unites without (i) disabling the patient for long periods or (ii) exposing patients to significant risks with lifelong disability.

Top three questions

1. In adult patients with a scaphoid fracture, do some imaging modalities provide better ability to determine union compared to other modalities?
2. In adult patients with a clear bicortical fracture of the scaphoid, does cast immobilization or screw fixation result in higher union rates and faster time to union?
3. In adults with clear bicortical fractures, are there certain fracture characteristics that influence union rates or the decision to treat operatively versus nonoperatively?

Question 1: In adult patients with a scaphoid fracture, do some imaging modalities provide better ability to determine union compared to other modalities?

Rationale

Union is the common endpoint used to define outcomes in scaphoid fractures. Clear definitions of union, time to union, partial union, and nonunion are needed.

Clinical comment

Union and time to union can be difficult to define and authors use different methods (i.e. x-ray vs computerized tomography) to diagnose union.

Available literature and quality of the evidence

The clinically relevant outcome for a scaphoid fracture is *union* of the fracture as determined by imaging. The imaging attributes which suggest that the fracture is uniting are:[7]

- Trabeculae crossing the fracture line on *all* imaging projections.
- Sclerosis at the fracture line on *all* imaging projections.
- Absence of a clear gap across the full width of the fracture line on *any* imaging projection.

For radiographs these attributes are difficult to assess confidently, and the assessment of union,[8] especially at early timepoints, is unreliable.[7] Computed tomography (CT) CT scan has been proposed as an alternative and some methods of assessing union and especially partial union have been suggested and tested but have not yet been established.[9–11] At present there is no clarity of definition and classification of union on imaging, although a framework for this has been suggested.[12]

Findings

Union

Union is established on imaging. Radiographic views of the scaphoid are usually taken to confirm the absence of adverse radiological features such as a gap at the fracture site or displacement. Very rarely, if an implant has been used, lucency or implant movement will suggest failure of union.[12] Radiographs taken 12 weeks after a scaphoid fracture do not provide reliable and reproducible evidence of healing.[7] The usual advice is that radiological union is only considered to have occurred when *bridging trabeculae* are seen across the whole cross-section of the scaphoid on

radiographs or a CT scan.[13] This is difficult to confirm, so it is sensible to identify failure rather than assume that *no gap* means the bone has united.

Time to union

Time to union is difficult to calculate as it depends on the interval of the imaging and how union was assessed. It is usually provided as a *mean* but reflects the first clinical timepoint where imaging obtained is judged to suggest fracture union.[14] "Measuring 'time to union' presupposes that the state of union has been clearly defined, that it can be reliably assessed using current techniques and that this state is measured continuously rather than at the usual intervals after intervention. Although the time to union is documented in a number of studies, this is based on the first visit after intervention when the surgeon has felt able to diagnose 'union.'"[12]

Partial union

Partial union is defined as the presence of a visible gap across part of the fracture site associated with probable *trabecular bridging* in other areas identified on radiographs but quantified on CT scan.[15] Partial union is common, being reported in up to 42% of patients. With trabeculae bridging across more than 25% of the cross-section of the scaphoid, it typically progresses to complete union without the need for further immobilization, although the wrist may need protection in a splint for heavy activity for a further four- to six-week period.[15]

Nonunion

Nonunion is the absence of radiographic signs of healing at 12 weeks with a clear gap on radiographs on any view and confirmed on a CT scan.[9],[11],[13] A high-quality CT scan (fine

cut, bone window) will help establish a diagnosis of nonunion, define the anatomy, and help with preoperative planning. Patients with an established scaphoid nonunion (whether they are symptomatic or not) who decide to be treated nonoperatively should be advised that osteoarthritis is a likely, and avoidable, eventuality.[16]

Resolution of clinical scenario

In our clinical practice, CT scans are only indicated to identify nonunion and quantify significant partial union. We do not routinely use CT scans to confirm union, owing to cost, capacity, and availability. We recognize, however, that many surgeons use CT scans to define union rather than relying on plain radiography.

Question 2: In adult patients with a clear bicortical fracture of the scaphoid, does cast immobilization or screw fixation result in higher union rates and faster time to union?

Rationale

The decision to treat undisplaced or minimally displaced scaphoid fractures with cast immobilization or with surgical fixation is one of the most controversial areas in the treatment of scaphoid fractures. Multiple studies have attempted to address this issue, but the answer is still unclear.

Clinical comment

When using a cast to immobilize the broken scaphoid, surgeons must decide on the type of cast used and the

duration of immobilization. An undisplaced or minimally displaced scaphoid fracture can be immobilized in a below-elbow plaster cast with the thumb free for as little as four weeks to achieve union.[17] The alternative is to operate and fix the broken scaphoid. The intervention must be explained, and the patient should understand the risks, benefits, and alternatives to surgery. Many patients assume that surgical fixation will allow immediate resumption of activity, regardless of its demands on the wrist, as if the fracture has “healed.” Patients must be made aware that fixation is only an internal splint holding the alignment of the scaphoid as the physiological processes of healing occurs.

Available literature and quality of the evidence

There are at least seven reported trials[14,18–23] comparing cast versus fixation and one multicenter cohort study[24] for the treatment of acute scaphoid fractures. There are numerous systematic reviews of these papers.[25–32]

Findings

About 50% of units in the UK (including the author's) use a below-elbow cast,[33] which leaves the thumb free and, by permitting pinch, retains function from the outset.[34] Others continue to use a so-called traditional scaphoid plaster cast, which immobilizes the thumb. With the thumb immobilized, the additional restriction of movement at the fracture site is very small. The thumb can be immobilized in two positions. A functional position permits opposition of the thumb allowing pulp-pinch and tripod-pinch. A thumb immobilized in extension renders pinch difficult, limiting prehension and activities of daily living. In summary, hand function is *good* in a below-elbow cast with the thumb left free, *adequate* in a scaphoid cast in functional position,

restricted in a scaphoid cast in a dysfunctional position, and *hugely compromised* in an above-elbow cast.

Surgical screw fixation is an alternative treatment option. The risks of surgery include infection (1%),[30] the need for additional surgery (7.7%),[30] chronic regional pain syndrome (2%),[30] and osteoarthritis, if the approach damages joint cartilage (40%).[35] Delayed union and nonunion (3–7%)[35,36] after internal fixation can occur if there is a loss of rigid fixation caused by screw malpositioning, fixation maintaining a gap, inadequate reduction, avascular necrosis (AVN) of the proximal pole,[37] or implant loosening. Chondrolysis and implant-related problems can also occur, especially if the hold is poor or the implant was long and protruding into a joint.

The literature has not been able to establish a significant difference between the two treatment methods for the rate of union: patient-reported outcome measures (PROMs) or re-operation/surgery for nonunion rate after acute fractures. A few have suggested that *time to union* and recovery of function is quicker after surgery. The studies included are small, with different timepoints and some reviews,[32] and meta-analyses have also included case series.[38–40]

Resolution of clinical scenario

We formulate an intervention plan with our patient having considered that:

- There is no difference in union rates between cast immobilization and fixation (overall quality: moderate).
- There is no difference in PROMs between these two alternatives (overall quality: very low).

- There are slightly more patients requiring re-operation than requiring early fixation for a nonunion (overall quality: low).
- And there is a higher complication rate in patients having immediate fixation (overall quality: low).

Our patients usually choose the nonoperative pathway and are prepared for fixation of a nonunion if required.

Question 3: In adults with clear bicortical fractures, are there certain fracture characteristics that influence union rates or the decision to treat operatively versus nonoperatively?

Rationale

Two factors that can modify a treatment pathway are fracture location and fracture displacement as these can change the natural history of this injury.

Clinical comment

Proximal pole fractures and displaced fractures have a higher likelihood of developing into a nonunion. In cases such as these, where it is considered unlikely that the fracture will heal with conservative measures, surgery could be considered from the outset.

Available literature and quality of the evidence

There is little literature reporting specifically on the outcomes of proximal pole fractures. Eight papers were identified which reported outcomes of proximal pole fractures separately.[34–41–47] Two of the papers were RCTs

with identified flaws in method so were regarded as providing level II evidence,[34,42] the remaining six papers were retrospective case series accounting for level IV evidence.

At present, there is no RCT comparing healing rates of displaced versus undisplaced scaphoid fractures. A meta-analysis[48] identified eight papers[4,34,46,49–53] reporting outcomes after cast immobilization in 232 displaced and 1303 undisplaced fractures. Two of these papers were RCTs with some flaws in method and so were considered to provide level II evidence,[34,49] six were case series of which one was prospective but all were considered as providing level IV evidence. One paper[52] was excluded and the pooled relative risk of nonunion for displaced fractures versus undisplaced fractures of the scaphoid treated in a plaster cast was 4.4. Review of case series of displaced fractures operated suggests a very low rate of failure of union (2 of 157 cases).[36,54–57]

Findings

Proximal pole fractures are uncommon and account for around 5% of all scaphoid fractures. They behave differently than waist or distal pole fractures.[58] This may reflect the intra-articular location and the precarious circulation of this region of the scaphoid.

Extracting information on proximal pole fractures is difficult as studies use different definitions of proximal fractures so the fractures so classified may not be only those located in the proximal 20%.[58] Eight papers were identified[34,41–47] reporting on 1147 scaphoid waist fracture, of which 1021 united, and 67 proximal pole fractures, of which 44 united. The relative risk of nonunion in proximal pole scaphoid fractures compared to fractures of the waist of the scaphoid is 6.3, although 69% of these

fractures will still unite if immobilized in a cast. There is no good evidence at present to suggest that early fixation of proximal pole fractures improves the union rate. The few that report surgery in 40 patients with a *proximal* fracture (and which may have included waist fractures) report union in 38.[59–61]

The second fracture attribute which may alter the pathway chosen is displacement of the fracture fragment. A scaphoid fracture is considered displaced if the fracture fragments have a step or gap ≥1 mm between the corresponding cortices on any radiological view, although the fragments may also angle or rotate. A step or gap ≥ 2mm is considered significantly displaced. Fracture displacement is better assessed on CT or magnetic resonance imaging (MRI) than on scaphoid series radiographs.[33] Angulation is more reproducibly measured using the height to length ratio[62] and the mean normal ratio is 0.61.[63] This needs to be >0.69 to consider it as a significant angular malposition. However, this method too is not fully robust.[63] A high-quality CT scan with multiplanar reconstructions in the axis of the scaphoid and using a bone window may provide better definition of fracture displacement.

The clinical impression is that fractures involving the proximal 20% and/or displaced fractures, with a 3 mm or more gap, do not unite as readily and as quickly as waist fractures so the case to consider surgical fixation is stronger. Although immobilization in a cast for six weeks will result in union of 80–85% of displaced fractures of the scaphoid,[34] the consequence of the fracture healing in a displaced position is malunion, but we do not clearly know what to tell our patients about symptoms they will experience if the scaphoid heals in a nonanatomical position. At present we know that there is a higher risk of

nonunion for displaced scaphoid fractures compared with nondisplaced fractures if treated in a cast. There is some weak evidence that fixation reduces the rate of nonunion. But we do not know if fixation reduces the rate of malunion or arthritis. This should be explained to patients.

Resolution of clinical scenario

We check if the fracture affects the proximal 20% and our counseling reflects the current evidence (overall quality: low). We then measure displacement as <1 mm, 1 to <2 mm and ≥2 mm step or gap and again modify our discussion with the patient based on the current evidence (overall quality: low).

Summary of answers

- In our clinical practice, CT scans are only indicated to identify nonunion and quantify significant partial union. We do not routinely use CT scans to confirm union, owing to cost, capacity, and availability.
- We formulate an intervention plan with our patient having considered that:

    There is no difference in union rates between cast immobilization and fixation (overall quality: moderate).

    There is no difference in PROMs between these two alternatives (overall quality: very low).

    There are slightly more patients requiring re-operation than requiring early fixation for a nonunion (overall quality: low).

    And there is a higher complication rate in patients having immediate fixation (overall quality: low).

Our patients usually choose the nonoperative pathway and are prepared for fixation of a nonunion if required.

- We check if the fracture affects the proximal 20% and our counseling reflects the current evidence (overall quality: low). We then measure displacement as <1 mm, 1 to <2 mm and ≥2 mm step or gap and again modify our discussion with the patient based on the current evidence (overall quality: low).

Clinical scenario

- A 39-year-old male presents with progressive wrist pain, possibly following a wrist sprain sustained 1.5 years ago, for which he did not seek medical attention.
- Physical examination reveals tenderness in the anatomic snuff box and a reduced range of motion.
- Computed tomography (CT) imaging confirms a nonunion of the scaphoid (Figure 151.1)

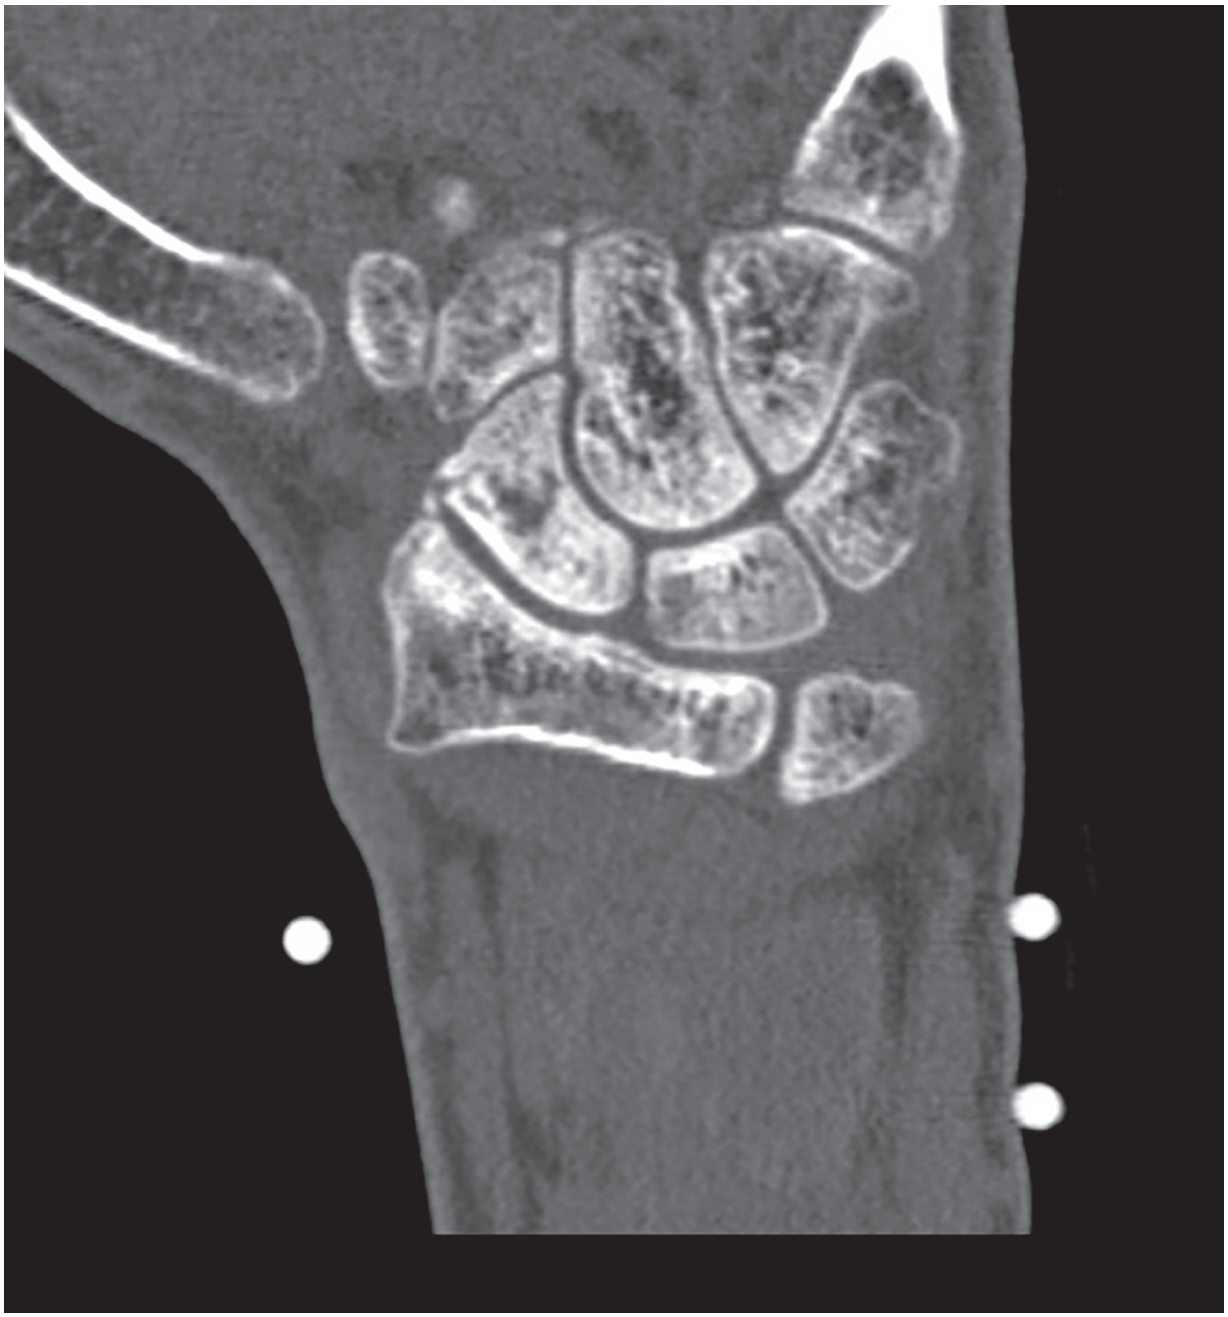

Figure 151.1 Coronal CT image of the wrist displaying a nonacute fracture of the scaphoid waist extending to the distal pole, with a wide fracture cleft and sclerosis of the fracture surface, confirming scaphoid nonunion.

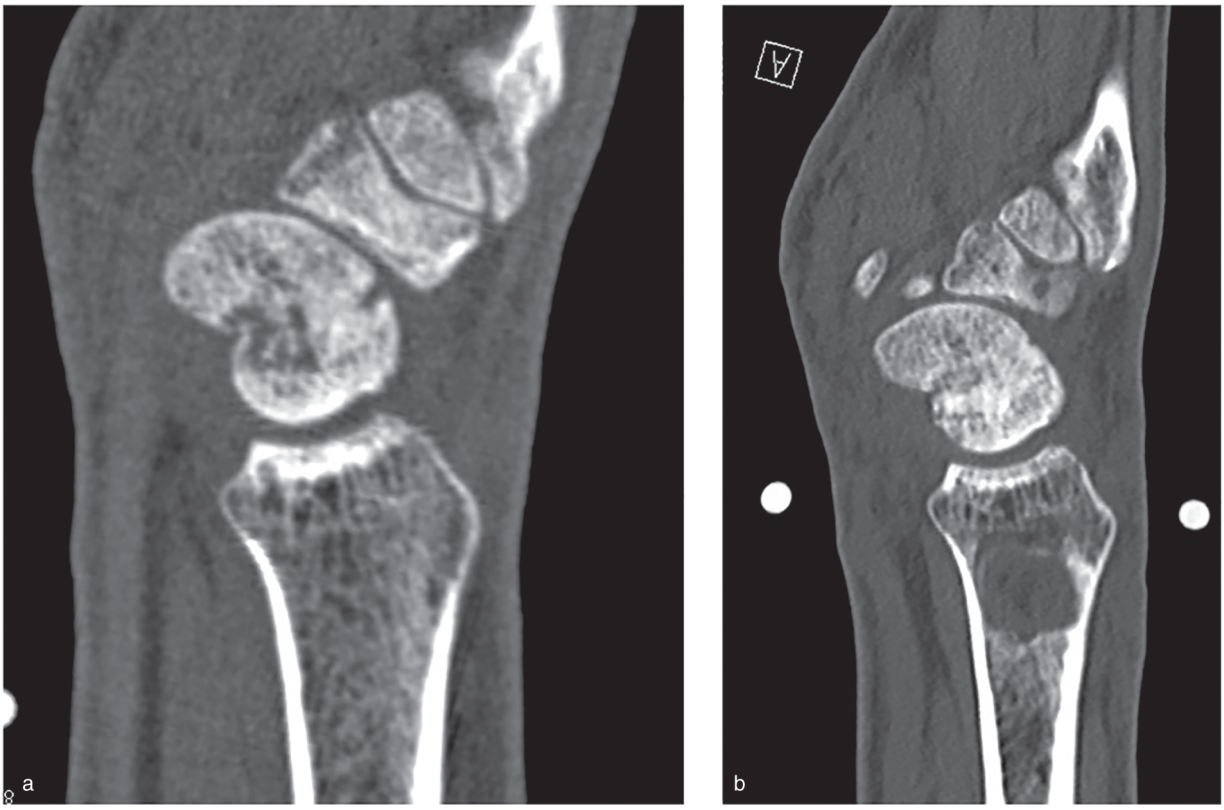

Figure 151.2 Resolution of clinical scenario: scaphoid reconstruction with a corticocancellous bone graft. (A) Preoperative sagittal CT image of the wrist shows a tendency toward a humpback deformity. (B) The patient is treated with a nonvascularized corticocancellous graft of the distal radius. The postoperative CT, three months after surgery, demonstrates improvement in scaphoid height and near complete consolidation.

Top three questions

1. In patients with a scaphoid fracture, which risk factors are associated with scaphoid nonunion?
2. In patients with a scaphoid nonunion, which management options, compared to others, yield the best outcomes?

3. In patients with scaphoid nonunion advanced collapse (SNAC), which treatment options, compared to others, yield the best outcomes?

Question 1: In patients with a scaphoid fracture, which risk factors are associated with scaphoid nonunion?

Rationale

Identification of risk factors associated with scaphoid nonunion contributes to the prevention, diagnosis, and tailored treatment in at risk patients.

Clinical comment

Although the majority of scaphoid fractures heal when treated conservatively, nonunion rates of up to 34% are reported in the literature.[1,2] The relatively high rates of nonunion can be attributed to the scaphoid's tenuous vascular supply and the poor diagnostic reliability of radiographs to diagnose acute scaphoid fractures. Identifying risk factors for nonunion may optimize treatment strategies. Assuming that surgical intervention increases rates of union in specific cases, these patients may be offered early surgical intervention.

Available literature and quality of the evidence

- Level I: 1 large inception cohort study.[3]
- Level II: 1 retrospective case control study.[4]
- Level III: 1 retrospective cohort study[5] and 3 systematic reviews with methodological limitations.[1,2,6]

- Level IV: 9 retrospective case series and reviews with methodological limitations.

Findings

Fracture location and displacement are considered important determinants for fracture union. Proximal pole fractures are at the highest risk for nonunion (10–34%)[1,7] compared to waist (0–33%)[8,9] and distal (0–2%)[10] pole fractures. The increased risk of nonunion in proximal pole fractures is typically attributed to the decreased arterial blood supply and associated risk of avascular necrosis (AVN).[1] In displaced fractures, generally defined as fractures with a gap of 1 mm or greater between fragments, nonunion rates of up to 55% have been reported.[11] CT is the recommended diagnostic test to identify fracture displacement and bony configuration of scaphoid fractures.[4] An exponential relationship exists between the amount of fracture diastasis on CT and the risk of nonunion.[4]

Delayed treatment, resulting from both patient delay and missed diagnosis, increases the risk of nonunion. Nonunion rates are higher in fractures diagnosed and immobilized after four weeks (40%) compared to those treated within four weeks (3%).[12] In a quantitative meta-analysis of 1827 patients with established scaphoid nonunion, Merrell et al. described union rates of 90 versus 80% when fractures were treated surgically within, or after, 12 months, respectively ($p < 0.0001$).[2]

A large inception cohort study by Zura et al. including 7149 scaphoid fractures, identified several risk factors for nonunion, including male sex, use of nonsteroidal anti-inflammatory drugs (NSAIDs) or opioids, and osteoarthritis.[3] Other studies reported higher success rates

in nonsmokers undergoing corrective nonunion surgery than smokers.[5,6]

Resolution of clinical scenario

- The risk of nonunion is increased in proximal pole fractures, displaced fractures, and fractures with signs of AVN (overall quality: moderate).
- Adequate diagnosis and early treatment reduce the risk of nonunion (overall quality: moderate).
- Smoking decreases the chance of successful scaphoid reconstruction (overall quality: low).
- Excessive use of NSAIDs or opioids should be avoided where possible (overall quality: low).

Question 2: In patients with a scaphoid nonunion, which management options, compared to others, yield the best outcomes?

Rationale

The aim of treating scaphoid nonunion includes union, the relief of symptoms, as well as the limitation of degenerative wrist arthritis, known as the SNAC wrist.[13]

Clinical comment

Persistence of unstable scaphoid nonunion leads to degenerative changes in the scaphoid, radial styloid, and ultimately pancarpal arthritis of the scaphocapitate and capitolunate joints.[13] A 97% incidence rate of degenerative changes in untreated symptomatic nonunions older than five years has been described.[14] However, the actual

correlation between symptoms and disease is poorly reported. It is not clear whether surgery significantly alters disease progression, even if union is attained.[15]

Available literature and quality of the evidence

- Level II: 3 randomized controlled trials (RCTs) with methodological limitations.[16–18]
- Level III: 1 RCT of limited methodological quality, 4 retrospective comparative studies with methodological limitations,[19–21] and 7 systematic reviews of uncontrolled comparative studies and case series.[2,6,22–26]
- Level IV: 159 retrospective case series.

Findings

Operative treatment

The prevailing treatment of scaphoid nonunion constitutes the use of a bone graft and internal fixation.[25] Bone grafts may be vascularized (VBGs) or nonvascularized (NVBGs). VBGs include pedicled grafts from the distal radius or free vascularized grafts from the iliac crest and the medial femoral condyle (MFC). NVBGs include various types of (cortico-) cancellous grafts, typically harvested from the iliac crest or distal radius.[15]

In a meta-analysis of 1602 patients, Pinder et al. reported comparable rates of union in VBGs (88%) and NVBGs (92%) with similar union rates.[25] However, the vascular status as well as the bony configuration should be taken into consideration when planning scaphoid reconstruction, using preoperative magnetic resonance imaging (MRI) or CT, respectively.[4,27]

In case of unstable nonunions with a humpback deformity and dorsal intercalated segment instability (DISI), structural corticocancellous grafts allow for the restoration of scaphoid height and carpal alignment.[26] In a systematic review by Sayegh and Strauch, union rates of corticocancellous grafts were comparable to nonstructural cancellous grafts (92% vs 95%, respectively, p = 0.26), while functional outcomes were significantly higher.[26]

Regarding the scaphoid's vascular status, proximal pole viability should be assessed preoperatively. Gadolinium-enhanced MRI has proven the most sensitive and specific diagnostic modality to assess the presence of AVN.[27] However, its correlation with rates of union after bone grafting remains inconclusive.[28] In the absence of AVN, NVBGs appear equivalent to VBGs in terms of union rate and functional outcome.[25,29] In case of AVN, VBGs are associated with higher rates of union than NVBGs.[2,23,25] Merrell et al. demonstrated VBGs to yield significantly higher rates in patients with AVN (88% vs NVBGs 47%, p <0.01) and in patients who had previous surgery (94% vs 81%, p >0.05).[2] There is no consistent high-quality evidence supporting the superiority of free VBGs versus pedicled VBGs.[6,30]

Regarding donor site morbidity, grafts from the distal radius (vascularized and nonvascularized) and free MFC are associated with the least donor site morbidity.[22,25]

Adjunctive treatment

Treatment modalities such as pulsed electromagnetic field (PEMF) therapy,[31] low-intensity pulsed ultrasound (LIPUS),[32] and the use of recombinant human bone morphogenetic proteins (rhBMP)[33] have been investigated as adjunctive therapy to increase union rates. Most studies

reporting on the use of such modalities are subject to important methodological limitations affecting outcome reliability and should be interpreted with caution. Overall, there is insufficient evidence supporting the use of these adjunctive treatment modalities.

Resolution of clinical scenario

- In the absence of proximal pole AVN, NVBGs and VBGs yield equivalent union rates and functional outcomes (overall quality: moderate).
- In nonunions with DISI deformity, structural corticocancellous grafts can provide a better restoration of carpal geometry (overall quality: moderate).
- In case of AVN, or following unsuccessful surgery, VBGs are associated with higher rates of union (overall quality: low to moderate).
- There is no consistent evidence supporting the superiority of free VBGs to pedicled VBGs in case of AVN (overall quality: low).
- There is insufficient evidence for the use of adjunctive treatments such as LIPUS, PEMF, or rhBMP (overall quality: low).

See Figure 151.2 for the resolution of the clinical scenario.

Question 3: In patients with scaphoid nonunion advanced collapse (SNAC), which treatment options, compared to others, yield the best outcomes?

Rationale

Proximal row carpectomy (PRC) and four-corner arthrodesis (4CA) are salvage procedures for stage II–III SNAC wrists. It is important to identify the relative advantages in terms of postoperative function, pain, and the risk of osteoarthritis associated with each procedure.

Clinical comment

In stage II and III SNAC wrists, or in the event of unsuccessful nonunion surgery, salvage procedures aim to alleviate pain and preserve wrist function.[15] Options include partial or complete wrist arthrodesis, PRC, radial denervation, radial styloidectomy, excision of the distal ununited scaphoid fragment, or excision of the proximal pole and replacement with a pyrocarbon implant.[34,35] Management will largely be dictated by the stage of degenerative arthritis, as classified by Vender et al.[13] In stage II–III wrists PRC and scaphoid excision with 4CA are the most commonly described interventions.

Available literature and quality of the evidence

- Level II: 1 RCT with methodological limitations.[36]
- Level III: 1 systematic review of comparative studies,[37] 1 systematic review of noncomparative retrospective case series,[38] and 13 retrospective cohort studies.[37,39]
- Level IV: 78 retrospective case series.

Findings

PRC and 4CA have proven equally effective in alleviating pain and comparable in terms of postoperative function.[37] A systematic review by Saltzman et al. reported no significant differences in the proportional change in grip strength (+17% 4CA, +19% PRC, $p = 0.8$), wrist extension (<+1% 4CA, PRC), flexion (−13% 4CA, −14% PRC, p =

0.88), and ulnar deviation (+1% 4CA, −4.8% PRC, p = 0.28).[37] The change in radial deviation was significantly greater following 4CA (+55% vs −30%, p = 0.02).[37] Studies report patient-rated wrist function to be better following PRC or similar following both procedures.[37,39] Brinkhorst et al. demonstrated patients in the PRC group to perform tasks significantly faster, except for activities requiring torque strength.[39] Importantly, Saltzman et al. reported the cumulative incidence of complications to be significantly higher in 4CA groups (29%, including 6.1% nonunion) than PRC (14%, p = 0.01).[37] Long-term follow-up studies establishing the incidence of osteoarthritis are scarce. Some studies report a higher incidence of osteoarthritis in PRC groups, but without correlation to clinical symptoms.[38] In a 17-year follow-up by Berkhout et al., no differences in radiographic osteoarthritis or correlation with pain were described between PRC and 4CA.[40]

Resolution of clinical scenario

- PRC and 4CA effectively alleviate pain and yield comparable results in terms of change in range of motion (overall quality: low).
- Patient-reported wrist function following PRC and 4CA is similar or better following PRC (overall quality: low).
- 4CA is associated with a higher overall complication rate (overall quality: low).
- There is inconsistent evidence on the incidence of osteoarthritis following PRC and 4CA (overall quality: low).

See Figure 151.3 for the resolution of the clinical scenario.

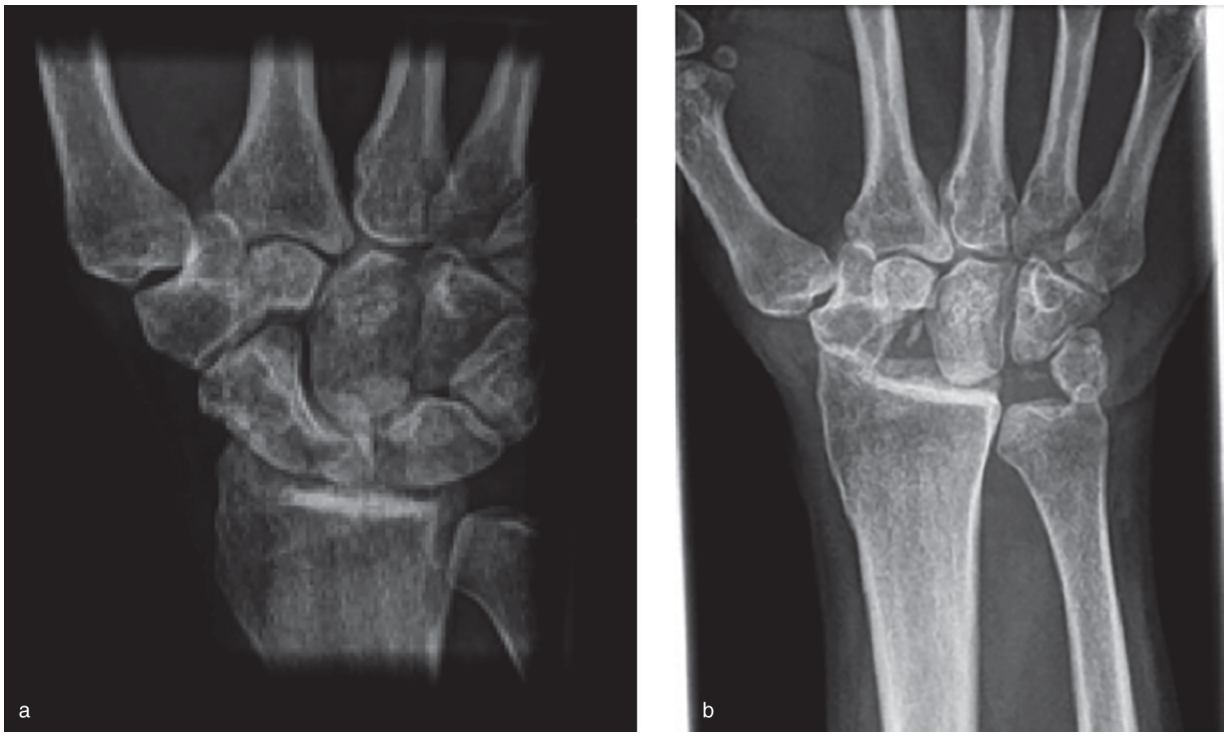

Figure 151.3 (A) Preoperative plain radiograph illustrative of a patient with a SNAC stage III, demonstrating degenerative changes of the proximal scaphoid (in this case following a proximal pole fracture), the radial scaphoid fossa and scaphocapitate and lunocapitate joint. (B) Postoperative plain radiograph following a PRC.

Summary of answers

- The risk of nonunion is increased in proximal pole fractures, fractures with AVN, and displaced fractures.
- Delayed treatment, use of opioids or NSAIDs, and smoking increase chances of nonunion and reduce chances of successful nonunion surgery.
- In the absence of AVN, scaphoid reconstructions with VBGs and NVBGs are equivalent in terms of union rates and functional outcome. Considering the technical difficulty of VBGs, NVBGs may be preferred.

- Structural bone grafts enable better restoration of carpal geometry in unstable scaphoid nonunions with DISI.
- In the context of AVN, VBGs yield superior union rates. There is no consistent evidence supporting the superiority of free VBGs compared to pedicled grafts.
- In SNAC stage II–III wrists, PRC and 4CA offer comparable results in terms of pain relief and range of motion.
- No evidence-based recommendations can be made with regards to the risk of osteoarthritis following PRC or 4CA.

152 Carpal Instability

Jessica B. Hawken MD[1] and Aviram M. Giladi MD MS[2]
[1] Department of Orthopaedic Surgery, MedStar Union Memorial Hospital, Baltimore, MD, USA
[2] Hand Surgery and Plastic Surgery, The Curtis National Hand Center, MedStar Union Memorial Hospital, Baltimore, MD, USA

Clinical scenario

- A 32-year-old, right-hand-dominant female presents eight weeks after falling onto her right wrist while playing rugby.
- She presents with persistent wrist pain despite nonsteroidal anti-inflammatory medications and bracing.
- The patient has findings on exam concerning for carpal instability; however, x-rays obtained in the office are negative for fracture, joint space widening, and carpal malalignment. A carpal ligament injury is suspected.

Top three questions

1. In patients with wrist pain, what is the role of arthroscopy in diagnosing and treating ligamentous injuries of the wrist?
2. In a young, healthy patient with subacute scapholunate ligament tear and no radiographic arthritic changes, what is the best treatment option to ensure optimal outcomes?

3. What are the best treatment options to ensure optimal outcomes for a patient with an isolated lunotriquetral injury and no radiographic arthritis?

Question 1: In patients with wrist pain, what is the role of arthroscopy in diagnosing and treating ligamentous injuries of the wrist?

Rationale

Carpal instability is difficult to diagnose. Physical examination is practitioner-dependent and there are few, if any, objective measurements of wrist stability. Radiographs may appear normal after a ligament tear because secondary ligamentous stabilizers delay static carpal changes, prompting a need for advanced imaging or direct visualization.

Clinical comment

Static and dynamic radiographs and advanced imaging studies such as arthrograms, ultrasound, computed tomography (CT), and magnetic resonance imaging (MRI) can fail to visualize ligament tears in the wrist. Arthroscopic evaluation remains the gold standard as it allows the ligaments to be directly visualized. The tears can then be described with a reproducible classification system (grade I–IV) defined by Geissler.[1] The role of arthroscopy is to determine whether a ligament is partially or completely torn and how this likely affects wrist kinematics.

Available literature and quality of the evidence

The use of arthroscopy in diagnosis of carpal ligament tears has been investigated for almost 30 years, mostly for

scapholunate and lunotriquetral ligament injuries. Most recently it has been compared to advances in MRI and CT modalities, including 3.0 Tesla (3T) MRI, and still found to be superior. Arthroscopic repair techniques are described in mostly level IV and V evidence, but do provide the added benefit of combining diagnostic and treatment modalities.

Findings

Radiography is noninvasive and can demonstrate static, chronic scapholunate instability.[2] Stress radiographs may demonstrate abnormalities not visualized on static films; however, “normal” films do not rule out pathology and may be technician-dependent.

Advances with 3T MRI systems allow for 3D sequences and multiplanar reconstructive options to visualize thin intercarpal ligaments during their oblique or curved courses.[3,4] In comparison to arthroscopy for the diagnosis of ligamentous injury, Ochman et al. found the sensitivity and specificity were 75 and 100%, respectively, for pathology seen on MRI and confirmed with arthroscopy.[5] Hafezi-Nejad reported magnetic resonance arthrogram (MRA) had the highest sensitivity and specificity for the diagnosis of scapholunate interosseous ligament (SLIL) tears (82.1 and 92.8%) when compared to 3T MRI and 1.5T MRI.[4] MRA is an expensive and time-consuming test. Lee et al. compared CT arthrography, conventional MRI, and MRA, and found that CT arthrography was the most sensitive, specific, and accurate (100% for all) of the three methods for diagnosing SLIL tears. Multidetector computed tomography (MDCT) Arthrography has sensitivity of 100%, specificity from 86–100%, and a sensitivity of 94% for detecting partial injuries.[6–8]

In Lindau's 2015 review, the role of arthroscopy in carpal instability was determined to be the most valuable

diagnostic tool despite the lack of any level I evidence on the topic. Arthroscopy allows for direct visualization of the ligaments, assessment of the type of injury, and the severity of the injury. It is highly sensitive and specific.[9] Disadvantages include that it is user-dependent, requires an invasive procedure with associated risks, the surgeon must determine whether findings are truly the pathology causing the patient's symptoms, and it is more expensive than imaging.

Resolution of clinical scenario

- With normal radiographs and suspicion of a ligamentous injury, advanced diagnostic techniques are required.
- MRI, MRA, and CT arthrography all provide advanced options for imaging, although all of these techniques still might miss ligament injuries. CT Arthrography is currently the best option, where available.
- Arthroscopy may be the appropriate next step instead of advanced imaging, as it provides high sensitivity and specific for diagnosing SLIL and lunotriquetral interosseous ligament (LTIL) injuries, and if injury is identified the surgeon may convert to reconstruction (open or arthroscopic) in the same operative session.
- If index of suspicion is low, advanced imaging provides a lower cost and lower risk option before a procedure is performed.

Question 2: In a young, healthy patient with subacute scapholunate ligament tear and no radiographic arthritic changes, what is the best treatment option to ensure optimal outcomes?

Rationale

Injury to the SLIL can lead to the development of deformity and arthritis about the wrist if not properly identified and treated early. Although management with direct ligament repair in the acute phase is generally the best option, the successful reconstruction of subacute injuries remains a challenge.

Clinical comment

SLIL injury results in dissociation of the scaphoid and the lunate, causing abnormal movement in the proximal carpal row and leading to cartilage wear and eventual arthritis. Recapitulating this relationship and preventing the aberrant biomechanics is the best way to avoid accelerated wrist degeneration; however, many of the techniques described and used have inadequate outcomes (stiffness, persistent pain, recurrent SL relationship changes, etc.).

Available literature and quality of the evidence

The majority of available evidence pertaining to the treatment of acute and chronic scapholunate injuries is limited to level IV and V studies; however, there are a few level III studies addressed here. Additionally, multiple narrative and literature reviews have attempted to address this issue.

Findings

The treatment options for symptomatic SLIL tears are based upon the chronicity of the injury, the degree of instability, and the presence or absence of wrist arthritis. Urgency is needed in diagnosing and treating SLIL injury because treatment within six weeks of injury has the best results, as demonstrated by Rohman et al. Treatment options include direct repair (open or arthroscopic), soft tissue stabilization (tenodesis, capsulodesis, bone-ligament-bone reconstruction, reduction and association of the scapholunate ligament [RASL]), or arthrodesis.[10]

Proponents of arthroscopic SL debridement and/or reconstruction have proposed specific indications for these techniques, including partial tears, patients wishing to avoid open surgery,[11] pediatric patients,[12] and injuries to the extrinsic ligaments of the wrist,[13],[14] but the efficacy of these procedures is still based on limited quality evidence. Arthroscopic thermal capsular shrinkage was reported by Mason and Hargreaves to achieve improvement or resolution of midcarpal instability. Hargreaves reported follow-up data and at four years, average loss of motion was 15% due to stiffness and no patients required reoperation, though several noted recurrences of instability.[15],[16] Using a similar concept for scapholunate (SL) injuries, in 2005 Darlis proposed debridement and thermal shrinkage for partial SL injuries.[17] A subsequent study by Lee in 2012 reported on 16 wrists with partial SL injuries treated with thermal shrinkage, all with good or excellent outcomes at an average of 53-month follow-up.[18]

Acute complete tears are treated with direct repair if there is sufficient ligament remnant, the scaphoid and lunate are reducible, and there is no evidence of wrist arthritis. For subacute tears where the ligament remnants are often no longer adequate, other techniques are required.[19_22]

Capsulodesis can provide short-term relief, but it does not entirely eliminate pain or significantly improve grip strength, and the repair attenuates over time. Megerle retrospectively evaluated 59 capsulodesis patients after an average of eight years. Eight of the patients required salvage procedure, Disabilities of the Arm, Shoulder, and Hand (DASH) scores were 28 on average, Modified Mayo Wrist Score was 61 on average, the mean carpal height decreased significantly, and 40 patients had evidence of degenerative arthritis.[23]

The majority of the higher-level evidence pertains to the other reported soft tissue stabilization techniques. Sousa et al. reviewed 22 patients who were treated with the modified Brunelli tenodesis with an average follow-up of five years. Patients had an average Visual Analog Scale (VAS) pain score of 2, a DASH score of 16, reduced range of motion and grip as compared to the contralateral side, and diastasis from 1.9 to 3.1 mm of the scapholunate interval.[24] Three-ligament tenodesis was reviewed in Garcia-Elias's 2006 paper that included 38 patients, 28 of whom had complete pain relief, eight had mild discomfort, and two had pain in most activities of daily life. Twenty-nine had resumed their job at two-year follow-up. Grip strength was reported at 65% of the contralateral, healthy, side.[25] Links et al. compared 23 patients treated with the four-bone Almquist tendon weave against 21 patients treated with the modified Brunelli technique, all performed by one surgeon. All patients had decreased scapholunate angles, though the modified Brunelli patients had superior outcomes in pain, DASH scores, range of motion, and grip strength at 2.5 years follow-up.[22]

Due to the success of bone–ligament–bone reconstruction in the knee, the same principle has been applied to reconstructing the SLIL with variable success. Nakamura

harvested the proximal half of the capitohamate ligament and inserted it into troughs made on the scaphoid and lunate. They reported eight excellent, five good, and two fair results using the Modified Mayo Wrist Score with two-years of follow-up.[26] The first dorsal compartment has been studied as a potential donor site in recent biomechanical studies with indications that it has comparable tensile properties to the SLIL.[27] This has yet to be evaluated in clinical practice.

After noting superior outcomes in patients with pseudarthrosis of the SL joint, RASL was developed using a Herbert screw to achieve union. In 33 cases, 22 patients reported good results and 11 reported poor results. Five of the poor results saw loss of fixation with the Herbert screw due to its rigidity. The scapholunate intercarpal (SLIC) screw (Acumed, Hillsboro, OR, USA) was developed to address this issue by allowing for *anatomic toggling* of 15–20° between the scaphoid and lunate.[28] Geissler et al. reported good outcomes in athletic patients with return to play at 1–2 weeks with a protective splint.[29]

Chronic tears that are not amenable to reconstruction are managed with scaphotrapezial–trapezoid or scaphocapitate fusions. Scapholunate fusions have also been attempted but largely have been abandoned due to issues with nonunions. Although arthrodesis stabilizes the scaphoid with respect to the other carpal bones and the radius, it alters wrist kinematics and has demonstrated eventual progression to wrist arthritis. These and other salvage options are reviewed in other chapters.

Resolution of clinical scenario

- For patients with an acute tear, direct repair is recommended.

- Tenodesis is demonstrated to have superior outcomes over capsulodesis or bone–ligament–bone reconstruction.
- Arthrodesis is a salvage procedure for chronic SLIL injuries or failed SLIL reconstruction.

Question 3: What are the best treatment options to ensure optimal outcomes for a patient with an isolated lunotriquetral injury and no radiographic arthritis?

Rationale

LTIL tears are less common than SLIL injuries and are more difficult to diagnose than SLIL. Recognizing the pathology and determining the correct treatment approach has limited available evidence.

Clinical comment

Patients with LTIL tears often present with vague, ulnar sided wrist pain, with or without signs of instability. Due to the difficulty in diagnosing these injuries, the majority of LTIL tears encountered will be chronic. Due to the biomechanics of the joint, surgical interventions for the LTIL focus on reconstructing the palmar component.

Available literature and quality of the evidence

Only level IV and V studies are available. Similar to SLIL injury, multiple review articles are available.

Findings

Unlike SLIL injuries, the literature on treatment of LTIL injuries is not centered around intervention timing, as the majority of LTIL pathology is identified late. Treatment options include soft tissue repair with tenodesis, ligament reconstruction, arthrodesis, and ulnar shortening osteotomy.

Tenodesis for LTIL reconstruction is described using a portion of extensor carpi ulnaris (ECU) (while maintaining the distal portion), passing it through two drillholes in the triquetrum, and securing it to itself after appropriate tensioning. Shahane reviewed 46 patients who had tenodesis for tenderness to palpation and positive ballottement test on examination, with step and gap in the LT joint seen arthroscopically. Using the Mayo Wrist Score, 40 of the 46 patients had satisfactory to excellent outcomes.[30]

Shin et al. compared ligament reconstruction, ligament repair, and arthrodesis. There was no difference in mean DASH scores for the three groups, with an average of 9.5-year follow-up. The nonunion rate in the arthrodesis group was 41%. Additional surgery including revision arthrodesis, ulnar recession, and hardware removal was required within five years for two of eight patients treated with lunotriquetral (LT) ligament reconstruction, 6 of 22 patients treated with LT ligament repair, and 14 of 22 patients treated with arthrodesis.[31]

LT arthrodesis is reported to have normal range of motion in 59–85% of patients, patient satisfaction varying from 0 to 93%, and 27–56% of patients still experiencing some pain. Nonunion rates are reported up to 57%. This procedure has overall poor postoperative outcomes.[32],[33]

Ulnar shortening osteotomy is an alternative to intracarpal surgery that increases strain in the ulnolunate and ulnotriquetral ligaments, thereby reducing motion at the

lunotriquetral joint. Mirza et al. reported on 53 post-traumatic cases and determined that 83% had good outcomes on the Gartland–Werley score, grip strength increased 41%, and all patients had clinical and radiographic union by 10 months. This study only followed patients for one year.[34]

Resolution of clinical scenario

- Patients who undergo ligamentous repair or reconstruction for LTIL injuries have superior outcomes to those who undergo arthrodesis.
- Ulnar shortening osteotomy is an extracarpal surgical alternative.

Summary of answers

- With normal radiographs and suspicion of a ligamentous injury, CT arthrography is currently the best diagnostic modality for ligamentous injuries of the wrist.
- Arthroscopy may be the appropriate next step instead of advanced imaging, as it provides high sensitivity and specific for diagnosing SLIL and LTIL injuries.
- Tenodesis is demonstrated to have superior outcomes over capsulodesis or bone–ligament–bone reconstruction. Arthrodesis is a salvage procedure for chronic SLIL injuries or failed SLIL reconstruction.
- Patients who undergo ligamentous repair or reconstruction for LTIL injuries have superior outcomes to those who undergo arthrodesis. Ulnar shortening osteotomy is an extracarpal surgical alternative with overall good outcomes in early reports.

153 Kienböck's Disease

Simon B. M. MacLean and Gregory I. Bain
Department of Orthopaedic Surgery, Flinders University, Adelaide, Australia

Introductory statement/disclaimer

Kienböck's disease is a rare condition. Literature on the topic therefore is limited and lacks quality studies with a high level of evidence. All evidence, therefore, is based on retrospective cohort studies, case series, and expert opinion. There are no high-quality comparative studies or randomized trials dictating the best treatment option.

There are a number of highly debated topics in Kienböck's disease. For example: “What is the natural history of the disease?” and “Which treatment is best?” These questions, although pertinent, remain unanswered.

The evidence provided in this chapter therefore represents a review of the literature, conclusions based on basic science studies, and concepts developed by the senior author.

Clinical scenario

- A 17-year-old boy presents with a two-year history of pain, swelling, and stiffness in his wrist.
- He has tried wrist splints and his GP injected his wrist last year with no benefit. He has tenderness over the carpus, and decreased grip strength.
- You arrange a number of investigations. An x-ray shows a sclerotic lunate. A computed tomography (CT) scan

shows a coronal lunate fracture. The remaining joint surfaces look normal. A gadolinium-enhanced magnetic resonance imaging (MRI) scan shows generalized signal loss in the lunate.

- He has failed nonoperative treatment for over a year and wants to know whether there is any other treatment available for him.

Top three questions

1. Do patients under 20 years of age have good outcomes with nonoperative treatment in Kienböck's disease?
2. What is the role of radial shortening osteotomy in improving outcomes in patients with Kienböck's disease?
3. Is arthroscopy warranted as an assessment and treatment tool in patients with Kienböck's disease?

Question 1: Do patients under 20 years of age have good outcomes with nonoperative treatment in Kienböck's disease?

Rationale

There are a number of treatment options well described in adults with Kienböck's disease. The disease is known to occur in younger patients as well. The best treatment option in this group is highly controversial.

Clinical comment

The condition can be highly disabling at a time of life when the patient is highly active. The natural history in this age group is unclear. The ideal treatment would allow the patient to rapidly return to functional activity.

Available literature and quality of the evidence

- Level IV: 2 case series, 3 case reports.

Findings

Irisarri's series reports his experience in 13 cases.[1] Four patients had *infantile lunatomalacia* (up to and including 12 years of age). All patients resolved with nonoperative management, with immobilization alone. All patients resolved symptomatically, although one patient had only partial remodeling of the lunate. Nine patients were treated with *juvenile lunatomalacia* (age 13 until skeletal maturity). After periods of immobilization, three patients remained symptomatic and were treated with radial shortening osteotomy. At a mean follow-up of five years, clinical and radiological outcome was good in this subgroup.

Iwasaki reported his experience with radial osteotomies in 11 patients between the ages of 11 and 19 who had failed nonoperative treatment for Kienböck's disease.[2] There were three patients with Lichtman stage II disease, two with stage IIIA disease, and six with stage IIIB disease. Nine patients with negative ulnar variance had radial shortening osteotomies, and two with zero or positive ulnar variance had lateral closing wedge osteotomies. Ten out of 11 patients had excellent clinical outcomes. Eight patients had radiographic improvement showing lunate revascularization. One patient had persistent wrist pain following surgery.

In other case reports, radial shortening or temporary scaphotrapeziotrapezoidal (STT) joint pinning for four weeks has been shown to lead to improvement in pain, function, and lunate revascularization.[3],[4] In two cases of patients with cerebral palsy and Kienböck's disease, temporary immobilization resulted in functional and radiographic resolution.[5]

Resolution of clinical scenario

The vast majority of patients with pediatric Kienböck's disease will resolve with a variable period of immobilization in a splint or cast. This usually leads to improvement both radiologically and clinically. In the older child or teenager with *juvenile osteomalacia*, recalcitrant cases do occur. *Ulnar-negative patients* may benefit from a radial shortening osteotomy. *Ulnar-neutral* or *ulnar-negative* patients may benefit from radial closing wedge osteotomy or temporary STT joint pinning.

Question 2: What is the role of radial shortening osteotomy in improving outcomes in patients with Kienböck's disease?

Rationale

Radial shortening osteotomy has been described as a means of correcting negative ulnar variance – which is thought to be a morphological risk factor for the development of Kienböck's disease.

Clinical comment

There are numerous surgical options described for the treatment of Kienböck's disease. There is debate as to which patients may benefit from radial shortening osteotomy. The long-term success of the procedure and its ability to slow or reverse the progression of the disease is controversial.

Available literature and quality of the evidence

- Level III: 1 retrospective cohort study.
- Level IV: 6 case series.

Findings

Several series reported good to excellent functional outcomes in adults at a minimum of two years' follow-up. Significant improvements have been shown for Disabilities of the Arm, Shoulder, and Hand (DASH) score, Mayo Score, Visual Analog Score (VAS), range of motion, and grip strength. Results have been shown to be maintained for up to 10 years.[6] Results have been shown to be comparable with radial closing wedge and capitate shortening osteotomies in comparative studies.[6–11]

Most series contain patients at Lichtman grades IIIa, IIIb, and IV. Despite the advanced stage of the disease in these patients, most studies report clinical improvement in symptoms. Lichtman grade has not been shown to improve after radial shortening osteotomies, and either remains static or slowly progresses.[12]

One study showed that the risk of development of ulnar-sided wrist pain increases with shortening of the radius more than 4 mm, and functional outcomes may be worse in patients >30 years old. Although initially indicated for patients with negative ulnar variance, to bring their ulnar to *neutral*, clinical results may be similar regardless of

preoperative ulnar variance.[12] In all studies there is a low reported rate of salvage procedures.

Resolution of clinical scenario

Evidence suggests that radial shortening osteotomy is an effective treatment for Kienböck's disease, even in patients with advanced Lichtman grade. There is no evidence in adults, however, that the disease stage regresses following this procedure.

Question 3: Is arthroscopy warranted as an assessment and treatment tool in patients with Kienböck's disease?

Rationale

Arthroscopy is regarded as the gold standard for assessment of the articular surfaces as it allows direct visualization and probing. It also allows assessment of the surrounding structures, including synovium, ligaments, and adjacent joints. Arthroscopic treatment is a minimally invasive method of treating Kienböck's disease and may have advantages such as accelerated rehabilitation and avoidance of extra-articular adhesions.

Clinical comment

Decision-making in the operative treatment of Kienböck's disease is challenging. Imaging helps to assess the osseous and vascular components of the disease. Arthroscopy gives the best assessment of the chondral component of the disease and helps dictate operative management – either arthroscopic or open.

Available literature and quality of the evidence

- Level IV: 3 case series.
- Level V: 4 expert opinion.

Findings

A case series reported arthroscopic assessment and debridement of seven patients with Kienböck's disease.[13] All seven patients had partial or complete tears of their perilunate ligaments. Five patients had synovitis. A full arthroscopic assessment followed by debridement of the chondral surfaces and ligaments was performed in all patients. At a 19-month follow-up, six reported good or excellent outcomes on the Modified Mayo Wrist Score, grip strength, and range of motion. There was further disease progression in three patients, but no cases of carpal collapse.

Excellent results have been shown for arthroscopic- and arthroscopic-assisted partial carpal fusions in Kienböck's disease.[14] In Ho's series, 12 patients had arthroscopic assessment and one of the following procedures: STT fusion, four-corner fusion and scaphoidectomy, radioscapholunate fusion, radiolunate fusion, and lunotriquetral fusion. Average follow-up period was 70 months. Full union was obtained in 9/12 patients. All patients had improvement in pain and a functional range of motion.

Rajfer described a technique of arthroscopic insertion of cancellous bone graft and BMP-2 into the lunate.[15] Graft from the distal radius or iliac crest was used. The lunate was enucleated of necrotic bone, and graft and BMP-2 (with collagen seal) tamped into the defect. All patients reported improvement in pain and DASH scores. Carpal height was maintained at follow-up.

Resolution of clinical scenario

The Bain and Begg classification was introduced in 2006 as a tool for assessing articular cartilage and planning treatment in Kienböck's disease.[16],[17] An articular-based algorithm has been developed by the senior author as a framework to help guide the treating surgeon.[18–21] Arthroscopy is an effective method of assessing the articular cartilage and surrounding structures in Kienböck's disease.

Summary of answers

- The majority of patients in this age group get excellent results with nonoperative treatment. In *juvenile* cases (over the age of 12 years) – some may fail to respond to conservative treatment. In these cases, radial shortening, radial lateral closing wedge osteotomy, and temporary STT pinning have been proven to be effective treatment options in small series.
- Radial shortening osteotomy has been shown to be an effective treatment for all Lichtman grades for pain, function, and range of motion. Patients under 30 years may have better results. The osteotomy does not reverse the disease process, however; carpal collapse may occur later and further salvage procedures may be warranted.
- Arthroscopy is the gold standard for assessment of the articular surfaces in Kienböck's disease. Further treatment can then be planned. Simple arthroscopic synovectomy or debridement has proven to be an effective treatment option, as has arthroscopic lunate forage and bone grafting. In small series, arthroscopic partial carpal fusions have shown high union rates and good functional outcomes.

154 Trapeziometacarpal Osteoarthritis

Jeremiah D. Johnson MD[1], Jennifer M. Brewer BA[1], and Jennifer Moriatis Wolf MD[2]

[1] Department of Orthopaedic Surgery, University of Connecticut, Farmington, CT, USA

[2] Department of Orthopaedic Surgery, University of Chicago, Chicago, IL, USA

Clinical scenario

- A 61-year-old, right-hand-dominant female presents with three years of progressive right base of thumb pain unrelated to any injury. She reports her pain is provoked by activities such as opening jars.
- On exam, she is tender over the trapeziometacarpal (TM) joint and pain is elicited with axial loading and extension of the joint.
- Her radiographs show narrowing of the TM joint with cystic changes and subchondral sclerosis, and small loose bodies.

Top three questions

1. In a patient who presents with symptomatic TM arthritis, what nonoperative intervention is most effective in relieving symptoms compared to placebo?
2. In a patient with TM osteoarthritis, which arthroplasty procedures have been shown to result in improved patient outcomes with the fewest complications?

3. In a patient who presents with symptomatic TM osteoarthritis, does implant arthroplasty or arthrodesis offer any advantages over trapeziectomy with or without ligament reconstruction and tendon interposition (LRTI)?

Question 1: In a patient who presents with symptomatic TM arthritis, what nonoperative intervention is most effective in relieving symptoms compared to placebo?

Rationale

There are many nonoperative treatments for TM arthritis. Treating physicians optimally want an effective intervention to relieve symptoms and maximize function for one of the most common joints affected by osteoarthritis.

Clinical comment

Conservative treatment of TM arthritis includes: therapy, orthoses (splinting), and corticosteroid injections. Hyaluronate injections have been described but are less commonly used. These treatments can be used in combination. It is essential to determine which conservative interventions provide patients with the best outcomes in order to guide treatment and manage symptoms long term.

Available literature and quality of the evidence

- Level I: 9 studies.
- Level II: 1 meta-analysis and 2 systematic reviews.

Findings

Corticosteroid and hyaluronate injections

A randomized controlled trial (RCT) comparing functional outcomes after intra-articular hyaluronic acid (HA) injections of the TM joint in 29 patients to saline placebo in 29 patients. The authors reported HA reduced pain Visual Analog Scale (VAS) scores and improved function (Dreiser's Functional Index) from baseline values, but did not reach a significant difference compared with controls at six months.[1] A meta-analysis compared HA injections in 169 patients and an unspecified placebo in 74 patients. The authors reported HA marginally improved functional capacity (standardized response means [SRM] −1.14; 95% confidence interval [CI]: −1.59 to −0.60) at 12 weeks, but provided no difference in unspecified pain scores.[2] The meta-analysis also compared corticosteroids injections in 147 patients and unspecified placebo injections in 74 patients. The authors reported no difference in pain scores at 24 weeks (SRM −1.20; 95% CI: −3.69 to 1.29). A RCT of 40 patients comparing hyaluronate and corticosteroids injections found corticosteroids was superior in reducing pain (4.9 mm ± 2.0 vs 5.7 mm ± 2.2) and improving hand function (Duruoz Hand Index [DHI]: 12.0 pts ± 8.7 vs 22.1 pts ± 12.5) for up to six months, but other studies have failed to replicate corticosteroid's superiority.[3] Two RCTs found no difference in pain and functional outcome scores up to six months after treatment between hyaluronate or steroid injections.[4,5] In a cohort of 80 patients, Heyworth et al. compared the two types of injections with saline placebo and reported no difference in VAS or Disabilities of the Arm, Shoulder, and Hand (DASH) scores between the three groups.[4] Stahl et al. found no difference in 50 patients treated with hyaluronate or corticosteroids but reported a significant reduction between baseline and six-month pain

VAS for both groups at rest (−2.2 mm ± 2.0, −2.2 mm ± 2.1) and after activity (−2.7 mm ± 2.2, 2.2 mm ± 1.9).[5] Two review articles concluded there was no difference in various pain or functional outcomes scores between hyaluronic and steroid injections.[6,7] A meta-analysis comparing HA and corticosteroids reported corticosteroid was superior in reducing pain measurements compared to HA (SRM 1.44; 95% CI: 0.14–2.74) but was heavily influenced by one RCT.[2]

Orthoses

An RCT compared custom neoprene orthoses (n = 57) with standard care at the discretion of their physician (n = 55), and reported a reduction in pain VAS with orthoses for up to 12 months (−22.2 mm ± 3.2 vs −7.9 mm ± 3.5).[8] Several RCTs compared types of orthoses in patients with TM OA.[8–12] Two studies compared prefabricated orthoses to custom orthoses. Weiss et al. found patients with prefabricated splints had better VAS pain (2.29, standard error of the mean [SEM]: 0.44 vs 3.59, SEM: 0.33) and satisfaction scores (7.5, SEM: 0.45 vs 4.9, SEM: 0.43) in a randomized, cross-over study of 25 patients.[10] Another randomized, crossover study of 63 patients demonstrated no difference in pain, but the Push Ortho Thumb Brace had higher satisfaction on the D-QUEST questionnaire (30.6, standard deviation [SD]: 3.9) versus a custom brace likely due to less interference with key grip (26.9, SD 4.9).[9] Spaans et al. reviewed 10 RCTs utilizing various orthoses and reported evidence for improved pain control but no improvement regarding function or strength.[7]

Hand therapy

Spaans et al. reviewed six RCTs comparing various hand therapy techniques with nontherapeutic ultrasound as a

control and reported all four techniques provided some reduction in pain without any notable improvement in function.[7] Unfortunately, all six studies had limited follow-up, ranging from two weeks to three months. One RCT (n = 40) comparing splinting to exercise therapy reported no significant differences between groups in VAS pain or Sollerman Test of Hand Function scores at six weeks.[13]

Resolution of clinical scenario

- Multiple RCTs have reported that corticosteroids and HA injections reduce patient's TM pain compared with baseline values; however, neither steroid nor hyaluronate showed superiority in pain relief or functional outcomes when compared with placebo for either intervention.
- There is growing evidence supporting bracing with custom or prefabricated splints as a method of providing long-term pain relief.
- There is no strong evidence supporting any specific orthosis as superior in terms of pain relief. However, some studies have suggested higher patient satisfaction with smaller, less bulky splints.
- There is no strong evidence that hand therapy provides long-term pain relief for symptomatic TM arthritis and only low-quality evidence therapy provides short-term pain relief.

Question 2: In a patient with TM osteoarthritis, which arthroplasty procedures have been shown to result in improved patient outcomes with the fewest complications?

Rationale

Multiple arthroplasty techniques are currently employed to treat TM osteoarthritis, and understanding the possible risks and benefits of different procedures will help guide surgical decisions.

Clinical comment

The current opinion regarding surgical treatment of TM osteoarthritis varies widely among surgeons. A simple trapeziectomy would likely provide relief of pain, but many surgeons advocate for tendon interposition (TI) and/or ligament reconstruction (LR) to fill the trapezial void and prevent subluxation of the metacarpal. Surgical procedures have evolved to produce varying techniques for ligament reconstruction and tendon interposition (LRTI).

Available literature and quality of the evidence

- Level I: 7 studies.
- Level II: 3 studies were identified including 1 meta-analysis.

Findings

One systemic review comparing trapeziectomy versus trapeziectomy with TI,[14–17] trapeziectomy with LR,[18,19] and trapeziectomy with LRTI,[16,20,21] failed to find any

additional benefit of TI, LR, or LRTI over a simple trapeziectomy in terms of pain, strength, satisfaction, and DASH scores.[22] Three RCTs reported LRTI was associated with an increased complication rate over simple trapeziectomy, but the studies only had a one-year mean follow-up.[16,17,21] Vermeulen et al. was unable to pool data for statistical analysis due to heterogeneity of patient population, surgical technique, and outcome measures.[22]

A Cochrane review comparing trapeziectomy and trapeziectomy with LRTI included five RCTs or quasi-RCTs with 376 participants[14,17,20,23,24] and revealed LRTI provided no addition benefit in terms of pain on a 0–100 mm scale (mean difference [MD]: −2.8 mm, 95% CI: −9.82 to 4.21) and function on a similar scale (0.03 points, 95% CI: −0.83 to 0.88%).[25] In addition, the meta-analysis reported no significant difference in mean adverse events with a rate of 10 and 19% (p = 0.07) in the trapeziectomy and trapeziectomy with LRTI cohort, respectively, but the data demonstrate a trend toward an elevated rate in the LRTI cohort (risk ratio [RR] = 1.89; 95% CI: 0.96–3.73). Gangopadhyay et al. included trapeziectomy with TI in their RCT evaluating 174 thumbs and demonstrated no difference in pain or strength in comparison to trapeziectomy at five-year follow-up.[23] Two studies compared trapeziectomy with LRTI (n = 25) and trapeziectomy with LR (n = 26),[18,19] and there was no difference in pain (RR = 2.8; 95% CI: 0.33–24.16), function scores (RR = 0.82; 95% CI: 0.63–1.06), and adverse events (RR = 1.41; 95% CI: −1.90 to 0.50) between the two groups.

Resolution of clinical scenario

- Current evidence has not revealed any additional benefit regarding LR, TI, or LRTI over simple

trapeziectomy in terms of pain relief or improved function.

- There appears to be a trend toward an increase in adverse events with the addition of LRTI when compared with trapeziectomy alone.

In a patient who presents with symptomatic TM osteoarthritis, does implant arthroplasty or arthrodesis offer any advantages over trapeziectomy with or without ligament reconstruction and tendon interposition (LRTI)?

Rationale

There is growing interest in alternative surgical techniques to treat thumb TM arthritis and improve patient outcomes following surgery.

Clinical comment

Trapeziectomy with LRTI is the most common surgical procedure for TM arthritis. However, many have expressed concern for shortening of the thumb, decreased thumb strength, and subluxation of the thumb metacarpal. Trapeziometacarpal arthrodesis (TMA) and arthroplasty have been explored as possible alternative to treat these concerns.

Available literature and quality of the evidence

- Level I: 2 studies.

- Level II: 4 studies and 1 meta-analysis.
- Level IV: 1 systematic review and 1 retrospective study were included in reviewing arthrodesis and implant arthroplasty procedures for TM arthritis.

Findings

Arthrodesis

A Cochrane review identified studies comparing trapeziectomy with LRTI versus TMA but was unable to draw any conclusions due to including only one study with incomplete statistical analysis.[25] Since then, Vermeulen et al. randomized 43 patients to LRTI or TMA utilizing a plate but prematurely terminated the study due to a significantly higher complication rate in the arthrodesis group (71% vs 29%, $p = 0.016$), especially regarding delayed union, nonunion requiring revision, neuromas, and complex regional pain syndrome.[26] Hippensteel et al.'s prospective study comparing LRTI and TMA with a locked plate reported no significant differences in QuickDASH scores, pinch or grip strength, and VAS pain scores.[27] Seven out of 25 (26%) TMA patients had radiographic nonunion and five (19%) required revision surgery compared to none in the LRTI cohort; however, the LRTI group had more superficial branch of the radial nerve paresthesias which eventually resolved (32% vs 0%, $p < 0.05$).

Implant arthroplasty

A Cochrane review identified two RCTs[28],[29] comparing trapeziectomy with TI ($n = 42$) versus the Artelon joint resurfacing implant ($n = 82$) and reported decreased pain in the TI cohort with tripod pinch (MD: −14 mm; 95% CI: −23.06 to −4.94), no difference in lateral pinch strength (MD: −1.09 kg; 95% CI: −2.4 to 0.22), and no difference in

treatment failure due to pain.[25] Tägil et al. randomized 13 patients each to trapeziectomy with TI and to a Swanson silicone implant and reported no difference in pain relief (MD: 5.0 mm; 95% CI: 7.41–17.41), lateral pinch strength (MD: 0.01 kp/cm^2; 95% CI: −0.09 to 0.11), or adverse events (RR = 0.20; 95% CI: 0.01–3.80).[30]

Overall, the studies comparing implant arthroplasty with trapeziectomy are of low quality and provide no strong conclusions regarding any benefit of arthroplasty over trapeziectomy. Huang et al. performed a systematic review of TM joint replacements and reported only two prospective controlled studies, five prospective cohort studies, and 26 retrospective studies.[31] The authors concluded there was no strong evidence implant arthroplasty provides better clinical results than trapeziectomy and some implants may have high failure rates. A retrospective review of the Norwegian Arthroplasty Register yielded 479 cases, including four different implants (Swanson Silastic, Swanson Titanium, Elektra, and Motec).[32] The authors reported pain and dislocation were the major reasons for revision and a cumulative five- and 10-year implant survivorship of 91 and 90%, respectively, with no significant difference between the four implants.

Resolution of clinical scenario

- Low-quality evidence has not revealed any advantages of arthrodesis over trapeziectomy with LRTI, and arthrodesis likely has an increased risk of adverse events.
- There is insufficient evidence to draw any conclusions comparing implant arthroplasty and trapeziectomy with LRTI.

Summary of answers

- Splinting patients with symptomatic TM arthritis can relieve pain for up to 12 months.
- There is no difference in pain relief among various TM splints.
- There is no strong evidence corticosteroids or HA improve TM osteoarthritis symptoms.
- Hand therapy may provide some short-term pain relief for patients with TM arthritis.
- LR, TI, or LRTI do not provide any advantages over trapeziectomy alone; however, the additional procedures may increase the risk of adverse events.
- TMA is not superior to trapeziectomy with LRTI and may have increased risks related to nonunion/malunion.
- There is insufficient evidence comparing implant arthroplasty with trapeziectomy and LRTI.

155 Carpal Tunnel Syndrome: Nonoperative Management

Thomas A. Miller MD FRCPC[1], Christopher Doherty MD MPH FRCSC[2], and Douglas C. Ross MD MEd FRCSC[2]
[1] Department of Physical Medicine & Rehabilitation, Western University, London, ON, Canada
[2] Roth-McFarlane Hand & Upper Limb Centre, Division of Plastic Surgery, Western University, London, ON, Canada

Clinical scenario

- A 52-year-old man works in an automotive plant, with repetitive tasks, presents with a six-month history of increasing nocturnal numbness, paresthesiae, in a median nerve distribution. His hands awaken him most nights. He has a tendency to drop screws if using his thumb and index finger without vision support. He is concerned that his occupation is causing the problem.
- Clinically, he has a positive Durkan's test, a positive Phalen's test, and a decrease in sensation in the median nerve territory that splits the ring finger. There is no thenar atrophy, and no focal abductor pollicis brevis (APB) weakness.
- NCS (nerve conduction studies) reveal focal slowing of the median nerve at the level of wrist with sensory comparison studies, and a cumulative sensory index >1.8 ms with no motor axonal loss, and normal electromyography (EMG) (needle EMG) of the thenar APB.
- He would like to understand his treatment options.

Top three questions

1. In patients with symptoms suggestive of carpal tunnel syndrome (CTS), how helpful is the clinical exam in the diagnosis of CTS?
2. In patients with symptoms suggestive of CTS, are electrodiagnostic studies (EMG/NCS) required in assessing and treating CTS?
3. In patients with mild to moderate CTS, what are, and how effective are, the nonoperative treatment options in mild to moderate CTS?

Question 1: In patients with symptoms suggestive of carpal tunnel syndrome (CTS), how helpful is the clinical exam in the diagnosis of CTS?

Rationale

CTS is the most common entrapment neuropathy presenting to physicians. The classic history is often diagnostic. It is characterized by sensory symptoms particularly nocturnal with frequent awakening or when talking on the phone or driving a car. Paresthesiae are confined to the hand, but often the pain and discomfort can be felt not only in the hand and wrist but also proximally in the arm, shoulder, or scapular area. The shaking or flicking of the hand has been reported to be highly suggestive of the diagnosis of CTS,[1] although other authors have shown it to be neither sensitive nor specific.[2]

Clinical comment

The sensory and motor exam are the basis for every good clinician's assessment of nerve pathology. Sensory testing is normal in 20–50% of patients depending on degree, thoroughness of examiner, and patient understanding. Light touch and pinprick are more useful than two-point discrimination.[3] Restricted sensory findings can be found if carefully examined and are due to the fascicular anatomy of the median nerve at the wrist.[4] Positive motor examination, weakness, and atrophy of thenar muscles (APB) are late findings.

Available literature and quality of the evidence

As with all clinical and laboratory testing, sensitivity (true positives) and specificity (true negatives) require a gold standard. There is no gold standard, and this remains controversial as will be highlighted in the second question, and most studies have either used clinical criteria or electrodiagnosis or a combination as the gold standard. In the majority of cases a careful history and physical are sufficient to make a diagnosis and initiate treatment decisions. However, many patients present with multiple problems and/or their presentations are atypical. This then requires electrodiagnostic testing to confirm the clinical impression of CTS.[5–9]

Findings

The American Academy of Orthopedic Surgeons (AAOS) Evidence based Clinical practice guidelines (AAOS) and the treatment and Management of CTS have produced 2 consensus guidelines from experts.[6,10]

A few conclusions are outlined:

- Strong evidence supports that thenar atrophy is strongly associated with ruling in CTS but poorly

associated with ruling out CTS.

- Strong evidence supports not using Phalen's test or Tinel sign as independent physical examination maneuvers to diagnose CTS, because when used alone each has a poor or weak association with ruling in or ruling out CTS.
- Moderate evidence supports not using carpal compression test, Phalen's test, two-point discrimination, or scratch collapse as independent physical examination maneuvers to diagnose CTS because alone each has poor or weak association in ruling in or ruling out CTS.[6]

Phalen's test results ranged in sensitivity (0.46–0.80) and in specificity (0.51–0.91); Tinel's sign from 0.28–0.73 in sensitivity and specificity of 0.44–0.95. The median nerve compression test ranged from 0.04 to 0.79 and specificity of 0.25 to 0.96. Many of the studies had poor study design, inconsistent data, and small data sets, and no single test has been identified as a gold standard.[11]

There is no consensus on combining diagnostic tests and which combination should be used, but most reviews suggest that this is prudent, common, and clinically relevant practice.[5,7,8,12–14]

The association of CTS to work and ergonomic factors remains an important topic given the costs of workmen's compensation. A meta-analysis of all studies between 1980 and 2009 using a case definition of CTS that included NCS abnormality, with signs and or symptoms, found the following risk factors to be significantly associated with an increased risk of CTS among workers: (i) vibration, (ii) hand force, and (iii) repetition (level I evidence). The results of this review also concluded no association to computer typing which agreed with other reviews.[15,16] The

challenge in ascribing etiology is the difficulty in evaluating CTS in the presence of concurrent non-neurologic and musculoskeletal factors such as age, obesity, cold, diabetes, and psychosocial factors complicating the presentations.

Resolution of clinical scenario

- While the literature varies, a combination of clinical symptoms and signs has been shown to diagnose CTS and its outcome, thus the reason it is referred to as a *syndrome*.
- In clinical practice the combination of signs, symptoms, and NCS (electrodiagnostic testing) are most commonly used to diagnosis and treat CTS.
- High force, vibration, and repetition can be associated with an increased incidence of CTS.

Question 2: In patients with symptoms suggestive of CTS, are electrodiagnostic studies (EMG/NCS) required in assessing and treating CTS?

Rationale

Electrodiagnostic studies are sometimes normal in patients who meet the clinical criteria of CTS (a possible false negative), and some authors have argued that NCS are unnecessary when the clinical examination is *classic*. Estimates vary between 5 and 25% and have led to more detailed and more sensitive comparison studies being recommended.[5,17] Conversely, NCS may also be abnormal in a person with a normal clinical examination (possible

false positive).[7,8,18] This has led to controversy in the literature in regard to the benefit of electrodiagnostic testing in patients with CTS.[6,19,20]

Clinical comment

A pragmatic recommendation is to think of the electrodiagnostic test as an extension of the clinical exam and allow the physician to correlate their clinical diagnosis with a physiological test of nerve function. Given the thousands of published papers on CTS, it remains surprising why this controversy is so entrenched and likely relates to posturing by specialty groups instead of a patient-centered approach.[6,13,20]

Available literature and quality of the evidence

The quantity of evidence to date is overwhelming for such a "simple" disorder. A literature search with the terms *carpal tunnel syndrome* and *electrodiagnosis* yielded over 1500 papers. The guidelines of both European and American experts are important starting points and are included as references for the reader.[5,6,21]

Findings

Robinson and colleagues suggested the sum of three comparison tests improve reliability, sensitivity, and specificity of NCS to diagnose CTS (thumb differential + ring differential +palm differential). An abnormal response is defined as 0.9 ms with sensitivity and specificity of 83 and 95%, respectively.[22,23] However, it is important to remember that multiple comparisons increase the risk of a type I error (false-positive result), and alternatively, finding more than one abnormality when assessing the median nerve across the wrist will lower the possibility of a type I error.[8]

Correlating clinical severity with neurophysiological studies remains a challenge in predicting outcome and can be divided into two main camps: a three-scale (the lumper) camp (mild, moderate, severe)[7] and a six-scale (splitter) camp of the UK and Italian groups.[24],[25]

Padua's group in Italy assessed 500 hands in a prospective study of CTS in 379 patients and developed a neurophysiological classification based on a six-point scale: Extreme (absent motor sensory), Severe (absence sensory, abnormal distal motor latency [DML]), Moderate (abnormal sensory CV, abnormal motor latency DML), Mild, Minimal (abnormal segmental/comparative test only), and Negative (normal tests). This improved sensitivity by 20% and correlated with outcomes.[25] In a later study, they showed that the scale correlated with clinical patient-rated outcomes in 100 consecutive patients with CTS.[26]

Using a large group of 8501 patients, Bland developed a similar six-point scale based on NCS and demonstrated a significant linear relationship between neurophysiological grading and clinical history.[24] The grade is normal (grade 0), very mild (grade 1), mild (grade 2), moderate (grade 3), severe (grade 4), very severe (grade 5), and extremely severe (grade 6).

The same group recently reviewed 3382 operations to develop prognostic models in CTS and the above neurophysiological scale. They found patients with moderately severe nerve conduction abnormalities, night wakening, a family history of CTS, and a good response to corticosteroid injection, and women had better outcomes.[21]

A study by De Kleermaeker looked at patients with clinically defined CTS and normal electrodiagnostic test results, and whether these patients benefitted from surgery for CTS. Of the 57 patients, 39 had surgery and 18 had

nonsurgical treatment.[27] Outcome was based on the Boston Carpal Tunnel Questionnaire at six-month follow-up.[27] Seventy percent of the surgically treated group were significantly improved and 39.6% reported full recovery. The Functional Scale and Symptom Scale improved in the surgical group.[27]

Resolution of clinical scenario

Based on the cumulative evidence shown above, for this patient we recommend the following:

- NCS severity can be used to assist choice of initial treatment, but should not dictate treatment. Patient factors such as social, employment, and degree of discomfort are important considerations.
- This patient has CTS, and given the fact that we lack a gold standard for diagnosis, clinicians should use all reasonable diagnostic measures including symptoms/signs and NCS to increase accuracy. NCS can document the state of neural dysfunction before treatment and allow for postintervention comparison when required.
- Before considering surgical intervention for peripheral nerve problems, a number of authors have suggested the use of a four-legged table analogy. Each leg consists of corroborative findings, and for the diagnosis to rest on the table you must have at least three legs. The legs are (i) symptoms, (ii) signs, (iii) neurophysiological findings, and (iv) imaging.[28]

Question 3: In patients with mild to moderate CTS, what are, and how effective are, the nonoperative treatment options in mild to moderate CTS?

Rationale

The nonoperative treatment of mild to moderate CTS can be divided into the following main categories: (i) activity modification, (ii) splinting, (iii) oral medications, (iv) physiotherapy and modalities, and (v) corticosteroid injection.

Clinical comment

The majority of studies and clinical practice guidelines suggest the following regimen: (i) activity modification and education, (ii) resting night splints for nocturnal numbness, (iii) a trial of corticosteroid injection, and (iv) if no improvement, or worsening of signs and symptoms, operative intervention and decompression should be considered.

Available literature and quality of the evidence

The Cochrane collaborations have issued a number of summary statements. Their review of splinting looked at 19 studies and approximately 1200 patients.[29] They concluded that there was limited evidence that a splint worn at night was more effective than no splint in the short term but more research is needed.[29] Their review on the usefulness of exercise and mobilization concluded limited evidence of benefit.[30] Conversely, there is good evidence (level I) supporting treatment with corticosteroid injection.[31–33]

Findings

The Cochrane review by Marshall et al. in 2007 looked at 12 studies and over 671 patients and supports at least over the short to medium term improvement with corticosteroid injection.[33] Subsequent studies and an open label UK study in over 240 patients randomized to steroid versus splinting found, in the short term, corticosteroid to be more effective than splinting for symptom relief at six-week follow-up.[32] They noted that the optimum dose and frequency of injection has not been established. Another study demonstrated the benefit/effectiveness of a second steroid injection (on relapse after primary injection) in a cohort of 230 patients.[31]

The AAOS reviews by Keith and Graham concluded that there is strong evidence to support treatment with immobilization (brace/splint/orthosis), and steroid injections whereas magnet therapy is of no benefit.[6],[11] They also concluded that there is moderate evidence to suggest that oral treatments (diuretic, Vitamin B6, gabapentin, astaxanthin, nonsteroidal anti-inflammatory drugs) are of no benefit compared with placebo. Finally, they concluded that oral steroids, and ketoprofen phonophoresis, could improve patient-reported outcomes compared to placebo (moderate evidence) and that there was limited evidence that therapeutic ultrasound and laser therapy is effective.[6]

Resolution of clinical scenario

Based on the cumulative evidence shown above, for this patient we recommend the following:

- Education and wrist splints nocturnally are effective with little possibility of negative effects.

- There is good evidence to support corticosteroid injection as a low-risk and effective treatment for CTS over the short term.

Summary of answers

- CTS can often be diagnosed on the basis of a combination of clinical symptoms and signs alone.
- In clinical practice, the combination of signs, symptoms, and NCS are most commonly used to diagnose and treat CTS.
- Occupational exposure to high force, vibration, and repetition may be associated with an increased incidence of CTS.
- Electrodiagnostic testing can be a useful adjunct in diagnosing CTS, and while severity findings on NCS may be used to assist choice of initial treatment they should not dictate treatment.
- Education and nocturnal wrist splints are effective initial treatments for many patients.
- There is good evidence to support corticosteroid injection as a low-risk and effective treatment for CTS over the short term.

156 Carpal Tunnel Syndrome: Operative Management

Douglas C. Ross MD MEd FRCSC[1], Christopher Doherty MD MPH FRCSC[1], and Thomas A. Miller MD FRCPC[2]

[1] Roth-McFarlane Hand & Upper Limb Centre, Division of Plastic Surgery, Western University, London, ON, Canada

[2] Department of Physical Medicine & Rehabilitation, Western University, London, ON, Canada

Clinical scenario

- A 57-year-old woman presents to her family physician with a six-month history of numbness and tingling in her thumb, index, and long fingers. This frequently awakens her at night.
- She works as an administrative assistant and spends much of her workday using a keyboard.

Top three questions

1. In patients with carpal tunnel syndrome (CTS), is electrodiagnostic testing necessary prior to carpal tunnel release (CTR)?
2. In patients undergoing CTR, is endoscopic carpal tunnel release (ECTR) advantageous relative to open carpal tunnel release (OCTR)?
3. In patients undergoing CTR, what type of anesthesia is best for CTR?

Question 1: In patients with carpal tunnel syndrome (CTS), is electrodiagnostic testing necessary prior to carpal tunnel release (CTR)?

Rationale

In order to decide upon the best surgical treatment of CTS, it is important to know when nonoperative treatment is unlikely to be successful and therefore surgery is indicated.

Clinical comment

In patients with severe CTS in which there is clear wasting of the thenar muscles (specifically abductor pollicis brevis) and objective sensory changes such as a decrease in two-point discrimination, the diagnosis of CTS is typically clear on the basis of clinical examination alone. However, many, and in fact the majority of, patients do not exhibit these clinical features.

Available literature and quality of the evidence

In a highly rigorous process, the American Academy of Orthopaedic Surgeons (AAOS) published an evidence-based set of guidelines for CTS (level IV evidence).[1]

Findings

The AAOS concluded that there was strong evidence that thenar atrophy “is strongly associated with ruling-in carpal tunnel syndrome”; they also concluded that common clinical signs such as Phalen's sign – when used in isolation – “has a poor or weak association with ruling-in or ruling-out carpal tunnel syndrome.” Conversely, they concluded that “limited evidence supports that a hand-held nerve

conduction study (NCS) device" be used to diagnose CTS. It is understood that a "hand-held NCS device" meant an office-based device used by surgeons who were not using American Association of Electrodiagnostic Medicine (AAEM) criteria for the diagnosis of CTS versus formal electrodiagnostic testing. In the body of the AAOS review,[1] the authors articulated this, and in an AAOS review on the diagnosis of CTS they recommended formal NCS be performed before surgical intervention (level II).[2]

The AAEM performed a meta-analysis of prospective studies which compared independently gathered clinical data with rigorously performed electrodiagnostic testing.[3] They concluded that "median sensory and motor NCS are valid and reproducible clinical laboratory studies that confirm a clinical diagnosis of CTS with a high degree of sensitivity and specificity." Although this level I evidence suggests that NCS is useful for *diagnosing* CTS, it does not address whether NCS is *necessary* for patients prior to carpal tunnel surgery.

Another way to examine this question is to ask whether NCS can predict outcomes after CTR and particularly whether patients with normal NCS benefit from CTR. The evidence in this question is of relatively low quality and contradictory. Longstaff et al. as well as Glowacki et al. found that clinical outcomes after CTR did not correlate with preoperative NCS,[4],[5] whereas Bland reviewed a large (n = 1268) group of patients and found that patients with either normal or severe findings on NCS had a higher rate of surgical failure (all level IV).[6]

The evidence to support preoperative NCS prior to carpal tunnel surgery is contradictory. There is good evidence to support the ability of NCS to *diagnose* CTS, but it is unclear whether the addition of NCS to clinical examination is necessary in all circumstances. Interestingly, when

presented with scenarios of patients with a low or medium probability of CTS (on clinical testing tools such as the CTS-6), participants in the AAOS appropriate use guidelines development supported the use of NCS to further investigate patients as *appropriate*.[7]

Resolution of clinical scenario

- NCS are sensitive and specific for the diagnosis of CTS.
- NCS are likely unnecessary in patients with advanced findings of CTS, such as thenar wasting or objective sensory deficits, but can differentiate other neurological pathologies, and assist in postoperative management when outcomes are poor or unexpected.
- NCS are likely useful in patients with mild clinical findings or atypical presentations.

Question 2: In patients undergoing CTR, is endoscopic carpal tunnel release (ECTR) advantageous relative to open carpal tunnel release (OCTR)?

Rationale

ECTR has been championed as a less invasive method of releasing the transverse carpal ligament which allows for an earlier return to work and normal activities of daily living (ADLs) relative to OCTR. Conversely, opponents of ECTR feel that complications may be more common.

Clinical comment

The debate as to whether ECTR provides benefits relative to OCTR has been a somewhat emotional one amongst

hand surgeons since ECTR was introduced in the 1990s. The early studies of Chow and Agee et al. suggested that the procedure could be done safely and with earlier return to ADLs and work (especially in Workman's Compensation patients).[8,9] Subsequent studies failed to confirm these findings. In addition, there were a significant number of case reports documenting major complications such as median or ulnar nerve injuries after ECTR.

Available literature and quality of the evidence

There have been a large number of studies comparing ECTR and OCTR including several prospective randomized trials.[10,11]

Findings

A Cochrane review in 2014 by Vasiliadis et al. reviewed 28 papers comparing ECTR and OCTR. They found a lower rate of minor complications and an earlier return to work (eight days on average) after ECTR. However, they concluded that "[the results] of this review are limited by the high risk of bias, statistical imprecision and inconsistency in the included studies."[12] A meta-analysis by Zuo et al. in 2015 examined 13 randomized trials and reached somewhat different conclusions, including no differences in return to work, overall complications, or patient satisfaction.[13] They did find a lower rate of hand pain at 12 weeks postsurgery after ECTR but a higher risk of nerve injury (risk ratio [RR] = 2.38).

Devana et al. utilized large databases to examine complications and costs of ECTR versus OCTR.[14] They were able to compare 72 116 patients who underwent ECTR with 495 164 patients who underwent OCTR in both a private and public insurance system in the United States. They found a significantly higher rate of wound complications

such as infection and dehiscence in the OCTR group. They also found a higher rate of median nerve injury in the OCTR group, although they did not comment on whether the difference was statistically significant. The costs associated with ECTR were significantly higher and in the case of the private insurance setting were more than 1.5× that of OCTR. This is similar to the findings of Thoma et al., who found the cost utility of ECTR was poor when comparing ECTR completed in a main operating room setting versus OCTR in a minor procedure room setting.[15]

Overall, the quality of the evidence comparing ECTR and OCTR is quite high. Although the conclusions are somewhat different in various studies, it appears that minor complications are slightly higher in OCTR and that the incidence of major complications such as nerve injury are not different between the two techniques.

There is likely little difference in outcomes whether the carpal tunnel is released endoscopically or by using an open technique. Relief of sensory symptoms is high in both techniques.

Resolution of clinical scenario

- Efficacy rates are largely equivalent for ECTR and OCTR.
- Minor complications are higher with OCTR relative to ECTR.
- The incidence of major nerve injury is likely no different between the two techniques.

Question 3: In patients undergoing CTR, what type of anesthesia is best for CTR?

Rationale

Hand surgery in general, and carpal tunnel surgery specifically, is increasingly being done using local anesthesia in a minor procedure room setting.[16]

Clinical comment

Since the end of the last century, surgery for CTS has evolved from a procedure that was done in an inpatient setting under general anesthesia to one done with regional anesthesia and sedation being completed as an outpatient. Both of these techniques typically employ a main operating setting with the presence of an anesthetist. More recently, CTR under purely local anesthesia and no sedation in a minor procedure setting has been advocated.[17] The latter has been termed *wide awake, local anesthesia* (WALA) hand surgery. Purported benefits of WALA include lower costs, improved patient safety, shorter wait times in a single payer system, and a smaller environmental impact.[18]

Available literature and quality of the evidence

Although there are an increasing number of reports of the use of WALA and CTR,[16],[17] there are relatively few papers comparing WALA to traditional anesthesia techniques.

Findings

Tulipan et al. reported on 230 patients undergoing OCTR and randomized to either WALA or monitored regional anesthesia.[19] Complications, outcomes using validated tools such as the Disabilities of the Arm, Shoulder, and Hand (DASH), as well as custom Likert scales, were no different between groups.

Nabhan et al. reported on a small group of 44 patients undergoing ECTR who were randomized to either WALA or

regional anesthesia.[20] They found no differences in complications or clinical outcomes but a shorter operating room time and tourniquet time using WALA. They concluded WALA was well tolerated and effective.

Foster et al. utilized a large database to examine the comparative costs of WALA versus regional or general anesthesia.[16] They identified 86 687 patients who had undergone CTR over a five-year period and found that just over 80% of procedures had been done under general or regional anesthesia. They found that WALA saved an average of $654/procedure and that if all CTR were done under local anesthesia the direct cost savings to the US healthcare system would be $2.3 billion over the next decade.

Overall, there is little literature directly comparing the use of WALA and general/regional anesthesia for carpal tunnel surgery. Multiple small case series have documented the safety and efficacy of WALA for CTR.

Local anesthesia is becoming increasingly used for carpal tunnel surgery. It appears that there are clear cost savings associated with WALA, and therefore it is particularly attractive in cost-constrained healthcare systems.

Resolution of clinical scenario

- Carpal tunnel surgery done under local anesthesia is safe and effective.
- WALA is associated with cost savings.
- At present, there is no high-quality evidence to suggest clinical outcomes are different depending on the type of anesthesia used for CTR.

Summary of answers

- NCS are unnecessary in all patients undergoing surgery (CTR) with clinical findings of CTS but are helpful in patients with mild clinical findings or atypical presentations, and are correlated with outcomes.
- Efficacy rates are largely equivalent for ECTR and OCTR, although minor complications are higher with OCTR relative to ECTR.
- The incidence of major nerve injury is likely no different between ECTR and OCTR.
- Carpal tunnel surgery done under local anesthesia is safe and effective, and has associated cost savings.

157 Carpal Tunnel Release: Minor Procedure Room or Operating Room?

Kevin Cheung MD and Hannah St Denis-Katz MD
Division of Plastic and Reconstructive Surgery, Department of Surgery, University of Ottawa, Ottawa, ON, Canada

Clinical scenario

- A 56-year-old woman presents with complaints of right-hand weakness and numbness that awakens her at night.
- On examination, she has wasting of the thenar eminence and positive Tinel's sign at the wrist.
- Electrodiagnostic studies show prolonged median motor latency and decreased sensory conduction across the wrist.
- You decide to offer an open carpal tunnel release (CTR).

Background

CTR is one of the most common hand surgeries.[1,2] Historically, the procedure has been performed primarily in the main operating room (OR).[3] With the use of local anesthetic, however, the procedure is now routinely performed in the minor procedure setting across North America.[1,2] We reviewed the evidence examining the benefits and possible risks of performing CTR in the minor procedure setting and discuss possible indications for release in the main OR.

Top three questions

1. For patients with carpal tunnel syndrome (CTS), does performing CTR in the minor procedure room, compared to the OR, result in lower costs and improved efficiency?
2. For patients with CTS, are there differences in patient outcomes and complication rates for CTR performed in the minor procedure setting compared to the main OR?
3. For patients with CTS, are there (relative or absolute) contraindications to performing CTR under local anesthetic in the minor procedure setting?

Question 1: For patients with carpal tunnel syndrome (CTS), does performing CTR in the minor procedure room, compared to the OR, result in lower costs and improved efficiency?

Rationale

Performing CTR in minor procedure setting, such as an office or ambulatory care clinic, has the potential to have a large impact on decreasing costs and improving efficiency.

Clinical comment

Several studies have demonstrated cost savings and an improvement in efficiency when performing CTR in the minor procedure setting as compared to the main OR.[14_6]

Available literature and quality of the evidence

Evidence available to address the question was primarily level II[1,6] and III[4,5] (prospective and retrospective cohort studies).

Findings

The high costs in the main OR are due to costs of full sterility, anesthesia, and nursing staff, and longer turnover times.[1] CTR in the minor procedure room eliminates the cost for an anesthesiologist as the local anesthetic is administered by the surgeon.[4] This translates to both cost savings and increased efficiency.

Leblanc et al. analyzed the costs and efficiency of performing CTR in the main OR versus the ambulatory setting in Canada.[1] They looked at costs of carpal tunnel surgeries in private office, clinic, and main OR which were all in the same hospital, performed using a wide awake approach with pure local anesthesia (no sedation, no tourniquet, and no anesthesia provider). They performed cost analysis including nonphysician salaries of each person directly or indirectly involved and cost of material for CTR by the same surgeon in all three venues. They reported that the cost for supplies and labor for CTR in the ambulatory setting was $36/case as compared to $137/case in the main OR in the same hospital. For the three different venues (office, clinic, and main OR), an efficiency analysis was performed for a standard three-hour surgical block for CTR. In a three-hour surgical block, surgeons were able to perform nine CTRs in the ambulatory setting versus four in the main OR.[1]

Cheung et al. performed a prospective cost-effectiveness analysis to compare open CTR at a center in Canada and one in the United States.[6] CTR was performed in the minor procedure and main OR setting at the Canadian and US center, respectively. Mean total costs from a societal

perspective were significantly less in the Canadian minor procedure room setting ($1581 vs $2179, respectively).

Chatterjee et al. calculated a total cost comparison, profit analysis, and assessment of efficiency of open and endoscopic carpal tunnel surgery in the United States in both the clinic and the main OR.[4] For open CTR, the main OR was more than four times as expensive as the clinic ($3469 vs $670). Clinic cases had a profit margin of $1186 per case, and procedures in the main OR incurred a loss of $650 per case after considering the cost of the procedure and the revenue earned. The most significant direct cost in the main OR setting was the presence of an anesthesiologist. For efficiency analysis, the researchers calculated that twice as many surgeries could be done in a clinic setting.[4]

Without the use of full sterility and the supplies of procedures needed in the main OR, there is also a hypothesized environmental impact due to a decrease in medical waste. Leblanc et al. estimated that the amount of garbage generated by the main OR setting is at least 10 times that of minor procedure field sterility.[7]

Resolution of clinical scenario

- There are significant cost savings and increased efficiency when open CTR is performed in the minor procedure setting in comparison to the main OR, where full sterility, higher turnover times, and the services of an anesthesiologist and additional nursing staff are required.
- Although the evidence is derived from a lower level of evidence study design (II and III), the conclusion of all these studies is the same, thus providing a strong

recommendation to perform CTR in the minor procedure room.

Question 2: For patients with CTS, are there differences in patient outcomes and complication rates for CTR performed in the minor procedure setting compared to the main OR?

Rationale

With an increasing number of hand surgeons in North America performing CTR surgery under local anesthetic in the minor procedure setting,[1],[2],[8] it is important to ensure that outcomes and the patient experience are not compromised. Some centers continue to use the main OR preferentially. Are complication rates and patient-reported outcomes comparable in the two settings?

Clinical comment

Surveys have shown that hand surgeons in UK and America continue to use general anesthetic for CTR because of the belief that local anesthetic is poorly tolerated by patients.[9] General anesthesia may impact associated medical conditions such as diabetes, cardiac disease and lung problems. In addition, postoperative side effects such as nausea and vomiting[8] are common. The use of local anesthesia alone avoids these issues and can be administered without the need of an anesthetist.[8] In deciding whether to perform carpal tunnel surgery in the minor procedure room versus the main OR, it is important to understand if there are any differences in outcomes, complications, and patient experience.

Available literature and quality of the evidence

Evidence to address the question was primarily level II[6–8,10] and III (prospective and retrospective cohort studies).

Findings

In a prospective cohort study of 1504 CTR procedures in five Canadian training centers, Leblanc et al. demonstrated a low incidence of infection and general safety of CTR in minor procedure setting.[7] They report six superficial infections (0.4%), and no deep postoperative infections requiring admission, incision and drainage, or intravenous antibiotics. Nosrati et al. investigated differences between the main OR and clinic setting with respect to complications and patient satisfaction and found no differences in rates of infection or nerve injury.[5]

In the prospective, cost-effectiveness analysis of patients undergoing open CTR, Cheung et al. demonstrated similar postoperative improvements in health-related quality of life regardless if surgery was performed in a minor procedure setting under wrist block or main OR setting under Bier block.[6] Clinically significant improvements were observed in both the Michigan Hand Questionnaire and EuroQol five-dimensional questionnaire (EQ5D).

Several studies have demonstrated that most patients prefer CTR under local anesthetic without sedation if offered in a positive manner.[10,11] Derkash et al. reported on 20 patients undergoing CTR in the office with wrist block anesthesia and wrist tourniquet that all were pleased with the office surgical procedure. One patient reported mild discomfort from the wrist tourniquet.[8] Barros et al. had patients complete a questionnaire following their surgery regarding their anesthetic experience, including the number of times they felt pain during the anesthesia

and the intensity of that pain.[11] Seventy-five percent of patients reported that the technique was the same or better than venous puncture and 81% reported that it was better than a dental procedure.

Davison et al. performed a prospective cohort study to examine the patient's perspective on CTR related to two types of anesthesia.[10] The first group of 100 patients had open CTR with only lidocaine and epinephrine in Saint John, New Brunswick, and the second cohort of 100 patients underwent endoscopic CTR with local anesthesia, IV sedation, and use of tourniquet in Davenport, Iowa. They used questionnaires completed by patients at their first postoperative visit to gather information on patient perspectives on the anesthesia experience. Interestingly, they found that patients generally liked whichever form of anesthesia that was provided and that wide-awake carpal tunnel surgery was well tolerated. Similarly, Baguneid et al. performed a prospective study to assess effectiveness, safety, and patient tolerance of CTR using local anesthetic and upper arm tourniquet.[9] Patients reported no discomfort or only slight discomfort for all aspects of the operation in 94% of cases. All patients preferred local anesthesia over general anesthetic.

Despite previous beliefs,[7] current evidence demonstrates that CTR performed in an ambulatory setting with local anesthetic is well tolerated by the majority of patients with low complication rates and high patient satisfaction.[6–8,10]

Resolution of clinical scenario

- CTR in the minor procedure setting under local anesthetic is well tolerated by most patients.
- Complication rates and patient-reported outcomes were comparable to CTR performed in the main OR.

Question 3: For patients with CTS, are there (relative or absolute) contraindications to performing CTR under local anesthetic in the minor procedure setting?

Rationale

There is evidence for cost savings, increased efficiency, comparable outcomes, and patient preferences for undergoing CTR in the minor procedure setting under local anesthetic. While this is an appropriate setting for most patients, it is important to identify any relative or absolute contraindications to performing CTR in the minor procedure setting.

Clinical comment

The minor procedure setting is an appropriate environment for most patients undergoing CTR, but there may be some situations where the main OR is indicated.

Available literature and quality of the evidence

Evidence available to address the question was primarily level II, III, and V, including prospective and retrospective studies, as well as literature reviews and expert opinion.

Findings

There are few absolute contraindications for CTR in the minor procedure setting. In fact, contraindications to general anesthesia, such as medical co-morbidity or pregnancy, may be an indication to consider local anesthetic. Grekin and Auletta discussed local anesthetic, its uses, and its contraindications.[12] Although it is rare to

have a true allergy to local anesthesia, this would be an indication for CTR to be performed in the main OR under general anesthetic.[11,13]

Presumed relative contraindications for CTR in the minor procedure setting may not be evidence based. While some surgeons will bring patients who are on antiplatelets or anticoagulants to the main OR for elective hand surgery, there is a lack evidence to support doing this. Several studies report no difference in bleeding complications if anticoagulation or antiplatelet therapy are continued for elective hand surgery.[14–16] Smit and Hooper reviewed a group of patients who had surgical treatment for CTS or Dupuytren's disease while anticoagulated on warfarin.[14] Surgery was carried out without stopping the warfarin, provided the INR was 3 or less. Open CTR was performed under local anesthetic with pneumatic tourniquet; there were no perioperative or postoperative bleeding complications.

Despite a lack of evidence, we hypothesize that other relative contraindications to CTR in the minor procedure setting include the inability to lie flat or still, such as Parkinson's disease or cognitive impairment. Patients undergoing other procedures under general anesthetic may wish to have concomitant CTR performed during the same anesthetic. Patient anxiety and preference may also be a relative contraindication, although there is evidence that when CTR under local anesthetic is presented to patients in positive manner it is generally well tolerated.[6–8,10]

Resolution of clinical scenario

- There are few relative and absolute contraindications to carpal tunnel surgery in the minor procedure setting.

Summary of answers

- There are significant cost savings and increased efficiency of CTR when performed in the minor procedure setting compared to the main OR.
- CTR in the minor procedure room setting is well tolerated by most patients.
- There is no increased risk of complications when CTR is performed in the minor procedure setting compared to the main OR.
- There are few relative and absolute contraindications to performing carpal tunnel surgery in the minor procedure setting.

158 Thumb Carpometacarpal Osteoarthritis

Ryan Wolek MD[1], Steven McCabe MD MSc[2] and Matthew Furey MD MSc[3]
[1] Lakeridge Health, Oshawa, ON, Canada
[2] Division of Orthopaedic Surgery, Department of Surgery, University of Toronto, Toronto, ON, Canada
[3] Division of Orthopaedic Surgery, Department of Surgery, University of Alberta, Edmonton, AB, Canada

Clinical scenario

- A 59-year-old right-hand-dominant woman who works as an administrator complains of pain at the base of her thumb, radiating along her thenar eminence and radial forearm.
- The pain has been present for a few years and has gradually worsened.
- She has difficulty opening jars and chopping vegetables due to this pain.

Top three questions

1. In patients with primary thumb carpometacarpal osteoarthritis (CMC OA), does intra-articular corticosteroid injection result in greater pain relief than placebo or hyaluronic acid?
2. In patients with primary thumb CMC OA, does an orthosis improve pain and function?

3. In patients with primary thumb CMC OA, does trapeziectomy plus ligament reconstruction and tendon interposition (LRTI) result in greater pain relief than trapeziectomy alone?

Question 1: In patients with primary thumb carpometacarpal osteoarthritis (CMC OA), does intra-articular corticosteroid injection result in greater pain relief than placebo or hyaluronic acid?

Rationale

Initial nonsurgical treatment of patients with thumb CMC OA typically involves joint injections and splinting. Intra-articular injections are a common presurgical intervention aimed mainly at pain relief. It is unclear which conservative measures, if any, are most effective.

Clinical comment

Intra-articular corticosteroid injections are thought to decrease pain and inflammation associated with osteoarthritis. Alternatively, intra-articular hyaluronic acid injections aim to supplement and increase the viscoelasticity of synovial fluid.

Available literature and quality of the evidence

The best evidence to answer this question comes from a recent systematic review that included meta-analyses of six randomized controlled trials (RCTs).[1–7] The majority of the studies were not of high methodological quality and many

sources of heterogeneity were present. This is level II evidence.

Findings

Pooled meta-analysis was performed on three sets of data: corticosteroid injection versus placebo, hyaluronic acid injection versus placebo, and corticosteroid versus hyaluronic acid. Analysis of corticosteroid injection versus placebo showed that individual study findings were mixed. Pooled analysis, with 82 patients in each arm, showed no difference between corticosteroid injection and placebo at 24 weeks post injection (Standardized response means [SRM]: −1.20; 95% confidence interval [CI]: −3.69 to 1.29). Earlier time points were unable to be pooled for analysis. Pooled analysis of hyaluronic acid versus placebo, with 74 patients in each arm, showed improvement in functional capacity in the hyaluronic acid group (SRM: −1.14 [−1.69 to −0.60]) at 12 weeks, but no difference in pain (SRM: −0.95 [−3.87 to 1.97]). Results at 24 weeks were unable to be pooled. Pooled analysis between corticosteroid and hyaluronic acid did not yield significant results at four and 12 weeks; however, differences were apparent at 24 weeks. Hyaluronic acid appeared superior on pulp pinch force (SRM: −1.66 [−0.75 to −2.57]), and corticosteroid superior for pain (SRM 1.44 [0.17–2.74]); however, the authors commented that the results at 24 weeks were almost entirely driven by one strongly positive study, while the other studies showed no effect.

Resolution of clinical scenario

- In patients with thumb CMC OA, there is weak evidence to support the use of corticosteroid and hyaluronic acid injections for relief of pain and improvement in function.

- Studies comparing the two forms of injection suggest that corticosteroid may be better for pain relief, whereas hyaluronic acid may be more useful for increasing functional capacity.

Question 2: In patients with primary thumb CMC OA, does an orthosis improve pain and function?

Rationale

Use of an orthosis is a common nonoperative treatment prescribed by family physicians, sports medicine physicians, and hand and wrist surgeons. Orthoses vary in their size, rigidity, and method of manufacture. Despite widespread use, optimal type and duration of use of splinting is unclear.

Clinical comment

Orthoses are prescribed to immobilize the first CMC joint in order to decrease pain and perhaps improve function.

Available literature and quality of the evidence

The current best evidence comes from a systematic review of 10 RCTs studying the effects of orthoses in patients with symptomatic thumb CMC OA.[8] This is level I evidence.

Findings

Ten RCTs were reviewed and the results of each study were synthesized to make conclusions; however, pooled meta-analysis were not performed. Two RCTs compared prefabricated versus custom orthoses.[9],[10] Both studies found that pain improved in both groups; however, custom-

made orthoses provided significantly better pain reduction in both studies. One of these studies also found an improvement in pinch strength and Disabilities of the Arm, Shoulder, and Hand (DASH) scores in both groups.[10] Weiss et al. compared short and long prefabricated orthoses and found that pain was improved in both groups.[11] They found that short orthoses were favored by most patients. Another RCT compared soft orthoses to rigid and semi-rigid orthoses and found no significant difference in pain scores between the two treatment arms.[12] Most patients preferred the use of the flexible orthosis, and most patients preferred to wear the orthosis for the entire day. One study compared two groups consisting of the use of an orthosis plus an exercise protocol and found that both groups improved in terms of pain, strength, and function.[13] No difference between the groups was found.

Resolution of clinical scenario

- In patients with thumb CMC OA, there is evidence to support the use of an orthosis for the reduction of pain.
- While custom-made orthoses appear to be superior in terms of pain reduction, there does not appear to be an effect of orthosis length or rigidity.
- Orthoses do not appear to alter overall function, strength, or dexterity.
- Most patients preferred to wear the splint for the entire day.

Question 3: In patients with primary thumb CMC OA, does trapeziectomy plus ligament reconstruction and tendon interposition (LRTI) result in greater pain relief than trapeziectomy alone?

Rationale

In patients with primary thumb carpometacarpal osteoarthritis, does trapeziectomy plus LRTI result in greater pain relief than trapeziectomy alone?

Clinical comment

Amongst surgeons who perform thumb CMC procedures, there is a continued trend toward utilization of trapeziectomy plus LRTI. In a recent study, 95% of surgeons utilize only one type of surgical procedure, and of these 93% exclusively perform trapeziectomy plus LRTI.[14]

Available literature and quality of the evidence

The best evidence available to address this question comes from a systematic review of 11 RCTs, quasi-randomized, and controlled studies,[15] in which meta-analysis was performed on data pooled from the included studies. Five of these studies compared trapeziectomy alone to trapeziectomy plus LRTI.[16–21] This is level II evidence; the authors of the paper concluded that the quality of available and included studies was low.

Findings

Meta-analysis of three studies which compared pain on a 100 mm Visual Analog Scale (VAS) found no difference on pain relief between trapeziectomy plus and trapeziectomy alone.[16,18–20] The mean reduction in pain with trapeziectomy plus LRTI was 2.8 mm (95% CI: −9.82 mm to 4.21 mm). Meta-analysis of two studies comparing the number of participants with resting pain found no difference between trapeziectomy plus LRTI and trapeziectomy alone (risk ratio [RR] = 1.18; 95% CI: 0.31–4.54).[17,21]

Furthermore, meta-analysis revealed that there was no difference between the two groups for physical function, as measured by the DASH score (SMD: 0.01 out of 100 points; 95% CI: −0.30 to 0.32). Meta-analysis of complication rates revealed that 19 out of 100 people who underwent trapeziectomy plus LRTI had an adverse event, and 10 out of 100 people who had trapeziectomy alone had an adverse event (RR = 1.89; 95% CI: 0.96–3.73). Adverse events included tendon rupture or adhesion, scar tenderness, recurrent pain, sensory changes, cut palmar cutaneous branch of the median nerve, neuroma, instability, de Quervain's syndrome, and complex regional pain syndrome.

Resolution of clinical scenario

- In patients with thumb CMC OA, trapeziectomy plus LRTI does not improve pain or function compared to trapeziectomy alone.
- Trapeziectomy plus LRTI may have a higher risk of complications.
- Despite the presence of level I and III evidence showing equivalent outcomes and a higher risk of complication in trapeziectomy with LRTI, there continues to be a trend toward its use in basal thumb osteoarthritis.

- There is evidence that trapeziectomy with LRTI has substantially more cost compared to the simpler trapeziectomy ($2576 vs $1268, respectively).[22]

Summary of answers

- In the nonsurgical management of thumb CMC OA, evidence supports the use of intra-articular injections for relieving pain and improving function. Corticosteroid injections may be better for pain relief, and hyaluronic acid may be more helpful for improving functional capacity.
- There is evidence to support the use of an orthosis to reduce pain in thumb CMC OA. While custom-made orthoses appear to be superior in terms of pain reduction compared to prefabricated splints, the type of orthosis (long, short, rigid, or flexible) does not appear to make a difference.
- In the surgical treatment of thumb CMC OA, trapeziectomy alone has equivalent outcomes in terms of pain relief and function when compared to trapeziectomy and LRTI. LRTI has a higher complication risk as well as healthcare cost.

159 Flexor Tendon Injuries: Surgical Management

Robert M. Szabo MD MPH[1] and Shima Sokol MD[2]
[1] Department of Orthopaedic Surgery, University of California Davis, Davis, CA, USA
[2] Albert Einstein College of Medicine, Bronx, NY, USA

Clinical scenario

- A 35-year-old woman presents with inability to flex her index finger after sustaining a laceration while cutting a bagel yesterday.
- She has a 1 cm transverse laceration over the palmar proximal phalanx and increased extension posture.
- She can't flex her proximal or distal interphalangeal joints. Her sensory exam is normal.

Top three questions

1. In patients with acute zone II flexor tendon lacerations, does multistrand core-suture repair result in fewer re-ruptures and better range of motion (ROM) compared to two-strand repairs?
2. In patients undergoing zone II flexor tendon repair, does release of the A2 or A4 pulley result in poorer outcome or bowstringing compared to preservation of these annular pulleys?
3. In cooperative patients with zone II flexor tendon lacerations, does wide awake, local anesthesia, no tourniquet (WALANT) flexor tendon repair improve

ROM and function compared to repairs done under regional or general anesthesia?

Question 1: In patients with acute zone II flexor tendon lacerations, does multistrand core-suture repair result in fewer re-ruptures and better range of motion (ROM) compared to two-strand repairs?

Rationale

Biomechanical studies have shown the strength of the repair increases with the number of suture strands crossing the repair site. However, suture techniques using more strands across the repair site are technically demanding and require increased manipulation of the tendon ends. Multistrand repairs are also bulkier, which may compromise tendon gliding under the pulleys.

Clinical comment

A tendon repair must be strong enough to allow for early ROM without creating too much bulk to impair tendon gliding within zone II.

Available literature and quality of the evidence

There is one randomized controlled trial (RCT),[1] one retrospective comparative study,[2] two level III meta-analyses,[3],[4] and one level IV systemic review comparing two-strand repair to multistrand repair.[5]

Findings

Overall, rupture rates for flexor tendon repairs using all methods average approximately 4%.[6,7] Although in vitro studies have confirmed increasing the number of core sutures across the repair site increases the strength of tendon repair in vitro,[8–14] the clinical benefits of increasing the number of core sutures have not been proven.

Several papers have tried to determine whether there is a benefit of multistrand repair over two-strand core suture repair. Navali and Rouhani published an RCT comparing flexor tendon repairs in zone II performed with a two-strand or four-strand core-suture repair.[1] They followed a passive ROM protocol after surgery which may have negated the principal advantage of multistrand repairs (early *active* motion). There was no statistical difference in clinical outcome between the two groups. There were two tendon ruptures in the two-strand repair group and none in the four-strand repair group. This difference was not statistically significant.

Hoffman et al. compared the clinical outcomes of 46 patients (51 digits) undergoing a six-strand Lim/Tsai repair to 25 patients (26 digits) treated with a two-strand modified Kessler stitch in zone II flexor tendon repairs.[2] The complication rate was lower in the six-strand group (4%) than in the two-strand group (23%). The rupture rate was also lower in the six-strand group (2% vs 11% in the other group), but this was not statistically significant. The two groups followed different rehabilitation protocols, confounding the results.

A systematic review of two-strand versus multistrand core suture techniques for flexor tendon repair found no difference in functional outcome.[4] There was a trend toward lower rupture rates in the multistrand repair group, but this difference was not clinically significant. Other meta-analyses evaluating flexor tendon repairs in all zones

have also failed to find a statistically significant difference in outcomes or rupture rates between two-strand and multistrand repairs.[3,5] One study found that a modified Kessler technique decreased the risk of adhesions by 134%.[6]

Resolution of the clinical scenario

- For zone II flexor tendon lacerations, we cannot recommend a multistrand repair over a two-strand repair.
- The benefit of adding increased strength with more core strands must be weighed against the risk of causing more bulk and adhesions to the repair.

Question 2: In patients undergoing zone II flexor tendon repair, does release of the A2 or A4 pulley result in poorer outcome or bowstringing compared to preservation of these annular pulleys?

Rationale

Traditionally, the A2 and A4 pulley have been preserved, repaired, or reconstructed during zone II flexor tendon repair to prevent bowstringing.

Clinical comment

Release or venting of these essential pulleys during zone II flexor tendon repair can facilitate repair, may improve tendon excursion, and decrease work of flexion.[15–22] The

practice of venting essential pulleys during flexor tendon repair is gaining wide clinical acceptance.

Available literature and quality of the evidence

There are two level IV studies describing outcomes after complete release of the A4 pulley during flexor tendon repair.[23–25] There is one small retrospective case series reporting the results of flexor tendon repair after complete release of the A2 pulley.[24] Tang and colleagues published a large prospective study describing results after zone II flexor tendon repairs involving release of various portions (including the A2 and A4 pulley) of the flexor sheath.[26]

Findings

Partial release or venting of the A2 and A4 pulley have been described to aid in tendon repair and allow for smooth gliding of the swollen and edematous tendon repair. Complete release of the A2 and A4 pulley was discouraged because of concern for bowstringing. In contrast, Kwai and colleagues reported the frequency and degree of venting of the A2 and A4 pulleys necessary either to perform a flexor tendon repair or to allow the repairs to run freely without snagging on the pulleys is greater in clinical practice than the earlier literature would suggest.[27] In addition, recent biomechanical and clinical research have challenged the need to preserve these “critical” pulleys.[18,19,22]

Several papers have described partial and even complete release of the A4 pulley during flexor tendon repair.[23,27,28] Moriya and colleagues reported on 15 patients, with 22 fingers, who had complete release of the A4, C2, and in some patients A3 pulley during zone II flexor tendon repair.[25] Good to excellent results were noted in 91% according to Strickland or Tang criteria. Two small fingers required tenolysis. Al-Qattan and Al-Turaiki published a

prospective study showing good to excellent results in patients requiring complete release of the A4 pulley or portions of the A2 pulley during zone II flexor tendon repair.[23] The authors attributed a decrease in rupture rate and PIP flexion contracture to generous venting of pulleys, including the critical A4 and A2 pulley.

With regard to the A2 pulley, biomechanical research suggests release of the A2 pulley may actually improve tendon excursion and decrease work of flexion.[29] Moriya and colleagues reported their results on seven fingers with zone II flexor tendon injuries requiring complete release of the A2 pulley.[24] Two patients required additional release of the C1 pulley. They had six (86%) good to excellent results according to Strickland and Tang criteria with no bowstringing. These results were compared to 33 patients who only underwent partial A2 pulley release, who had 73% good to excellent results. Two patients (29%) required tenolysis in the complete A2 pulley release group compared to only one finger (3%) in the partial release group. There were two clinical failures according to the Tang criteria in the partial release group but none in the complete release group.

Tang and colleagues reported intern results of 300 flexor tendon repairs in which up to 2 cm of tendon sheath was released to allow for unimpeded motion of the tendon.[26] Venting was performed in different portions of the sheath depending on location of the tendon injury. Good to excellent results were found in over 83% of repairs with only one rupture in the entire series. They did not find any clinically significant bowstringing even in cases were complete release of the A2 or A4 pulley was required.

A systemic review of venting of the pulley system with early active mobilization (114 digits) compared with no venting and passive flexion active extension mobilization (335

digits) showed a trend toward an improvement in the incidence of excellent outcomes but not to statistical significance.[4] However, this study did not specify which pulleys were released or the extent of release and involved different postoperative mobilization programs.

Resolution of the clinical scenario

- Partial release of “critical” pulleys is acceptable to aid tendon repair and allow for smooth gliding of the repaired tendon.
- Early clinical evidence suggests complete A4 release during flexor tendon repair does not adversely affect outcome after surgery.
- There is still insufficient clinical data to support complete release of the A2 pulley during flexor tendon repair.

Question 3: In cooperative patients with zone II flexor tendon lacerations, does wide awake, local anesthesia, no tourniquet (WALANT) flexor tendon repair improve ROM and function compared to repairs done under regional or general anesthesia?

Rationale

In recent years, there has been increasing interest in performing hand surgery under WALANT. The use of WALANT in hand surgery has been shown to be safe and well-tolerated by patients.[29],[30] Flexor tendon repair under WALANT is gaining attention.

Clinical comment

By having the patient actively flex their finger after flexor tendon repair, the surgeon is able to test the integrity of the repair and ensure the repair is gliding smoothly in the tendon sheath.

Available literature and quality of the evidence

Lalonde first described his method for wide awake flexor tendon repair in 2009.[31] Since then, Higgins and his colleagues have published one level IV retrospective chart review on patients undergoing wide awake flexor tendon repair.[32]

Findings

Lidocaine with epinephrine allows for anesthesia and a bloodless field without tourniquet. The patient can then actively flex their finger before skin closure to ensure there is no gapping or triggering at the repair site and smooth gliding of the repaired tendon under the pulleys.[33] Higgins and colleagues reported the results of 68 patients, undergoing two 122 wide awake flexor tendon repairs: three patients had re-rupture (4.4%) or four tendons of 122 repairs (3.3%).[32] Results included patients undergoing two- and four-strand core repairs with epitendinous suture in zone I–IV, 25 flexor pollicis longus repairs, and six cases where the zone was not documented. Final ROM was not presented.

Despite the potential advantages of WALANT for flexor tendon surgery, a recent survey of 410 members of the ASSH, revealed only 20% of surgeons reported using WALANT for flexor tendon repairs.[34] The authors speculated WALANT for flexor tendon surgery has not been widely adopted by hand surgeons in the United States

because of the invasiveness of the procedure and lack of evidence showing an improvement in outcome.

Resolution of the clinical scenario

- WALANT may help improve the quality of flexor tendon repair; however, evidence showing a clear advantage or improvement in outcomes compared to regional and general anesthesia is lacking.
- The surgeon should continue to perform flexor tendon repair in the manner which they feel most comfortable.
- The surgeon should continue to perform flexor tendon repair in the manner in which they feel most comfortable.

Summary of answers

- For zone II flexor tendon lacerations, there is insufficient clinical evidence to recommend a multistrand repair over a two-strand repair.
- Early clinical evidence suggests complete release of the A4 pulley during zone II flexor tendon repair can safely aid flexor tendon repair and does not lead to bowstringing.
- There is still insufficient evidence to recommend complete release of the A2 pulley during flexor tendon repair.
- WALANT anesthesia is safe for flexor tendon repair surgery but has not been shown to improve clinical outcomes in flexor tendon surgery

160 Flexor Tendon Injuries: Rehabilitation

Matthew McRae MD, Mark McRae MD, Daniel Waltho MD, and Jenny Santos MSc
Division of Plastic Surgery, Department of Surgery, McMaster University, Hamilton, ON, Canada

Clinical scenario

- A 40-year-old male lacerates both flexor digitorum profundus (FDP) and flexor digitorum superficialis (FDS) of the long finger over the proximal phalanx while using a knife to cut food.
- This is repaired using four core strands with a 4-0 braided polyester suture, a 6-0 monofilament epitendinous repair of the FDP, and a two-strand figure-of-eight repair of both slips of FDS with 4-0 braided polyester suture.
- The referral from the surgeon asks for a splint and range of motion (ROM) exercises.

Top three questions

1. In adults with zone II flexor tendon injuries, would an early active ROM rehabilitation protocol result in better finger ROM than early controlled passive ROM?
2. In adults with zone II flexor tendon injury, does immediate initiation of motion result in better total finger ROM than those initiated in a delayed fashion?
3. In adults with zone II flexor tendon injury, after surgical repair does splinting in a neutral wrist position

result in better total finger ROM than with the wrist held in flexion?

Question 1: In adults with zone II flexor tendon injuries, would an early active ROM rehabilitation protocol result in better finger ROM than early controlled passive ROM?

Rationale

Early motion protocols have greatly improved outcomes after flexor tendon surgery. There has been considerable debate on the optimal postoperative rehabilitation strategy for zone II flexor tendon repairs. Medical professionals remain divided on protocols that employ only passive flexion or a combination of passive and active flexion.[1–3]

Clinical comment

Zone II flexor tendon injuries are associated with poorer outcomes than injuries in other parts of the flexor tendon system. Following repair, there is a competing demand on the tendon for gliding through the sheath to prevent adhesions and minimizing excessive forces on the repair to prevent rupture. Although, intuitively, early active motion will decrease adhesions and improve outcomes, this is not necessarily supported in the literature.

Available literature and quality of the evidence

- Level Ib: randomized controlled trial (RCT).[4]
- Level IIb: RCT.[5]
- Level V: expert opinion.[6]

Findings

Trumble et al. compared a group of patients using early passive ROM using a passive flexion and active extension protocol with a group using a combined passive and active flexion rehabilitation protocol employing place and hold.[4] The total finger ROM was significantly better ($p < 0.05$) in the combined passive and active place and hold group ($\mu 156° \pm \sigma 25°$) compared to the early passive ROM only group ($\mu 128° \pm \sigma 22°$). Rupture rates appeared to be equivalent between early passive ROM only and early active with place and hold groups.

A second RCT by Farzad compared early active motion with a place and hold and early passive motion only. This study showed a significant increase in total active motion ($p = 0.001$) eight weeks after surgery in the early active motion group ($\mu 146° \pm \sigma 29°$) than the early passive motion group ($\mu 114° \pm \sigma 38°$). There were no ruptures reported among the 54 patients. This trial represents level II evidence due to underpowering of the control and study groups.[5]

A review by Tang highlighted the challenges in comparing outcomes even amongst what appeared to be similar therapy protocols. These authors compiled flexor tendon repair therapy protocols of 10 of the world's leading hand surgery centers and showed great variability in the protocols used as well as variability in the method of passive and/or active ROM utilized by each center. Synergistic wrist movement in passive motion protocols and midrange finger active motion are two examples of state-of-the-art strategies that could improve tendon excursion while minimizing force applied to a healing tendon.[6]

Resolution of clinical scenario

- Patients with isolated flexor tendon lacerations in zone II likely benefit from an early active ROM protocol that combines elements of early passive motion and early active motion with place and hold, which will result in the greatest total arc of motion for the repaired fingers.
- There is no increase in rupture rates of the repaired tendon(s) compared to passive ROM protocols with active extension.
- There are a large variety of postoperative flexor tendon protocols that vary by center. There is a trend toward a combination of early passive with early active ROM in leading hand surgery centers.

Question 2: In adults with zone II flexor tendon injury, does immediate initiation of motion result in better total finger ROM than those initiated in a delayed fashion?

Rationale

Early motion postflexor tendon repair has resulted in dramatically improved composite motion of the fingers compared to immobilization. The decision of when to commence early motion therapy after surgery varies by center.

Clinical comment

Early motion protocols can be considered those that begin motion within seven days of repair.[7] *Work of flexion* reflects the resistance against which a repaired tendon must pull to permit gliding within the sheath.[8] The goal is to minimize the forces that prevent active motion via the repaired flexor

tendon. The foremost postoperative factor that can increase work of flexion in the first week after surgery is finger edema, while adhesions and joint stiffness introduce a further component resisting motion beyond seven days. Proponents of immediate *passive* motion suggest that immediate motion after surgery can help reduce edema and prevent tendon adhesion.[9] Others suggest that a short period of rest (3–5 days) to the hand following surgery allows clots to stabilize and edema to improve, making motion more comfortable and effective.[8],[10]

Available literature and quality of the evidence

- Level III: 1 retrospective cohort.[11]
- Level V: 1 biomechanical study[12] and 3 expert opinions.[8],[9],[13]

Since the level of evidence available in this area is level III–V, key results should be considered cautiously.

Findings

Immediate *passive* motion, as early as postoperative day one, is employed at many hand surgery centers, including the two RCTs performed comparing early active and early passive ROM. Advantages for early ROM would be prevention of stiffness and edema and early evaluation and monitoring for early signs of infection.[4],[5]

Arguments against postoperative day one passive movement include patient discomfort and the possibility of causing fresh bleeding around the tendon that could cause worsened adhesion formation.[8] Biomechanical studies in animal models recommend against waiting more than seven days for motion, while also suggesting that postoperative day one *active* motion may be detrimental.

Immediate postoperative *active* movement in a chicken model of flexor tendon repair showed an increased work of flexion in the immediate postoperative period of the first three days due to edema. By 7–9 days, the force required to actively move the tendon again increased due to adhesion formation.[12]

In a canine model of active motion after flexor tendon repair of a lacerated tendon, work of flexion remained high at three days, dropped at day five and then increased by day seven following the procedure. It was hypothesized that the force increased at day seven due to adhesion formation, resisting the gliding tendon. It was hypothesized that the decreased work of flexion at day five was due to decreased extrinsic forces on the tendon, such as edema resolution in surrounding tissue.[13]

A study in Taiwan looked at patients with any tendon injury of the hand. Those that started rehabilitation with motion at under one week required fewer therapy visits, were in therapy for a shorter time, and required fewer revision surgeries than those who initiated therapy at over one week. This resulted in both better clinical results and cost savings.[11]

Resolution of clinical scenario

With the goal of maximizing finger ROM after zone II flexor tendon repair:

- This patient should begin early motion within seven days after zone II flexor tendon repair.
- Passive motion can commence as early as postoperative day one. Evidence is contradictory on whether a short period of immobilization of 3–5 days is beneficial.

- Active motion should be delayed until 3–5 days after surgical repair.

Question 3: In adults with zone II flexor tendon injury, after surgical repair does splinting in a neutral wrist position result in better total finger ROM than with the wrist held in flexion?

Rationale

Traditionally, the wrist is held in a position of slight flexion after flexor tendon repair to reduce force exerted on the healing tendon repair and to permit passive ROM. Early active motion protocols often have the wrist held in neutral or slight extension.

Clinical comment

The flexor tendon repair must be protected after surgery as unrestrained movement or accidental forced flexion can overpower the repair resulting in gapping and possible tendon rupture. The position of the wrist during the rehabilitation period has been said to influence the force that the tendon is subjected to in passive and active ROM.

Available literature and quality of the evidence

- Level V: 3 animal studies,[14–16] 1 biomechanical study,[17] and 2 expert opinions.[18,19]

As the level of evidence available is level V, key results and recommendations should be considered cautiously.

Findings

Flexion of the wrist does reduce the maximum force (deliberate or inadvertent) that can be generated through a flexor tendon. Burssens et al. tested uninjured human hands and showed that the maximum grip force increased progressively by changing the wrist from a position of flexion to one of extension. The maximum force that can be generated by the muscles in the forearm via the flexor tendon decreases with wrist flexion.[18]

In a canine model of passive and active motion measuring force through the tendon, peak tendon force was 2–3 times greater with the canine wrist in extension than in flexion. Passive tension on the tendon decreased substantially from extension to flexion. With stimulation of the muscle simulating active motion, a significant decrease in force was measured in the tendon when the wrist was flexed instead of extended.[16]

In a canine model of flexor tendon repair with passive ROM, extension of the wrist allowed for greater excursion of the tendon than fixed flexion of the wrist. Fixed flexion of the wrist may limit passive tendon excursion, particularly in a flexor tendon sheath that has been subjected to the trauma of tendon repair.[14]

In a biomechanical model in uninjured human fingers, the force required to actively flex the fingers is deemed to be lowest with the wrist in 45° extension and metacarpophalangeal MCP joints flexed and interphalangeal IP joints straight. This is compared to the wrist in a neutral or flexed position, where the resting tension of the intrinsic/extensor tendons impose a greater extension force that counters flexion.[17]

In a study that used buckle force transducers on uninjured flexor tendons in the carpal tunnel, with active motion, the

force on the FDS tendon increased with wrist flexion while the force generated through the FDP did not change between flexed or neutral positioning of the wrist. They advise the wrist to be held in neutral for early active ROM to reduce force on the FDS tendon.[19]

A study in human cadavers highlighted the merits of synergistic wrist extension in reducing the tension of the finger flexors during active finger flexion.[15] Additionally, international leaders in flexor tendon repair advocate a neutral, hinged splint or slight extension of the wrist for initiation of early active ROM protocols after flexor tendon repair.[6]

Resolution of clinical scenario

There is limited evidence supporting one position of the wrist over another depending on the goal of rehabilitation.

- Slight flexion of the wrist limits the active force possible through the repaired tendon and may be ideal prior to initiating an active motion protocol, to prevent inadvertent use and to protect a weak repair.
- Passive motion flexor tendon excursion may be augmented with wrist extension.
- For early active ROM of the fingers, the wrist should not be flexed but rather in neutral or slight extension to reduce the force required for active motion via the repaired tendon.

Summary of answers

- Early active ROM with place and hold results in greater finger ROM than passive flexion only.
- Motion should commence within seven days of repair.

- Rehabilitation with active motion should be initiated 3–5 days postoperatively. Passive motion may commence as early as day one.
- Wrist flexion reduces the force that can be generated through a flexor tendon; however, wrist flexion also limits passive tendon excursion and increases the force required through the flexor tendon for active flexion.

161 Extensor Tendon Injuries

Noor Alolabi MD[1], Monica Alderson MSc[2], and Carolyn M. Levis MD MSc[2,3]
[1] Division of Hand Surgery, Mayo Clinic, Rochester, MN, USA
[2] St. Joseph's Healthcare, Hamilton, ON, Canada
[3] McMaster University, Hamilton, ON, Canada

Clinical scenario

- A 35-year-old self-employed male contractor cutting dry wall with a knife.
- The blade slipped causing a 4 cm laceration to the dorsum of his nondominant hand.
- The patient severed the extensor tendons to the four fingers between the metacarpophalangeal (MP) joints and the wrist; he is unable to extend his fingers.

Top three questions

1. In patients with fully lacerated extensor tendons, does a multistrand core suture technique result in better functional outcomes when compared to other techniques?
2. In patients with fully lacerated extensor tendons, does an early active range of motion (ROM) rehabilitation protocol result in better outcomes when compared to immobilization?
3. In patients with fully lacerated extensor tendons, what preoperative factors contribute to better functional outcomes?

Question 1: In patients with fully lacerated extensor tendons, does a multistrand core suture technique result in better functional outcomes when compared to other techniques?

Rationale

The strength of an extensor tendon repair dictates which postoperative rehabilitation protocol may be implemented. The repair needs to be strong enough to withstand an early ROM protocol and prevent rupture or tendon gaping.

Clinical comment

The goal of extensor tendon repair is to create sufficient repair strength to prevent rupture, safely engage in postrepair therapy, and allow the patient to return to work and activities of daily living as soon as possible. There is less controversy about the technique of repairing extensor tendons compared to flexor tendons. Most experts would agree that a strong repair that will withstand tension during early ROM protocols is advisable. A bulky repair that can be detrimental in flexor tendon repairs within the fibro-osseous tunnel is less problematic in extensor tendon repairs.

Available literature and quality of the evidence

- Level IV: 2 case series.
- Level V: 6 cadaver studies.

Compared to the literature concerning flexor tendon repair techniques, there are few studies on extensor tendons. Most of the research is on in vitro cadaveric models, with only two clinical studies with a low level of evidence.

Findings

The studies investigated different suture techniques and their biomechanical performances in tendon shortening, stiffness, and final load to failure as measures of ultimate strength. In 1992, Newport and William showed that for zone VI lacerations the Kleinert-modified Bunnell repair was strongest compared to mattress, figure-of-eight, and modified Kessler techniques.[1] Three years later, a second study concluded that the modified Bunnell and modified Kessler techniques were the strongest for zone IV and were suitable for dynamic or active ROM in short arcs.[2]

In 1997, Howard et al. showed that the augmented Massachusetts General Hospital (MGH) Becker technique had the highest strength when repairing zone VI tendon lacerations compared to the modified Bunnell and modified Krackow–Thomas methods.[3] Similarly, Woo et al. found that the augmented Becker repair had the greatest ultimate strength and significant greater resistance to gaping compared to double figure-of-eight, double modified Kessler, and six-strand double-loop.[4] Chung et al. showed that using the modified Becker with one cross-stitch provided superior mechanical properties compared with two or three cross-stitches.[5]

The running-interlocking horizontal mattress (RIHM) repair in zone VI was shown by Lee et al. to be significantly stiffer, results in less shortening and faster to perform as compared to the augmented MGH Becker and modified Bunnell.[6] The results were further augmented by a retrospective clinical study by Altobelli et al. illustrating the RIHM technique to be strong for immediate controlled active motion.[7]

In the only prospective clinical study, Namazi et al. showed that a roll stitch technique when used in zone V repairs had a superior outcome compared to the modified Kessler core suture technique.[8]

Resolution of clinical scenario

- A multistrand interlocking extensor tendon repair such as a modified Bunnell, augmented Becker, or RIHM is stronger than other suture techniques and is recommended.
- A roll stitch technique may produce less extension lag when compared to a modified Kessler core suture technique.
- Overall quality: low.

Question 2: In patients with fully lacerated extensor tendons, does an early active range of motion (ROM) rehabilitation protocol result in better outcomes when compared to immobilization?

Rationale

There continues to be debate in the literature and clinical community about the most effective postoperative management of primary extensor tendon repair in zones V–VII. Traditional programs statically splint the injury for up to four weeks and then start to mobilize.[9] This can result in joint capsule tightness, adhesions, and/or extensor lag.[10–15]

Rehabilitation protocols for extensor tendon repair have evolved from passive mobilization allowing active flexion and assisted extension to early active motion protocols. Variable study designs with differing results exist, making the ideal protocol controversial.

Clinical comment

In this particular patient, an injury in zone VI significantly increases the risk for adhesions due to the anatomy of the dorsum of the hand. Since the patient is self-employed, the rehabilitation protocol selected that allows for rapid return to normal activities could be a priority for him. That being said, given the multiple tendon involvement and his work requiring complex hand coordination, a protocol that maximizes overall outcome would also be a consideration in protocol choice. A protocol that would allow him to work with assured repair protection with the least demanding home exercise program would likely be preferable to the patient as well.

Available literature and quality of the evidence

The available evidence evaluating different treatment protocols for extensor tendon repairs in multiple zones is summarized in Table 161.1.[11–35] The quality of the studies is varied, ranging from level IV to I evidence, and uses different outcomes measures. There are four meta-analyses that have attempted to synthesize the research to date to provide clarity in clinical decision-making.

RCT: randomized controlled trial

Findings

Talsma et al. performed a meta-analysis integrating early findings from four randomized controlled trials (RCTs) and one cohort study design.[36] They found that early outcomes (four weeks) after immobilization were significantly worse compared to those of either

passive or active early mobilization protocols. While findings suggested that protocols of early passive motion had greater benefit than those with early active motion, there was no significant difference found between the two protocols at three months postoperatively. They concluded that there was no superiority of any of the protocols researched.

Since 2000, a focus on more protocols and those that include early active motion has enhanced the available evidence for review. Hammond et al. completed a meta-analysis including 19 articles with varying levels of evidence from case series to RCTs.[37] They showed that early active motion programs had the lowest complication rate. Immobilization required more tenolyses, and loss of ROM, while dynamic splinting protocols demonstrated potential extensor lag. The variability of protocols, research design, and statistical reporting methods precluded them from comparing treatment outcomes.

Wong et al. completed a systemic review for repairs of zones IV–VIII attempting to more closely examine the orthotic factors affecting treatment protocol and outcomes.[38] Eleven studies were reviewed showing that early active motion protocol is superior to other protocols. However, similar to Hammond et al.,[37] the extensive research variability limited conclusions that could be made as to which protocol and splint was superior.

Ng et al.[39] completed a systemic review of controlled trials of rehabilitation protocols for acute extensor tendon repairs excluding mallet fingers or thumbs. All prospective RCTs or quasi-RCTs comparing rehabilitation programs were included. Five studies were analyzed representing static immobilization, dynamic splinting, and early active mobilization. The results showed that total ROM outcomes for both dynamic mobilization and early active mobilization were essentially the same but were significantly better compared to immobilization. Recovery was also faster in both mobilization protocols resulting in faster recovery. There was no greater utilization of therapy services for any of the protocols and there was only a 3% tendon rupture rate (two in early active mobilization and one in dynamic protocols). The authors identified that, since the outcomes were statistically the same, the rationale to choose one protocol over another would be related to implementation or patient-related factors. They concluded that using early active motion is superior since it is less technical and complicated, making it easier for the therapist and the patient.

Resolution of clinical scenario

- The available meta-analyses suggest that an early active mobilization program is superior to both passive and full immobilization. The combined data support faster recovery time and decreased complication rates.
- The Immediate Relative Active Motion protocol has a number of beneficial factors, as outlined in Svens et al.[34] The yoke splint design has a low profile and allows the patient to work with adequate protection and is referred to as the standard protocol for injuries affecting one or two digits. Specific to this case, the patient has injured all the tendons in zone IV negating the use of this protocol.
- An active protocol, such as in Patil and Koul[35] or Bulstrode et al.,[12] where a simple static splint is used which can be readily worn to protect the nondominant hand at work and a simple block that can be removed to do exercises, may be the solution in this case.

Question 3: In patients with fully lacerated extensor tendons, what preoperative factors contribute to better functional outcomes?

Rationale

Understanding the extent and severity of the injury could help predict the functional outcome of the patient's hand. This can further assist the patient, surgeon, therapist, and employer in directing care, rehabilitation, and return to work.

Clinical comment

The goal of management should be to allow the patient to return to the preinjury state whenever possible. Being able to predict what factors are important for recovery may allow us to better inform patients as well as change any modifiable factors to enhance final outcomes.

Available literature and quality of the evidence

- Level IV: 3 case series, 1 retrospective, and 2 prospective studies.

The search did not yield true outcome studies from prospective trials; however, there were some individual case series.

Findings

In 1990, Newport et al. retrospectively studied 62 patients and showed that 64% of patients with extensor tendon lacerations without associated injuries (fracture, dislocation, joint capsule, or flexor tendon damage) achieved good or excellent results, whereas only 45% of patients with associated injuries did. Injury of tendons in distal zones (I–IV) had significantly poorer results when compared to more proximal zones (V–VIII) with evidence of increased total extensor lag and loss of flexion.[19]

In contrast, in 2007, Carl et al. performed a prospective study of 203 tendon repairs and showed that injuries in zones I, II, IV, and V obtained good or excellent results in the majority of patients, whereas the outcome was significantly worse after tendon repair in zones III and VI.[28] However, they noted a higher frequency of complex injuries with concomitant soft tissue and bony injuries when zones III and VI lacerations were present. Similar to Newport et al., they concluded that recovery of finger function after primary extensor tendon repair depends on the complexity of trauma and the anatomical zone of tendon injury.[19]

Mehdinasab et al. conducted a prospective case series of 72 extensor tendons repaired and found that the best results were obtained in zones III and V, and the worst were in zones I, II, and IV.[40]

Resolution of clinical scenario

- Patients undergoing repair of extensor tendons achieve better functional outcomes when compared to those with associated injuries (e.g. soft tissue or bone fractures).
- The anatomical zone of tendon laceration affects the ultimate functional outcome; however, there are inconsistencies in the literature as to which zones recover best.

Summary of answers

- A multistrand interlocking extensor tendon repair such as a modified Bunnell, augmented Becker or running interlocking horizontal mattress is stronger than other techniques.

- A roll stitch technique may produce a decreased extensor lag when compared to a modified Kessler core suture technique.
- An early active mobilization protocol produces better outcomes provided the repair supports active forces and the specific protocol is matched to the patient's abilities and functional needs.
- Functional outcomes of patients with repaired extensor tendon lacerations are worse when there are other associated complex injuries.
- The anatomical zone of tendon laceration affects the ultimate functional outcome, though inconsistencies exist in the literature as to which zones recover best.

162 Dupuytren's Disease

Lauren Willoughby BMSc MD FRCSC[1], Daniel Waltho MD[1], Marta Karpinski BHSc[2], and Achilleas Thoma MD MSc[1,3]

[1] Division of Plastic Surgery, Department of Surgery, McMaster University, Hamilton, ON, Canada

[2] Faculty of Health Sciences, McMaster University, Hamilton, ON, Canada

Clinical scenario

- A 65-year-old man is referred to you complaining of progressive curling of his ring and little fingers, and inability to straighten his fingers.
- His father had a similar problem, and so does his older brother. He does not report pain, but the contracted fingers make it difficult for him to put on gloves in the wintertime, and to perform many tasks of daily living.
- Examination demonstrates pre-tendinous cords extending from the proximal palm to the middle phalanx of these digits, with inability to passively extend the metacarpophalangeal (MCP) and proximal interphalangeal (PIP) joints. He is able to flex the digits to the palm.

Top three questions

1. In patients with Dupuytren's disease (DD), is collagenase injection superior to open partial palmar fasciectomy in correcting extension deficits?

2. In patients with DD, which treatment – limited palmar fasciectomy or collagenase injection – offers the patient better prognosis in terms of (i) fewer and less severe postprocedural complications and (ii) lower rates of disease recurrence?
3. In patients with DD, which of the following common treatment options results in the lowest disease recurrence rate: collagenase, open fasciectomy, or percutaneous needle fasciotomy (PNF)?

Question 1: In patients with Dupuytren's disease (DD), is collagenase injection superior to open partial palmar fasciectomy in correcting extension deficits?

Rationale

There is no consensus on the most effective treatment for DD. Currently, the two most common treatments for DD are partial palmar fasciectomy and collagenase injection.[1] Fasciectomy involves the surgical excision of the diseased cords, while injections with collagenase from *Clostridium histolyticum* degrade collagen within the cords, allowing them to be subsequently broken by forced digital extension.[2]

Clinical comment

Fasciectomy procedures are more invasive, historically requiring operating room access under general anesthesia, use of a tourniquet, and a more prolonged rehabilitation period. In contrast, collagenase injection has a faster patient recovery time and can be easily performed in an

office or clinic setting without sedation, and requires fewer follow-up appointments. This reduces healthcare costs and improves patient access to treatment.[3,4]

Available literature and quality of the evidence

The highest level of evidence comparing palmar fasciectomy with collagenase is available from four retrospective cohort studies (level III).[4–7]

Findings

Two retrospective cohort studies comparing these treatment modalities found that treatment with limited fasciectomy (LF) is superior in correcting extension deficits.[5,6] In the study by Muppavarapu et al., the researchers analyzed results from 117 patients who underwent treatment with either LF or collagenase injection.[5] After a mean follow-up duration of 14.2 months for the collagenase group, and 16.3 months for the LF group, significantly more joints treated with LF met the primary outcome measure of contracture reduction to 0–5° ($p = 0.0001$). The mean residual contracture for all joints was 28.4° in the collagenase group and 11.8° in the LF group ($p = 0.001$), although the MCP joints generally responded better to both treatments than PIP joints.[5] Similarly, in a retrospective analysis of 37 patients, Wei et al. found greater contracture corrections in patients treated with LF, compared to collagenase.[6] The mean passive extension deficit achieved in joints treated with LF and collagenase was 3.9° and 6.5°, respectively, in MCP joints ($p = 0.02$), and 6.5° and 40.6°, respectively, in PIP joints ($p = 0.0001$).[6]

In contrast, Zhou et al. used a propensity-matched score to compare 66 patients treated with collagenase to 66 patients treated with fasciectomy between 6 and 12 weeks

postoperatively.[7] They found no difference in correction of MCP joint contractures; however, LF was superior in correcting PIP joint contractures (25° vs 15° contracture correction, p = 0.01).[7] In a much smaller study, Naam compared 25 patients treated with collagenase to 21 fasciectomy patients and found post-treatment range of motion (ROM) at the MCP joint was greater for collagenase-treated patients.[4] However, when the researchers compared the mean increase in ROM from baseline, no significant difference was found between the two groups. Overall, the study found no significant differences in post-treatment contractures between the two groups.[4]

Resolution of clinical scenario

- Currently, available evidence suggests that LF is equal, or superior, to collagenase in correcting extension deficits.
- LF is superior to collagenase in correcting PIP joint deformities.
- Therefore, your patient should be advised that LF may be better than collagenase to correct their extension deficits, especially at the PIP joint.

Question 2: In patients with DD, which treatment – limited palmar fasciectomy or collagenase injection – offers the patient better prognosis in terms of (i) fewer and less severe postprocedural complications and (ii) lower rates of disease recurrence?

Rationale

Safety is paramount when deciding upon an appropriate treatment, particularly when a variety of treatment modalities exist. When deciding between comparably efficacious treatments, the physician should aim to choose the intervention that is safest. In DD patients, disease recurrence is a common post-treatment event, and is to be expected as currently available treatments do not definitively cure the condition. The surgeon should consider the intervention that will reduce disease recurrence, or prolong the time to re-contracture. Comprehensive knowledge backed by high-quality evidence is essential when counseling patients.

Clinical comment

Complications range from relatively minor and easily treated, such as skin splitting and local infection, to more severe and difficult to treat, such as tendon rupture, digital nerve injuries, and joint stiffness. Reported recurrence rates also range substantially from 12 to 100%, and vary depending on the treatment, length of follow-up, and the authors' definition of recurrence.[8] Ideally, the treatment of choice should be both safe, and minimize the need for repeat treatment.

Available literature and quality of the evidence

The highest-quality evidence comparing adverse events in LF and collagenase includes four retrospective cohort studies (level III).[4–7] Additional evidence on safety of collagenase includes a recent randomized controlled trial (RCT) (level I), and review of prospective trials (level II).[9,10] The highest-quality evidence assessing recurrence in both LF and collagenase comes from a retrospective cohort study (level III).[4] Additionally, two randomized,

placebo-controlled trials[11],[12] (level I) and one high-quality prospective cohort study[13] (level II) assess recurrence in collagenase-treated patients.

Findings

Safety

Complications following treatment with collagenase injection are common, but are usually less severe than those following LF. In a retrospective cohort study by Zhou et al., serious adverse events were found to be much more common after LF compared to collagenase injection ($p = 0.042$).[7] Serious complications such as nerve injury and tenosynovitis were found in patients treated with LF, and no such events were reported in the collagenase group. Additionally, Muppavarapu et al. reported one case of digital neurovascular injury and two cases of deep wound infection in LF-treated patients, but no such serious complications following collagenase treatment.[5] In the studies by Naam and Wei et al. severe complications were absent in both treatment groups.[4],[6]

The relative incidence of mild complications between the two treatments in unclear based on currently available literature.[4]–[7] Wei et al. reported similar minor complications rates of 45 and 42% in the collagenase and LF treatment groups, respectively;[6] however, Muppavarapu et al. found that over 70% of collagenase-treated patients experienced a mild adverse event.[5] Common minor complications of collagenase treatment include peripheral edema, mild contusion, extremity pain, hematoma, and skin tears. Minor complications following LF include paresthesia, wound dehiscence, neurapraxia, and hematoma.[4]–[7]

The safety profile of collagenase has also been assessed in several prospective RCTs. Badalamente et al. analyzed the four major clinical trials for collagenase injection (CORD I and II and JOINT I and II) and found serious adverse events in 0.5% of cases, including two cases of tendon rupture.[10] The most common complications encountered in these studies included peripheral edema (58%) and contusion (38%). One RCT found that the most common adverse events associated with collagenase injections were contusions, extremity pain, and localized swelling, with contusions and swelling being dose-dependent.[9] There were no serious adverse events reported in this trial.

Recurrence

Limited evidence is available comparing recurrence rates of collagenase injections and fasciectomy. Naam et al. found no instances of disease recurrence (defined as an increase of ≥20° from the point of correction) in either group, after two years.[4] However, smaller re-contractures were reported in 10 patients. A recurrence in contracture of 15° from the point of correction was reported in one fasciectomy patient, and recurrences of 10° were found in five collagenase patients and four fasciectomy patients.[4]

In placebo-controlled RCTs evaluating collagenase injections, patients who had a successful correction of contracture to within 0 to 5° of full extension had no disease recurrence (defined as ≥20° extension deficit) at 90 days and one year following treatment.[11],[12] However, in an observational study with a five-year follow-up, 47% of successfully treated joints had recurrence (39% occurred in MCP joints and 66% in PIP joints).[13]

Resolution of clinical scenario

- Collagenase injections are safe, and complications appear to be primarily nonsevere.
- The patient should be counseled that risk of serious adverse events is lower after treatment with collagenase injection.
- There is currently insufficient evidence to conclude which of the two approaches (collagenase or fasciectomy) is associated with the lower rates of disease recurrence.
- The patient should be counseled that the disease is most likely to recur at their PIP joint.

During a discussion with your patient, he reveals that he is most concerned about *recurrence* of his DD. If possible, he asks to receive the intervention that will most successfully prevent recurrence. In light of the patient's priorities, and lack of clear evidence about relative recurrence rates between collagenase and fasciectomy, you decide to additionally consider PNF to determine which intervention offers the lowest recurrence rate. PNF is another commonly performed treatment for DD, and involves division of the diseased cords with a hypodermic needle.[1]

Question 3: In patients with DD, which of the following common treatment options results in the lowest disease recurrence rate: collagenase, open fasciectomy, or percutaneous needle fasciotomy (PNF)?

Rationale

The concerns of your patient are not unusual. In one study, patients reported recurrence rate to be the most important factor they considered when choosing a treatment for their DD.[14]

Clinical comment

Many researchers theorize that surgical excision of Dupuytren's cords is most effective at reducing disease recurrence. This is because surgical intervention removes the diseased tissue from the hand, while the cords remain in the hand after less invasive treatments such as PNF and collagenase injections.[15]

Available literature and quality of the evidence

The highest level of evidence includes studies of varying methodological quality comparing open fasciectomy, PNF, and collagenase. One long-term follow-up of patients from a previous RCT compares fasciectomy and PNF (level II).[16] Another high-quality RCT compares fasciectomy to a modified PNF technique (level I).[17] Collagenase and PNF are compared in two RCTs (level I).[18],[19] The highest level of evidence comparing recurrence rates in collagenase and fasciectomy is a retrospective cohort study (level III).[4]

Findings

Long-term data from an RCT comparing LF and PNF reported significantly higher recurrence after five years in the PNF group (20.9% recurrence following LF vs 84.9% with PNF, $p < 0.001$; 95% confidence interval [CI]: 1.597–2.628).[16] In both groups, recurrence rates were significantly lower in older patients ($p = 0.005$). Kan et al. used a modification of the PNF technique by adding autologous fat graft and compared this to LF in an RCT.[17] Recurrence rate in patients treated with this technique was

not significantly different from those treated with LF (p = 0.107), although subjects were only followed for one year.

Recurrence rates of collagenase injections and PNF were not found to be significantly different in two level I RCTs. In the RCT comparing PNF and collagenase in DD affecting the MCP joint, only one patient in each group developed recurrence after one year.[19] In PIP joints, recurrence rate was 83% (95% CI: 68–99) in the collagenase group, and 68% (95% CI: 46–91) in the PNF group after two years (p = 0.25).[18] In a study comparing recurrence rates in patients undergoing fasciectomy or collagenase injection, no instances of recurrence were reported in either group two years after treatment.[4]

Resolution of clinical scenario

- The patient should be counseled that treatment with fasciectomy has a lower recurrence rate than PNF. If they prefer a less invasive treatment, there is no significant difference in recurrence rates between PNF and collagenase injection.
- Although early data show a combined PNF and lipofilling treatment has a disease recurrence rate similar to fasciectomy, long-term recurrence rates are unknown.

Summary of answers

- Based on available evidence: LF is superior to PNF and collagenase in improving contractures in DD and has the lowest rate of recurrence.
- Patients can return to normal activities more quickly with less-invasive procedures, such as PNF or collagenase.

[1] Michigan Medicine, Ann Arbor, MI, USA

[2] Plastic and Reconstructive Surgery, Johns Hopkins Medicine, Baltimore, MD, USA

[3] Section of Plastic Surgery, Department of Surgery, University of Michigan, Ann Arbor, MI, USA

Clinical scenario

- A 58-year-old Caucasian woman reports a several-month history of generalized fatigue and “stiffness” of both hands that lasts through the morning.
- She notices painful swelling of the joints in her fingers.
- She describes throbbing pain that she rates as an 8 on a Visual Analog Scale (VAS) of 0 to 10.

Top three questions

1. In rheumatoid arthritis (RA) patients, does small joint synovectomy improve pain and joint swelling compared to nonsurgical management?
2. In RA patients, does flexor tenosynovectomy improve extensor lag and pain compared to nonsurgical management?
3. In RA patients, does metacarpophalangeal (MCP) joint arthroplasty improve hand function compared to nonsurgical management?

Question 1: In rheumatoid arthritis (RA) patients, does small joint synovectomy improve pain and joint swelling compared to nonsurgical management?

Rationale

Synovial proliferation in the small joints of the hand causes joint tenderness, swelling, and limited range of motion, and to a considerable degree the synovitis also propagates progressive joint destruction. Hand surgeons use open and arthroscopic techniques to remove the infiltrative synovium to ameliorate symptoms, improve function, and halt destructive synovitis.

Clinical comment

Swelling of a patient's joints could be an indication of proliferative synovitis. Small joint synovectomy can have a role in managing patients with persistent pain after six months of medical therapy, provided they show no joint cartilage and bone destruction.

Available literature and quality of the evidence

Level I: 2 randomized controlled trials (RCTs).

Findings

In a study conducted by the Arthritis and Rheumatism Council and British Orthopaedic Association, patients were randomized to synovectomy (n = 13 patients, 41 MCP joints) or to nonsurgical management (n = 9 patients, 28 MCP joints).[1] The patients were examined after three years. There were no significant differences between the

groups in terms of pain (p = 0.32), range of motion (p = 0.13), swelling (p = 0.40), tenderness (p = 0.33), or grip strength (p = 0.88). All of the patients who underwent synovectomy said that they would agree to the surgery again.

Thompson et al. randomized RA patients affected by synovitis into two groups: MCP synovectomy or a nonsurgical splinted group.[2] At the two-year follow-up, there were 45 patients in the surgical group and 42 patients in the nonsurgical group. Results demonstrated significantly improved grip, palmar pinch, and joint tenderness in the surgical group compared to the nonsurgical group (p values not provided). There was no significant difference between the groups in joint swelling. Subjective assessment by the patient in terms of pain, functional ability, grip strength, and appearance were higher in the surgical group. In terms of radiographs, the authors stated that “all groups deteriorated to an approximately equal degree in respect of the MCP joints.”

Resolution of clinical scenario

- Performing small joint synovectomy, when there is persistent pain and functional limitation in the absence of joint destruction, may provide symptomatic relief of limited duration.

Question 2: In RA patients, does flexor tenosynovectomy improve extensor lag and pain compared to nonsurgical management?

Rationale

The prevalence of flexor tenosynovitis in rheumatoid disease has been reported to be between 42 and 55%.[3,4] Current thought is that patients can achieve considerable improvement in functional ability with flexor tenosynovectomy.

Clinical comment

When a patient with RA has difficulty with active digital flexion, it is important to determine whether the problem is in the flexor tendons or in the joints. If the problem lies in the flexor tendons, the patient will have full passive flexion of the joint, but the active flexion is limited because swelling in the flexor tendons restricts tendon excursion. If the problem is isolated to the joints, the patient will have limited joint motion, both in passive and active motion. Hypertrophic synovial infiltration within the flexor tendon sheath presents with bulges along the tendon sheath, and these bulges often occur at the weaker, stretched cruciform pulleys.[5] A plain radiograph should be obtained to rule out concomitant proximal interphalangeal (PIP) joint disease.

Available literature and quality of the evidence

Level IV: 3 retrospective case reviews.

Findings

Jackson and Paton performed flexor tenosynovectomy in 21 patients (36 fingers) over a period of four years and assessed their results 6 to 37 months postoperatively.[6] They developed a motion scoring system that incorporated the ability to flex combined with residual fixed flexion deformities at the MP and PIP joints. It ranged from excellent (full movement with no extensor lag) to good (extensor lag at the MP and PIP joints <30°, vertical distance from fingertip to palm <2 cm) to fair (extensor lag

at the MP and PIP joints <30°, vertical distance from fingertip to palm 2–4 cm) to poor (extensor lag at the MP and PIP joints >30° or vertical distance from fingertip to palm >4 cm). Using this scale, 44% had excellent results, 31% good, 11% fair, and 14% poor.

In a retrospective case study by Tolat et al., 43 RA patients (49 hands, 424 flexor tendons) were assessed at a mean of five years and seven months after tenosynovectomy and tenolysis.[7] All patients improved in pain score from a mean preoperative score of 7.5 (fair) to a mean postoperative score of 0.9 (excellent), assessed via VAS of 0 to 10. The mean postoperative satisfaction score was 2.2 (excellent), also assessed via VAS of 0 to 10. Using the Jackson and Paton scoring system, 31% of patients had excellent flexion, 14% had good, 22% had fair and 33% had poor flexion. There was a complication rate of 18% (nine hands) including three minor infections and six categorized as major complications (four cases of recurrence with formation of further adhesion, one postoperative tendon rupture, and one intraoperative fracture of the proximal phalanx).

Wheen et al. reviewed the results of 15 patients (18 hands, 61 fingers) who underwent digital flexor tenosynovectomy at a mean of four years prior.[8] Using slightly modified Jackson and Paton criteria, they found that 31% had excellent flexion, 36% good, 21% fair, and 11% poor. The active flexion deficit, measured in centimeters, improved significantly from 4.3 (3.8–4.7) preoperatively to 2.1 (1.8–2.6) at final assessment ($p < 0.01$). Four patients (22%) reported that their function was completely restored, 13 (72%) that it was improved, and one (6%) that there was no change. Nineteen fingers (31%) showed signs of recurrence or underwent re-operation.

Resolution of clinical scenario

- Flexor tenosynovectomy can provide functional benefit for patients with impairment of active flexion caused by synovitis.
- Patients should be counseled regarding the possibility of recurrence, which has been shown to occur at a rate of 10–31% approximately five years after surgery.

Question 3: In RA patients, does metacarpophalangeal (MCP) joint arthroplasty improve hand function compared to nonsurgical management?

Rationale

Owing to the progressive nature of RA, joint destruction can reach a stage in which a surgical salvage procedure such as MCP joint arthroplasty is necessary.

Clinical comment

The MCP joint is most commonly affected in RA. End-stage destruction of these joints can render patients functionally impaired with unappealing appearance of their hands. The course of MCP joint disease in RA is caused by synovial infiltration and subsequent attenuation of joint support structures. Radial and ulnar sagittal bands that stabilize the extensor tendon over the MCP joint are stretched by synovitis. The radial band is further weakened by the gripping motion involved in daily activities that causes progressive ulnar displacement of extensor tendons characteristic of rheumatoid hands. As a result, ulnar lateral bands contract to further accentuate the drift of the extensor tendons. Furthermore, the proximal phalanx itself

may become volarly subluxed. These structural changes adversely affect the functional ability of the hand and cause cosmetic concerns for patients. This degree of joint destruction is a clear indication for joint replacement.

Available literature and quality of the evidence

- Level I: 1 RCT.
- Level II: 1 prospective cohort study.

Findings

A clinical trial assessed 33 patients (40 hands) who were randomized to receive Swanson MCP joint implants (n = 20 hands) or NeuFlex MCP joint implants (n = 20 hands).[9] The NeuFlex implant is preflexed to 30° to enhance joint flexion and diminish peak stresses.[10] Patients were assessed preoperatively and 12 months postoperatively. Preoperative active range of motion did not differ between the groups. At 12 months, active flexion was significantly better in the NeuFlex group for all four digits (all $p < 0.01$), but there was no difference in active extension. Both groups significantly improved from their preoperative values in terms of extension, flexion, arc of motion, and ulnar deviation (all $p < 0.001$). Patients were also assessed with the Michigan Hand Questionnaire (MHQ), which is a hand-specific, patient-reported questionnaire that measures function, activities of daily living, work, pain, aesthetics, and satisfaction.[11],[12] Patients in both groups showed significant improvement in all domains from preoperative values. Patients in the Swanson groups scored significantly better postoperatively in the Function domain ($p = 0.03$) and the Aesthetics domain ($p = 0.03$) compared to the NeuFlex group. There were no complications in either group. The authors concluded that both groups obtained satisfactory clinical improvement and the greater flexion in

the NeuFlex group was not accompanied by greater function as reported by patients via the MHQ.

In a prospective, multicenter cohort study by Chung et al., RA patients with severe MCP joint deformity elected to participate in a surgical group that underwent silicone metacarpophalangeal joint arthroplasty (SMPA) using the Swanson implant or in a nonsurgical group that was managed medically (non-SMPA).[13] Follow-up was performed at three, five, and seven years and included 23 SMPA and 52 non-SMPA patients at the final follow-up. The main outcome measure was the MHQ. Over the seven years of follow-up, although the SMPA group scored worse on the MHQ than the non-SMPA group, the SMPA group showed large improvements from their preoperative scores that were maintained over time. Grip strength did not improve postoperatively in the SMPA group. Ulnar drift, extensor lag, and MCP joint arc of motion were all worse in the SMPA groups at baseline ($p < 0.001$ for extensor lag and arc of motion) compared to the non-SMPA group, but consistently showed better results for the SMPA group at each follow-up. There was one mild adverse event (Kirschner wire infection) and three moderate implant-specific adverse events that all required re-operation (one due to ulnar deviation, one due to implant dislocation, and one due to MCP joint sepsis). The majority of implants did not show signs of fracture when assessed via radiographs.

Resolution of clinical scenario

- MCP joint arthroplasty can deliver improved hand function, appearance, and ability to perform activities of daily living.
- Functional and aesthetic improvements from MCP joint arthroplasty are maintained over time, with low rates of implant fracture.

Summary of answers

- In patients with persistent pain and functional limitation from small joint synovitis, synovectomy can provide short-term symptomatic relief.
- Flexor tenosynovectomy can effectively improve flexion hampered by synovial proliferation along the tendon sheath. Due to the progressive nature of RA, re-operation may be required.
- MCP joint arthroplasty provides long-term improvement in subjective outcomes and should be considered in end-stage destruction of MCP joints.

[2] Michael G. DeGroote School of Medicine, McMaster University, Hamilton, ON, Canada

[3] Division of Plastic Surgery, Department of Surgery, McMaster University, Hamilton, ON, Canada

Clinical scenario

- You are paged to the Emergency Department to see a 20-year-old male carpenter with a traumatic amputation of the index and long digits of his dominant hand in a table saw accident. The injury occurred at the level of the proximal phalanx.
- The injury occurred three hours prior to Emergency Department presentation. The amputated digits were placed on ice following the injury. Hemostasis was achieved through direct pressure to the area of injury.
- Radiographs of the stump and amputated digits show clean amputations.

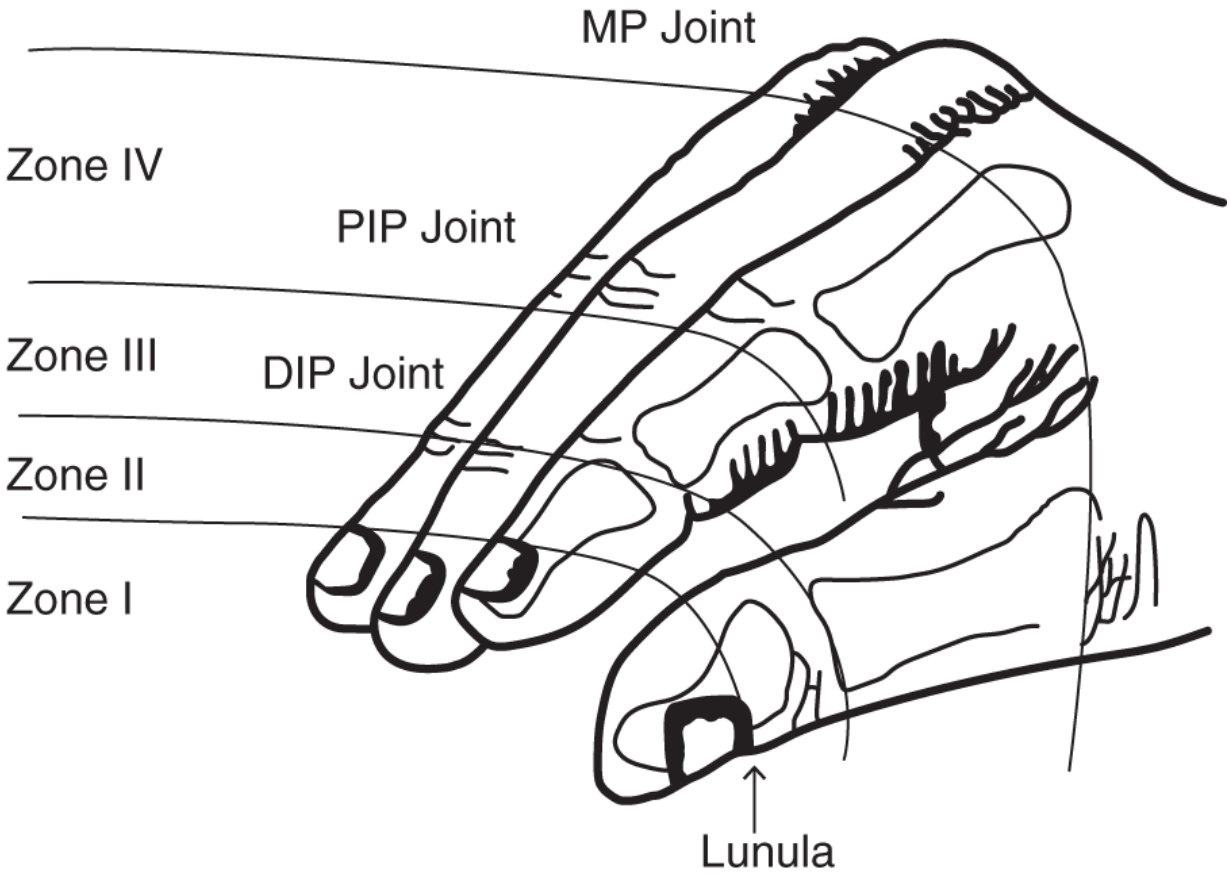

Figure 164.1 Tamai classification of zones in digital amputation: zone I (distal to lunula), zone II (proximal to lunula, distal to DIP joint), zone III (proximal to DIP joint, distal to insertion of FDS tendon), and zone IV (proximal to FDS tendon insertion, distal to MP joint). DIP, distal interphalangeal; PIP, proximal interphalangeal; MP, metacarpophalangeal. Source: Lee et al.[4]

Top three questions

1. In patients requiring replantation, how many veins should be anastomosed when performing digital replantation to achieve optimal outcomes?
2. In patients undergoing replantation, does prophylactic anticoagulation and/or do antithrombotic agents

ordered postoperatively prevent thrombosis compared to placebo or control?

3. In patients who have undergone replantation, does early range of motion (ROM), compared to delayed ROM, restore total ROM more effectively?

Question 1: In patients requiring replantation, how many veins should be anastomosed when performing digital replantation to achieve optimal outcomes?

Rationale

In 1978, Tamai et al. reported that two veins should be anastomosed for each artery repaired during digital replantation.[1] In contemporary practice, there exists little consensus among microsurgeons regarding the optimal number of veins that must be repaired when performing digital replantation surgery (Table 164.1).[2]

Clinical comment

Though bone, tendon, and nerve repair correlates with long-term functional outcomes, venous outflow remains the most important factor influencing replantation success in the immediate postoperative period.[2],[3] While a surgeon may not have a choice on the matter if only one or multiple veins are not present, the question is: what if multiple veins exist? How many should one repair per digit? While it is considered to be favorable to anastomose as many veins as possible, a balance must be achieved between ischemia time, survival rate, and overall operation time.[4]

Available literature and quality of the evidence

At present, the highest-quality evidence for venous anastomosis in the setting of digital replantation consists of retrospective cohort trials. Seven retrospective cohort studies were identified consisting of 1317 replanted digits (level III evidence).[2,4–9]

Findings

A retrospective cohort study by Ryu et al. assessed the relationship between the number of venous anastomoses and replantation survival in 143 cases.[5] No significant correlation was identified between the number of veins anastomosed and replantation survival (p = 0.689).

Efanov et al. reviewed 101 digital replantations and concluded that single vein repair corresponded to an increase in replantation failure when compared to two vein anastomoses (p = 0.032; risk ratio [RR] = 1.27; 95% confidence interval [CI]: 0.991–1.343).[2] A significant increase in replantation failure was also demonstrated in cases of no vein repair versus two vein anastomoses (p = 0.008; RR, 1.49; 95% CI: 1.026–1.735). However, no significant difference was identified between one vein versus no vein anastomosis (p = 0.502; RR = 1.179; 95% CI: 0.834–2.102].

Huang and Yeong (n = 31) as well as Neto et al. (n = 50) failed to reach statistical significance when comparing one vein versus no vein anastomosis (p >0.05) and one vein versus multiple vein anastomosis (p = 0.105), respectively.[6,7]

Lee et al. and Matsuda et al. (n = 847 total digital replantations) provided recommendations for optimal venous anastomosis at each Tamai amputation zone (Figure 164.1).[4,8]

Zone 1

- Lee et al. (n = 162) recommended the repair of at least one vein. The authors demonstrated statistically significant survival in digits with one repaired vein versus no vein repair (p = 0.008).[4]
- Matsuda et al. (n = 21) showed no difference in survival with no vein versus one vein repair at this level.[8]

Zone 2

- Lee et al. (n = 203) recommended the repair of at least as many veins as arteries and demonstrated that vein anastomosis versus no vein repair resulted in a significant increase in replant survival (p = 0.001).[4]
- Matsuda et al. (n = 46) recommended the repair of at least one vein and demonstrated a significant difference in survival between no vein versus one vein repair.[8]

Zone 3

- Lee et al. (n = 182) recommended that at least two veins be anastomosed, and demonstrated statistical significance when they compared venous anastomosis versus no anastomosis (p = 0.025).[4]
- Matsuda et al. (n = 63) demonstrated statistical significance between one vein versus two vein anastomoses and therefore recommended that at least two veins be repaired at this level.[8]
- A study by Chaivanichsiri and Rattanasrithong (n = 61) reported a statistically significant benefit by repairing at least one vein at Tamai zone 3, but reported no

significance when more than one vein was anastomosed.[9]

Zone 4

- Lee at al. (n = 84) demonstrated a significant replantation survival benefit with venous repair (p = 0.001) and recommended an equal ratio of artery to vein anastomosis.[4]
- Matsuda et al. (n = 86) reported a significant increase in survival when two or more veins were repaired versus no repair; however, there was no significant difference between one vein anastomosis versus two or more veins. Thus, Matsuda et al. recommended that only one vein be repaired at this level.[8]

Table 164.1 Number of anastomosed veins and associated survival rates (%). Source: Modified from Efanov et al.[2], Lee et al.[4], Ryu et al.[5], Matsuda et al.[8], Chaivanichsiri and Rattanasrithong[9]

No. of veins repaired	None	One	Two or more
Zone I			
Lee et al.[4]	73.2% (104/142)	90.0% (18/20)	N/A
Matsuda et al.[8]	85.7% (12/14)	66.7% (4/6)	100.0% (1/1)
Efanov et al.[2]	100.0% (5/5)	87.5% (7/8)	100.0% (1/1)
Ryu et al.[5]	94.2% (65/69)	93.0% (40/43)	96.8% (30/31)
Zone II			
Lee et al.[4]	49.0% (25/51)	80.8% (101/125)	92.6% (25/27)
Matsuda et al.[8]	38.5% (5/13)	81.0% (17/21)	83.3% (10/12)
Efanov et al.[2]	N/A	75.0% (3/4)	100.0% (3/3)
Zone III			
Lee et al.[4]	47.6% (10/21)	76.5% (78/102)	88.1% (52/59)
Matsuda et al.[8]	0.0% (0/1)	59.1% (13/22)	87.5% (35/40)
Efanov et al.[2]	N/A	100.0% (7/7)	100.0% (8/8)

No. of veins repaired	None	One	Two or more
Chaivanichsiri and Rattanasrithong[9]	40.0% (2/5)	84.4% (27/32)	91.7% (22/24)
Zone IV			
Lee et al.[4]	N/A	74.5% (35/47)	100.0% (37/37)
Matsuda et al.[8]	33.3% (1/3)	84.2% (16/19)	89.1% (57/64)
Efanov et al.[2]	28.6% (2/7)	67.5% 27/40	90.9% (10/11)

( ), number of replanted digits

Resolution of clinical scenario

Based on the cumulative evidence shown above, for this patient we recommend the following:

- While literature reports vary, a greater number of venous anastomoses tend to confer a higher survival rate in cases of digital replantation.
- Recommendations regarding the optimal number of vessel anastomoses vary at each Tamai amputation level.
- As this likely represents a zone IV amputation, we would attempt to repair at least two or more veins for each digital artery.

Question 2: In patients undergoing replantation, does prophylactic anticoagulation and/or do antithrombotic agents ordered postoperatively prevent thrombosis compared to placebo or control?

Rationale

Survival of amputated digits following replantation has been reported at 70–90%, with arterial and venous thrombosis considered the leading causes of failure.[10] At present, there is a lack of consensus regarding the effectiveness and duration of postoperative anticoagulation/antithrombotic therapy with substantial variability in surgeon practice.[11]

Clinical comment

Theoretically, anticoagulant/antithrombotic therapy has the potential to improve outcomes following digital replantation by inhibiting thrombus formation.[10]

Available literature and quality of the evidence

There is a paucity of evidence addressing the topic of anticoagulation following digital replantation. The highest level of evidence evaluating outcomes of antithrombotic therapy following digital replantation includes one prospective cohort study (level II)[10] and two retrospective cohort studies (level III).[12],[13] Further evidence comparing the effectiveness of low-molecular-weight heparin (LMWH) versus unfractionated heparin (UFH) consists of one Cochrane systematic review of randomized controlled trials (RCTs) (level I).[14]

Findings

A prospective cohort study (n = 477) assessed the role of antithrombotic therapy (dextran with LMWH versus dextran with prostaglandin E1, vs no antithrombotic therapy) in the setting of papaverine administration. Dextran with LMWH (odds ratio [OR] = 0.93; 95% CI: 0.4–2.2; p = 0.85) and dextran with prostaglandin E1 (OR = 1.09; 95% CI: 0.5–2.6; p = 0.83) demonstrated no advantage when compared to no antithrombotic therapy.[10]

In a retrospective cohort study, Nikolis et al. (n = 281) concluded that routine use or no use of intravenous (IV) heparin therapy with acetylsalicylic acid (ASA) following digital replantation did not significantly impact the final outcome of replantation success in two patient cohorts (cohort 1, n = 175, p = 0.275; cohort 2, n = 106, p = 0.440].[12]

In another retrospective cohort study, Lee et al. (n = 61) examined the success rate of artery-only distal digital replantation (Tamai zone I and II) with controlled continuous heparinization (CCH) when compared to intermittent bolus heparinization (IBH).[13] They concluded that the CCH group had a statistically significant higher replantation success rate when compared to IBH (91.17% vs 59.25%, p = 0.032).[13]

A Cochrane systematic review of RCTs by Chen et al. assessed whether subcutaneous LMWH improved salvage rates following digital replantation secondary to traumatic amputation.[14] The review identified two RCTs involving 122 replanted digits, both comparing the efficacy and safety of LMWH versus UFH; no RCTs were found to compare LMWH to placebo or other forms of anticoagulation. Replantation success did not differ between the LMWH and UFH groups (Trial 1: RR = 1.00; 95% CI: 0.89–1.13; Trial 2:

RR = 1.03; 95% CI: 0.87–1.22). The reported incidence of postoperative arterial thrombosis and venous insufficiency was not significantly different between groups (LMWH: RR = 1.08; 95% CI: 0.16–7.10; UFH: RR = 0.81; 95% CI: 0.20–3.27).[14] The study authors concluded that there was no difference in the success of replantation with LMWH versus UFH; an increased bleeding tendency was noted with UFH, although this was not deemed statistically significant.

Resolution of clinical scenario

Based on the cumulative evidence shown above, for this patient we recommend the following:

- There is limited evidence to demonstrate the effectiveness of postoperative prophylactic antithrombotic therapy following digital replantation.
- Heparinization is recommended as confidence intervals seem to have more weight on the beneficial side despite nonstatistically significant p values.
- In cases where postoperative heparinization is used, higher replantation success has been shown when CCH is used compared to IBH in distal digit amputation.
- Replantation success does not differ between subcutaneous LMWH and UFH.
- Based on the above evidence we should implement CCH postoperatively.

Question 3: In patients who have undergone replantation, does early range of motion (ROM), compared to delayed ROM, restore total ROM more effectively?

Rationale

For patients, finger amputation is associated with emotional, social, and physical trauma. The primary goal for patients following successful digit replantation is to regain use of function and return to regular activities.[15]

Clinical comment

Extensor and flexor tendon ROM requirements in replantation can be conflicting. Despite this rehabilitation following digital replantation has been associated with satisfactory long-term functional outcomes. At present, therapists and surgeons recommend early mobilization to improve function in the postoperative period.[15],[16]

Available literature and quality of the evidence

The highest level of evidence to address this topic is of variable methodological quality. Two retrospective cohort studies assessed functional outcomes of rehabilitation following successful replantation (level III).[15],[16] Three studies presented rehabilitation protocols and described the biomechanical implications of early active motion in cases of digital replantation (level V).[17]–[19]

Findings

A retrospective observational study by Ross et al. assessed total active movement (TAM) outcomes in 103 digital

replantations.[16] Patients that commenced therapy prior to day 14 of injury had a statistically significant improvement in TAM when compared to patients whose therapy commenced after day 14 ($p = 0.0001$); this corresponded to TAM values of 165 versus 121° at 25 months' follow-up, respectively.

A retrospective cohort study by Ugurlar et al. assessed the functional results of rehabilitation following digital replantation in 160 amputated digits.[15] In all cases, rehabilitation was started in the fourth to eighth postoperative week and continued until the 24th week. According to Tamai criteria outcomes were excellent in 36 (26.7%) patients, good in 54 (40%) patients, average in 27 (20%) patients, and poor in 18 (13.3%) patients.[20] The authors concluded that postoperative rehabilitation should be initiated as soon as possible after surgery.

Chan and LaStayo, Scheker and Hodges, and Silverman and Gordon presented mechanism-based reasoning for early protective motion (EPM) programs following digital replantation.[17],[18],[20] EPM is initiated at postinjury day five and attempts to reintegrate the patient into their work environment at 3–6 months.

Resolution of clinical scenario

Based on the cumulative evidence shown above, for this patient we recommend the following:

- Postoperative rehabilitation should be started for this patient within 14 days of injury as it is associated with a statistically significant improvement in TAM.
- The goal of rehabilitation will be to reintegrate this patient to their work environment at 3–6 months postoperatively.

Summary of answers

- A greater number of venous anastomoses confer a higher survival rate in cases of digital replantation, and this is more important as the level of amputation becomes more proximal.
- There is limited evidence supporting the use of prophylactic antithrombotic therapy following digital replantation.
- In cases of distal digital amputation, CCH has a higher replantation success rate than IBH.
- Postoperative rehabilitation started within 14 days of injury is associated with a statistically significant increase in TAM.

165 Ulnar Neuropathy

Christopher Doherty MD MPH FRCSC[1], Thomas A. Miller MD FRCPC[2], and Douglas C. Ross MD MEd FRCSC[1]

[1] Roth-McFarlane Hand & Upper Limb Centre, Division of Plastic Surgery, Western University, London, ON, Canada

[2] Department of Physical Medicine & Rehabilitation, Western University, London, ON, Canada

Clinical scenario

- A 53-year-old man presents with an eight-month history of progressive numbness in the ulnar nerve distribution and weakness with fine motor tasks.
- Examination demonstrates abnormal sensation in the small and half the ring fingers; as well as the dorsal sensory branch. Ulnar innervated intrinsic function is weak, graded Medical Research Council (MRC) 3 out of 5 and evidence of muscle wasting.
- Nerve conduction study and electromyographic (EMG) findings show isolated compressive neuropathy at the elbow with evidence of axonal loss and denervation to the first dorsal interossei and abductor digiti quinti.

Top three questions

1. In patients with ulnar neuropathy, what are the indications for surgical management versus nonoperative management?

2. In patients with ulnar nerve distribution symptoms, what is the most effective surgical technique for managing compressive ulnar neuropathy at the elbow?
3. In patients with severe ulnar neuropathy, are there adjunct procedures to augment intrinsic muscle dysfunction?

Question 1: In patients with ulnar neuropathy, what are the indications for surgical management versus nonoperative management?

Rationale

The decision to manage cubital tunnel syndrome nonoperatively versus surgically is based on clinical and electrodiagnostic characteristics. The distance between site of compression at the elbow and motor targets can result in variable recovery of musculature after surgical release given the time it takes for axons to recover down the length of the nerve.[1] In some circumstances, attempting nonoperative treatment may delay nerve recovery and it is prudent to recognize when prompt release is required.

Clinical comment

McGowan grade 3 ulnar neuropathy presents the difficult challenge of improving patient sensory symptoms and reinnervating the ulnar-innervated intrinsic musculature. Neuromuscular junction atrophy is an important consideration as the nerve recovers after release. Given the distance from the elbow to the hand, and the rate at which axons recover after release, the recovery of intrinsic function can be variable resulting in modest patient

outcomes.[1],[2] Failure to intervene surgically may result in delay of recovery of intrinsic musculature and permanent dysfunction.

Available literature and quality of the evidence

Nonoperative management of cubital tunnel syndrome includes nerve gliding exercises, splinting the elbow in an extended position, padding over the cubital tunnel, and avoidance of pressure over the nerve and elbow flexion. Currently, there are no randomized controlled trials (RCTs) comparing conservative versus surgical management.[3] One RCT exists comparing two forms of conservative treatment demonstrating reasonable effectiveness for mild to moderate disease.[4] Patients in this study with muscle dysfunction (McGowan 3) showed no improvement in muscle strength with conservative measures. This study is level I evidence; however, it only compares two forms of conservative management instead of conservative versus surgical management.

In a prospective study by Dellon et al., 128 patients with various degrees of cubital tunnel syndrome were followed nonoperatively with an average follow-up of 58 months.[5] A requirement for surgical intervention defined failure of conservative management. In general, patients with mild symptoms required surgical management less often versus moderate to severe disease. In patients experiencing symptoms only with no objective findings, nonoperative measures were successful 89% of the time. Those with abnormal sensorimotor thresholds were successful 67% and only 38% with abnormal sensorimotor density. This is level IV evidence.

Dellon et al. also published a review of the literature analyzing all work evaluating conservative and surgical management prior to 1988, which included more than 2000

patients.[6] They concluded that, in mild disease, conservative management produced excellent sensory results in an estimated 50% of patients compared to 90% using operative techniques. In moderate to severe disease, Dellon et al. concluded that nonoperative measures were “completely unsuccessful” and that surgical management is indicated.[6] This is level IV evidence.

Eisen and Danon also produced level IV evidence following 30 patients over 22 months. This study supports nonoperative measures in patients with mild disease.[7] They defined electrodiagnostic parameters suggesting operative management is required in those with motor conduction velocity less than 41 m/s across the elbow and a motor latency from above elbow greater than 10.2 ms.

Overall, quality of evidence is weak with one RCT and none comparing conservative to surgical management. Two level IV studies exist examining indications for conservative versus operative management.

Findings

Conservative measures have been shown to be effective in patients with mild and possibly moderate disease (McGowan grade 1 or 2) with no evidence of intrinsic muscle abnormality. Failure to improve symptoms in mild to moderate disease is an indication for surgical management. Surgical management should be considered in severe disease – McGowan grade 3. Electrodiagnostic studies with motor conduction velocity less than 41 m/s and motor latency greater than 10.2 ms is also an indication for surgical management. The decision to offer surgical management should also consider overall patient factors and may differ on a case-to-case basis.

Resolution of clinical scenario

- Nonoperative management is primarily recommended for mild disease with symptoms only.
- In this case, there are objective findings of motor dysfunction and severe compression; therefore, surgical management is suggested.

Question 2: In patients with ulnar nerve distribution symptoms, what is the most effective surgical technique for managing compressive ulnar neuropathy at the elbow?

Rationale

Surgical management of cubital tunnel syndrome is among the most debated topics in peripheral nerve surgery as multiple options exist.[8] In general, the most common contemporary techniques are simple decompression versus anterior transposition of the ulnar nerve.[9]

Clinical comment

With multiple techniques available for surgical management of cubital tunnel syndrome, selecting a technique that is supported by the best available evidence is important. In managing a patient surgically, the goal is to ensure the ulnar nerve is free from further compression and to maximize symptom resolution with sensory and motor recovery.

Available literature and quality of the evidence

The highest-level evidence to address this question analyzes the efficacy of various decompression or transposition techniques. There is relatively strong

evidence with multiple level I RCTs and meta-analyses.[3,10–17]

Bartels et al. performed a prospective RCT comparing simple decompression versus subcutaneous transposition of the ulnar nerve in patients who had varying degrees of severity.[10] This study is graded as level I evidence. Clinical outcomes at one year were assessed in 152 patients, with 75 patients randomized to simple decompression and 77 to subcutaneous transposition. At all follow-up visits, there was no significant difference in clinical outcomes between groups, although there was a trend toward favoring subcutaneous transposition at one year (risk ratio [RR] = 0.8; 95% confidence interval [CI]: 0.6–1.1). Sixty-five percent of patients and 70% with subcutaneous transposition achieved good to excellent results, respectively. There was a higher complication rate in the subcutaneous transposition group, with scar hypersensitivity being the most common.[10]

In a second publication with this cohort, a cost analysis was performed, which reviewed professional fees, opportunity cost from sick leave, operating time, and resource costs.[11] Simple decompression was associated with overall less cost per patient (mean €1124 vs €2730) and less operating time.[11]

Nabhan et al. also performed a prospective RCT comparing simple decompression versus subcutaneous transposition in 66 patients with 9-month follow-up.[12] This is graded level I evidence. Thirty-two patients underwent nerve decompression and 34 subcutaneous transposition. At three- and nine-month postoperative evaluation, both groups showed improvement with respect to pain, sensory, and motor findings. There was no statistically significant difference between the two groups.[12]

In another prospective RCT, Gervasio et al. analyzed simple decompression versus anterior submuscular transposition in patients with severe cubital tunnel syndrome.[13] This study is graded as level I evidence. Severe cubital tunnel syndrome was defined according to the Dellon classification – grade 3.[5] Seventy patients met inclusion criteria with 35 randomized to decompression and 35 to transposition. Mean follow-up was 47 months for each group. Clinical results were graded with a Bishop score. Fifty-four percent of patients in the simple decompression group achieved excellent results and 51% in the transposition group achieved the same score. No statistical difference was noted for clinical outcome between groups. Both groups showed overall improvement of electrophysiology for motor and sensory response in approximately 50% of cases, with no significant statistical difference. No major complications were noted, with more scar hypersensitivity in the simple decompression group versus the transposition.[13]

Zhong et al. performed an RCT of 278 patients who underwent either subcutaneous transposition or submuscular transposition with z-lengthening.[14] This study is graded as level I evidence. Patients had varying degrees of severity (McGowan grade 1–3). Electrophysiology outcomes alone were followed for up to two years postoperatively. All patients demonstrated significant improvement in sensory and motor conduction velocity from pre to postop. McGowan grade 1 patients were found to have no difference between subcutaneous and submuscular transposition. In those with McGowan grade 2 and 3, patients with submuscular transposition had significantly better electrophysiology outcomes at two years. There were no clinical outcomes assessed.[14]

Zarezadeh et al. performed a prospective RCT comparing anterior subcutaneous transposition versus submuscular.[15] This is level I evidence; however, there may have been some biases with blinded assessments in this study. Forty-eight patients were divided evenly and followed over 12 months postoperatively. The two groups were comparable with respect to sensation, muscle strength, and muscle atrophy. Pain was improved in the submuscular group.[15]

There are also meta-analysis reviewing this subject. A Cochrane review article (2016) was published by Caliandro et al., who originally reviewed this topic in 2010 and updated it in 2012.[3] With respect to surgical management of compressive ulnar neuropathy at the elbow, their meta-analysis included four updated RCTs. Their analysis revealed no significant difference in clinical outcomes comparing simple decompression versus transposition (RR = 0.93; CI: 0.80–1.08). The same result was found when analyzing neurophysiological outcomes, with mean difference in conduction velocity of 1.47 m/s (CI: −0.94 to 3.87). Lastly, there was a significant increase in wound infections with the transposition group.[3]

In their meta-analysis, McAdam et al. examined literature comparing anterior transposition versus simple decompression.[8] Studies included in the meta-analysis were either RCTs or cohort analysis. This is level II evidence. Ten studies were included for analysis. With respect to anterior transpositions, studies included either subcutaneous or submuscular transposition. There was no significant difference between those patients undergoing transposition versus simple decompression with an odds ratio of 0.75 (CI: 0.54–1.04). A sub-analysis was performed comparing subcutaneous transposition or submuscular versus simple decompression. There was no difference

between subcutaneous transposition or submuscular transposition in comparison to simple decompression.[8]

Another meta-analysis on this topic was published by Chen et al. in 2014.[16] Thirteen studies were included for analysis. Studies comprised of prospective randomized and cohort analysis as well as retrospective cohort analysis. This is level II evidence. The odds ratio between anterior transposition and simple decompression was 0.91 (CI: 0.67–1.23). There was a significantly decreased risk of complications in the simple decompression group with an odds ratio of 0.32 (CI: 0.17–0.60).[16]

In a similar fashion, Liu et al. specifically compared anterior subcutaneous versus submuscular transposition in a meta-analysis.[17] Two RCTs and one quasi-randomized trial met criteria for analysis. This is level II evidence. Risk ratio of clinical improvement between these techniques was 1.05 (CI: 0.86–1.25).[17]

Findings

Overall, reasonably good evidence exists examining various surgical techniques for addressing cubital tunnel syndrome. Level of evidence presented here is I–II.

Of the RCTs, there has been no study that demonstrates a significant difference between simple decompression, subcutaneous transposition, or submuscular transposition. The most commonly debated techniques are simple decompression versus subcutaneous transposition. Bartels et al. showed a risk ratio 0.8 (CI: 0.6–1.1) between these methods demonstrating their equivalence.[10] Similarly, in their sub-analysis, McAdam et al. demonstrated an odds ratio of 0.836 (CI: 0.562–1.242) between these techniques.[8] Caliandro et al. revealed a risk ratio of 0.93 (CI: 0.80–1.08).[3]

There is less quality evidence in comparing submuscular versus subcutaneous transposition. McAdam et al. had an odds ratio of 0.836 (CI: 0.562–1.242) for subcutaneous transposition versus 0.596 (CI: 0.341–1.044) for submuscular transposition when comparing to simple decompression.[8] Liu et al. demonstrated a risk ratio of 1.05 (CI: 0.86–1.25) comparing subcutaneous to submuscular transposition directly.[17]

In some studies, complications were noted to be lower in the simple decompression group (RR = 0.32, CI: 0.17–0.60;[17] RR = 0.32, CI: 0.14–0.69).[10] Whereas, there was no difference in complications in the majority of other studies.

Resolution of clinical scenario

- High-quality evidence supports no significant difference in clinical and neurophysiological outcomes between simple decompression and anterior subcutaneous transposition.
- Some studies demonstrate a reduced complication rate with simple decompression.
- There is no difference in clinical outcomes between subcutaneous and submuscular transposition.

Question 3: In patients with severe ulnar neuropathy, are there adjunct procedures to augment intrinsic muscle dysfunction?

Rationale

As described previously, severe ulnar neuropathy resulting in intrinsic muscle dysfunction muscle recovery is variable

following simple decompression or anterior transposition. A distal nerve transfer would be helpful to maximize intrinsic muscle recovery.

Clinical comment

In this clinical setting, the patient has an eight-month history of ulnar innervated intrinsic muscle dysfunction with evidence of wasting. EMG findings demonstrate axonal loss with denervation. Rennervating affected musculature is of utmost importance.

Available literature and quality of the evidence

There is very limited literature on this topic. The level of evidence is III or V, primarily composed of one cohort study and case series or case reports.

The original description of a distal nerve transfer that may be applied to severe cubital tunnel syndrome is an extension of the anterior interosseous nerve (AIN) to ulnar end-to-end transfer, by Isaacs et al.[18] In this nerve transfer, the AIN is divided distally and coapted to the side ulnar motor fascicle proximal to the wrist. The main advantage to this technique is the ulnar motor fascicle is preserved as opposed to an end-to-end coaptation where the motor fascicle is divided and therefore completely downgraded. The reverse end-to-side transfer allows for recovering axons from the elbow to still reach the hand intrinsic musculature while augmenting the motor fascicles distally. The term *reverse end-to-side transfer* is used by Isaacs et al. to distinguish it from the historically used term *end-to-side transfer*, where the recipient nerve is cut and coapted into the side of the donor nerve, which remains in continuity.

Baltzer et al. present a retrospective matched cohort study. This is level III evidence. Thirteen patients with high ulnar

nerve injury or compression were matched in age, mechanism of injury, and level of injury with those who did not receive the transfer. Patients had at least one-year follow-up. Eleven patients demonstrated ulnar intrinsic recovery versus five in the nontransfer group, which was statistically significant.[19]

Kale et al. present one case report using this nerve transfer. Quality of evidence is level V. Follow-up was one year demonstrating recovery of ulnar intrinsic function.[20]

Our group has presented a case series of 30 patients with McGowan grade 3 cubital tunnel syndrome and a mean follow-up of 16 months (work yet published).[21] To our knowledge, this represents the largest cohort of patients presented to date. This is level V evidence. The technique involves anterior ulnar nerve transposition and concurrent AIN to ulnar reverse end-to-side transfer. Patients demonstrated a significant improvement in mean MRC intrinsic muscle strength, from 1.85 preoperatively to 3.02 postoperatively ($p = 0.001$). To demonstrate the effectiveness of this transfer, we compared the McGowan grade 3 cubital tunnel cohort with a group of patients with complete nerve transection at or above the elbow, in other words a total downgrade of ulnar nerve function. At final follow-up, there was no significant difference in mean MRC between these groups: 3.02 versus 3.11, respectively.

Findings

There is little evidence assessing the addition of a distal nerve transfer to augment axonal recovery distally in the setting of McGowan grade 3 ulnar neuropathy. The existing literature is graded level III or V evidence. Case series demonstrate a better-than-expected recovery of intrinsic recovery with the addition of an AIN to ulnar reverse end-

to-side transfer. Future work with higher-quality evidence is required.

Resolution of clinical scenario

- A distal nerve transfer has been described to augment ulnar-innervated intrinsic muscle recovery.
- There is little literature to support its use, and future work is required.

Summary of answers

- Nonoperative management is recommended for patients with mild, symptomatic ulnar neuropathy.
- In cases with objective findings of motor dysfunction and severe compression, surgical management is recommended.
- There is no significant difference in clinical and neurophysiological outcomes between simple decompression and transposition.
- A distal nerve transfer has been described to augment ulnar-innervated intrinsic muscle recovery, but limited evidence exists to support this.

166 Finger Fractures

Claire Ryan MD and David Ring MD PhD
Department of Surgery and Perioperative Care, Dell Medical School – The University of Austin at Texas, Austin, TX, USA

Clinical scenario

- A 31-year-old woman presents to the Emergency Department after being struck on the right small finger while playing field hockey.
- Physical examination reveals a diffusely swollen and tender small finger but with no deformity.

Top three questions

1. How long should patients with extra-articular small finger metacarpal (aka *boxer's*) fractures be immobilized to achieve optimal outcomes?
2. Should open reduction and internal fixation (ORIF) or a dynamic external device be used for the management of patients with unstable proximal interphalangeal (PIP) joint fracture/dislocations to optimize outcomes?
3. Which is a better treatment for achieving optimal outcomes in patients with extra-articular metacarpal and phalanx fractures: pinning or ORIF?

Question 1: How long should patients with extra-articular small finger metacarpal (aka boxer's) fractures be immobilized to achieve optimal outcomes?

Rationale

Extra-articular small finger metacarpal fractures are extremely common and treatment methods vary widely from no immobilization to casting for up to six weeks.

Clinical comment

These fractures are generally treated nonoperatively but often occur in patients who may be poorly compliant with removable splints and early motion regimens.

Available literature and quality of the evidence

There are several high-quality studies which examine this question including multiple level I studies.[1–5]

Findings

Statius Muller et al. randomized 40 patients with boxer's fractures to either cast immobilization for three weeks versus one week of soft bandaging followed by mobilization.[1] Angulation up to 70° was accepted without reduction. At three months postinjury, there was no statistical differences with respect to range of motion (ROM), satisfaction, pain perception, return to work and hobby, and need for physiotherapy. Kuokkanen et al. randomized 29 patients to either closed reduction and rigid immobilization or immediate mobilization.[3] Patients treated without immobilization regained grip strength and ROM

slightly earlier, but by three months the two groups were equivalent. They concluded that reduction and immobilization were not necessary.

Braakman et al. prospectively randomized 50 patients to either ulnar gutter casting or functional taping for four weeks.[4] The functional taping group showed significantly earlier return of ROM and strength, but by six months there was no difference between the groups. There was no difference in increased fracture angulation between the groups. Similarly, van Aaken et al. compared buddy taping with early mobilization to closed reduction and casting for the treatment of small finger metacarpal neck fractures.[5] The authors found no significant difference in functional outcomes, patient satisfaction, or metacarpophalangeal (MCP) joint motion between the two groups at four months.

Two trials compared cast immobilization and a custom functional fracture brace (level II evidence).[6],[7] Konradsen et al. found significantly better wrist, MCP, and PIP motion after three and four weeks, respectively, in the brace group, but no differences after three months.[6] Sørensen et al. noted that only 42% of the brace group completed treatment, pointing to the challenges with compliance in this patient group.[7] However, in those who completed treatment, there was no difference in ROM.

Sletten et al. randomized 85 patients with small finger metacarpal neck fractures with >30° palmar angulation found that patients who were treated with a week of splint immobilization followed by buddy taping had similar functional outcomes and satisfaction scores as patients who underwent operative treatment with closed reduction and bouquet pinning (level I).[8]

In a systematic review of studies of the treatment of small finger metacarpal neck fractures, Dunn et al. found that

reduction and cast immobilization did not provide superior ROM, grip strength, or healing compared to treatment with a soft wrap without any reduction attempt.[9] In a Cochrane review, Poolman et al. criticized the lack of consistent, validated outcome tools in all studies but concluded: “No single non-operative treatment regimen for fracture of the neck of the fifth metacarpal can be recommended as superior to another” (level V).[10]

Although multiple different treatments are utilized by hand surgeons, there is good evidence that cast immobilization is unnecessary in the treatment of small finger metacarpal neck fractures. Level I evidence suggests an earlier improvement in ROM and grip strength will occur in patients treated with functional bracing or even taping. However, at medium-term follow-up, there is no significant difference in outcomes such as pain and ROM.

Resolution of clinical scenario

- Early mobilization with either functional bracing or taping does not affect the final outcome of closed metacarpal fractures and appears to be associated with an earlier return of finger motion and grip strength.
- Immobilization is also effective with good long-term outcomes and can be utilized at the discretion of patient and surgeon.

Question 2: Should open reduction and internal fixation (ORIF) or a dynamic external device be used for the management of patients with unstable proximal interphalangeal (PIP) joint fracture/dislocations to optimize outcomes?

Rationale

Unstable PIP fracture/dislocations are amongst the most challenging injuries faced by hand surgeons.

Clinical comment

PIP fracture/dislocations are often associated with suboptimal outcomes. Fracture fragments are typically small and comminuted which does not allow for rigid fixation. In addition, the PIP joint is intolerant and becomes stiff after even minor trauma. Trying to choose the “best” treatment for an individual patient is difficult for the hand surgeon.

Available literature and quality of the evidence

A randomized controlled trial (RCT) and three retrospective case series exist on this topic.

Findings

Aladin et al. prospectively randomized 19 patients to closed reduction and trans-articular Kirschner wires (K-wires) or ORIF (lag screws or cerclage wire).[11] The authors reported the ORIF group as two separate subgroups with cerclage wiring associated with a 30° fixed flexion deformity (FFD)

and an arc of motion of 48°. By comparison, K-wire and lag screw fixation had FFDs of 0° and 4°, respectively, and arcs of motion of 75° and 73°. There was no statistical comparison of treatment groups, but the authors concluded that K-wire fixation was technically simpler with similar outcomes.

Three retrospective case series reported on internal screw fixation (level IV).[12–14] Seven retrospective case series reported on various types of dynamic traction/external fixation (level IV).[15–21] The average arc of PIP joint motion was 88.7° with a range from 70° to 165°. Complication rates ranged from 8 to 63%. There was no clear advantage of one approach over another.

There is minimal level I evidence to support one treatment paradigm over the other. Multiple case series document similar ranges of motion at final follow-up. Because of the heterogeneity of fracture patterns, a large clinical trial to account for different types of fracture patterns is required to resolve this question.

Resolution of clinical scenario

- There is no high-level evidence to support one type of treatment as being superior to another.
- Data from one RCT suggest that less invasive treatment has the advantage of technical simplicity while producing similar outcomes.

Question 3: Which is a better treatment for achieving optimal outcomes in patients with extra-articular metacarpal and phalanx fractures: pinning or ORIF?

Rationale

ORIF with plates and screws provides excellent stability which allows early motion; however, it causes additional soft tissue trauma, which may lead to extensor and/or flexor tendon adhesions potentially limiting ultimate ROM. Closed reduction and K-wire pinning is less expensive, simpler, and may limit soft tissue trauma; however, the lack of rigid fixation may not allow for early motion therapy protocols.

Clinical comment

The ideal treatment of extra-articular finger fractures remains controversial. Despite the conceptual advantages of ORIF in providing stability and alignment, pinning frequently offers a good alternative. Individual fractures (metacarpal, proximal phalanx, distal phalanx) and fracture patterns (oblique, transverse, comminuted vs simple) make comparison of specific treatment techniques challenging.

Available literature and quality of the evidence

An RCT, as well as a systematic review of RCTs along with expert opinion, exists on this topic.

Findings

Horton et al. prospectively randomized 40 patients with long oblique proximal phalanx fractures to either

percutaneous K-wire fixation versus open reduction and lag screw fixation (level I).[22] At a mean follow-up of 40 months, the authors found no differences in pain, malunion, ROM, or grip strength.

A systematic review by Yammine et al. (level V) of RCTs or quasi-RCTs comparing antegrade intramedullary nailing (AIMN) with other fixation techniques for fifth metacarpal neck fractures found patients treated with AIMN to have better grip strength, pain scores and ROM when compared to fixation with plates or transverse pins.[23] Conversely, Ozer et al. compared retrospective cohorts of patients with metacarpal fractures treated with intramedullary nail fixation of extra-articular fractures with plate and screw fixation and found no significant differences in total active motion or Disabilities of the Hand, Arm, and Shoulder (DASH) scores regardless of fracture location (level III).[24]

Most literature consists of expert opinion such as the articles by Henry and Kozin et al.[25],[26] Their recommendations are based on their considerable experience and are specific to individual fractures (level V). A single prospective RCT addressed a very particular fracture pattern which lends itself to screw fixation.[22] It is likely that the results of that study are not generalizable to other types of fractures.

Resolution of clinical scenario

- There are insufficient data to recommend one fixation technique over another.
- At present, the choice of treatment depends on the individual fracture characteristics and surgeon/patient preference.

Summary of answers

- Early mobilization with functional bracing or taping is associated with earlier return of motion and grip strength.
- There is no good evidence to support the use of any specific surgical technique over another.
- The choice of treatment should be guided by fracture characteristics and surgeon/patient preference.

IX Oncology

167 Radiation Therapy in Soft Tissue Sarcoma

Anthony Bozzo MD MSc[1], Aaron Gazendam MD[1], and Kurt R. Weiss MD[2]
[1] Division of Orthopaedic Surgery, Department of Surgery, McMaster University, Hamilton, ON, Canada
[2] University of Toronto, Toronto, ON, Canada

Clinical scenario

- A 50-year-old woman presents with a growing mass in the medial thigh. On examination there is a firm 15 cm mass in the adductor compartment. Magnetic resonance imaging (MRI) confirms a tumor with heterogeneous signal characteristics. The neurovascular bundle is displaced but not encased. A biopsy performed at the regional tumor center is consistent with a high-grade undifferentiated pleomorphic sarcoma. Systemic staging is negative for metastasis.
- Will the patient receive radiation therapy (XRT) as part of her management?
- The patient asks if she will receive XRT before or after surgery.
- Apart from local recurrence, short- and long-term treatment morbidity remain important considerations for patients undergoing treatment with surgery and XRT.

Importance of the problem

Radiation-induced cell death is brought about by direct DNA damage and the production of free radicals. Tumors with varying DNA concentrations and local oxygen tensions respond differently to identical doses of radiation. The presence of prior surgery also affects tumor cell sensitivity.[1] The exact timing, sequence, and dose of XRT remain controversial. A recent population-based review of over 8000 soft tissue tumors documented the distribution of soft tissue sarcomas (STS) to be the lower extremity (32%), upper limb (13%), and axial (55%).[2]

Top three questions

1. Is there evidence to use XRT in the management of STS?
2. What are the relative advantages and disadvantages of pre- versus postoperative XRT?
3. What are the short- and long-term complications of XRT?

Question 1: Is there evidence to use XRT in the management of STS?

In patients undergoing wide resection for soft tissue sarcoma, does the use of XRT result in better local control and overall survival compared to surgical resection alone?

Rationale

STS constitute 1% of all cancer diagnoses and the incidence is estimated at 1 per 30 000. The mainstay of treatment is wide surgical excision. XRT is used in the management of STS, with the goal of extending the *virtual margin* to the surrounding tissues.[3]

Clinical comment

Limb-sparing surgery plus XRT is as effective as amputation for the local control of STS.

Available literature and quality of the evidence

STS are rare and there is a paucity of level I evidence upon which to base treatment decisions.

Findings

There is agreement that local control is important, and some authors have correlated local recurrence with diminished overall survival. Most studies are retrospective with small (average 182, range 41–517) numbers of patients. There are two systematic reviews that included 4579 patients, and there is significant overlap between these reviews. There are three randomized controlled trials (RCTs) that evaluated 298 patients. A systematic review concluded that XRT in addition to limb-sparing surgery improves local control for extremity STS over surgery alone, but does not affect overall survival.[4] A review of RCTs in extremity STS found that limb-sparing surgery plus XRT is equivalent to amputation for local control.[5] Furthermore, adding XRT to surgical resection significantly improves local control over surgery alone but does not improve overall survival. The first RCT compared limb-sparing surgery plus postoperative XRT to amputation in 43 patients.[6] At the time of this study, amputation was the standard of care for local control of STS. The authors found no significant differences in local recurrence ($p = 0.06$; odds ratio [OR] = 6.32; 95% confidence interval [CI]: 0.32–125.52) or overall survival ($p = 0.99$; OR = 0.86; 95% CI: 0.13–5.89) at five years. They concluded that limb-sparing surgery plus XRT is a reasonable alternative to amputation. The next two RCTs compared limb-sparing surgery alone to

limb-sparing surgery plus postoperative RT. Pisters et al. (n = 164 patients) reported a significant improvement (p = 0.002; OR = 0.23; 95% CI: 0.08–0.66) in local control with surgery plus brachytherapy compared with the surgery alone in patients with high-grade tumors.[7] Brachytherapy did not provide an advantage in patients with low-grade tumors. There were no differences between the two treatment groups in terms of metastatic disease (p = 0.60; OR = 0.74; 95% CI: 0.35–1.56) or five-year survival (p = 0.65; OR = 0.8; 95% CI: 0.35–1.81). Yang et al. stratified 141 patients into high- and low-grade tumors.[8] All patients had surgery and were randomized to receive external beam XRT or not. XRT significantly improved local control in both high-grade (p = 0.003; OR = 0.05; 95% CI: 0.00–0.81) and low-grade (p = 0.02; OR = 0.08; 95% CI: 0.01–0.70) tumors. However, there were no differences in overall survival at 10 years (p = 0.71; OR = 0.93; 95% CI: 0.40–2.15). An outcomes study involving 8249 patients using the Florida Cancer Registry demonstrated that surgical resection (p <0.001) and XRT (p <0.001) were the only treatment variables to improve survival.[9] The findings of earlier studies from the 1980s and 1990s are in line with the newer RCTs and systematic reviews.[10–17]

Resolution of clinical scenario

- XRT plus limb-sparing surgery is as effective as amputation for the local control of extremity STS (overall quality: high).
- XRT plus limb-sparing surgery is superior to surgery alone for the local control of high-grade extremity STS (overall quality: high).
- XRT does not impact overall survival (overall quality: high).

Question 2: What are the relative advantages and disadvantages of pre- versus postoperative XRT?

In patients receiving XRT for management of their soft-tissue sarcoma, does preoperative XRT result in better survival outcomes compared to postoperative XRT?

Rationale

Sarcomas are best treated by multidisciplinary teams and individualized treatment plans. The relative advantages and disadvantages of pre- versus postoperative XRT must be related to each patient.

Clinical comment

There are potential advantages and disadvantages to both pre- and postoperative XRT. Both strategies are successfully used to treat patients. Preoperative XRT is associated with a higher rate of wound complications but better long-term functional outcomes.

Available literature and quality of the evidence

High-quality evidence exists to answer this question.

Findings

Advantages and disadvantages

Potential advantages of preoperative XRT include smaller radiation dose and treatment volume, greater sensitivity of the tumor to radiation, no delay in the initiation of XRT, less long-term tissue toxicity (joint contracture, fibrosis, edema, and fracture), and the ability to administer a postoperative radiation boost if desired. Reported advantages of postoperative XRT include immediate

surgery, better-quality tissue for pathologic evaluation, and fewer wound complications.

Level I, III, and IV data report statistically smaller treatment doses and fields with preoperative XRT: preoperative XRT is typically ~50 Gy, whereas postoperative treatment is typically 66 Gy.

Recurrence and survival

No studies have shown a significant difference in local recurrence or metastatic disease with either pre- or postoperative XRT. A Canadian RCT comparing pre- and postoperative XRT reported a slight survival advantage of preoperative XRT at three years ($p = 0.05$; OR = 0.47; 95% CI: 0.23–0.97) which did not persist with longer-term follow-up.[18,19]

Al-Absi et al. performed a meta-analysis comparing pre- and postoperative XRT for local recurrence and overall survival.[20] Of 1098 patients, 526 had preoperative XRT. Although there were fewer local recurrences in the preoperative group, this finding was dependent on whether a random- or fixed-effect statistical model was used. The authors stressed that these findings should be interpreted cautiously due to heterogeneity within the meta-analysis (heterogeneity $p = 0.26$, variability = 25%). They concluded that the timing of XRT is unlikely to affect survival. The decision to use preoperative or postoperative XRT is based on the expected advantages of one treatment strategy versus the other. Preoperative XRT might be chosen if the tumor is in close proximity to critical structures (e.g. femoral artery) and smaller radiation doses/volumes are required. Complex soft tissue reconstructions could make preoperative XRT desirable. Alternatively, patients unable to tolerate a wound complication might benefit from postoperative XRT.

Resolution of clinical scenario

- Preoperative XRT utilizes smaller treatment volumes and lower overall radiation dosages than postoperative XRT (overall quality: high).
- Pre- and postoperative XRT have equivalent efficacy in terms of local control and overall survival (overall quality: high).

Question 3: What are the short- and long-term complications of XRT?

In patients receiving XRT for the management of their soft-tissue sarcoma, does preoperative XRT result in better functional outcomes compared to postoperative XRT?

Rationale

Pre- and postoperative XRT cause distinct complications. Immediately following preoperative XRT, wound complications are the most common problem, particularly in the management of lower limb lesions. The longer-term effects of postoperative XRT on normal tissues increase the probability of developing limb and joint stiffness, fibrosis, edema, and long bone fracture.

Clinical comment

Multiple studies have demonstrated that preoperative XRT increases the probability of wound complications compared with postoperative XRT, which can cause adverse long-term functional consequences. Wound complications are challenging but manageable problems. In contradistinction, once the long-term effects of XRT have established themselves in the limb, they are difficult to manage.

Available literature and quality of the evidence

Moderate- to high-quality literature exists on this topic.

Findings

Short-term complications

Even without adjuvant treatment, wound complications are to be expected following STS excision. In a consecutive series of 98 patients managed with STS excision without adjuvant treatment, the wound complication rate was 40%.[21]

A Canadian RCT demonstrated 35% (31 of 88 patients) versus 17% (16 of 94 patients) wound complication rate in the pre- versus postoperative XRT groups, respectively ($p = 0.01$; OR = 2.65; 95% CI: 1.33–5.30) with the predominant effect almost entirely confined to the lower limb.[18]

The retrospective data of Cheng et al., Pollack et al., and Cannon et al. independently reported that preoperative radiation leads to increased rates of wound complications in the lower limb compared to postoperative XRT.[22–24] Specifically, Cheng et al. reported wound complications in 15 of 48 (31%) preoperative XRT patients compared with 5 of 64 (8%) postoperative XRT patients ($p = 0.001$; OR = 5.36; 95% CI: 1.79–16.08).[22] Pollack et al. reported wound complications in 32 of 128 (25%) preoperative XRT patients compared with 10 of 165 (6%) postoperative XRT patients ($p < 0.001$; OR = 5.17; 95% CI: 2.43–10.99).[23] Finally, Cannon et al. reported complications in 90 of 269 (34%) preoperative XRT patients and 23 of 143 (16%) postoperative XRT patients ($p < 0.001$; OR = 2.63; CI: 1.57–4.38).[24]

Long-term complications

Rimner et al. retrospectively reviewed 225 thigh tumors.[25] Overall complication rates at five years were edema (13%), joint stiffness (12%), wound reoperation (10%), nerve damage (8%), and bone fractures (7%). In this study 69% of these patients were treated with brachytherapy, while 31% received external beam XRT. Cannon et al. reported on 412 patients at 20 years following external beam XRT and found that chronic radiation related complications were higher in patients with a tumor located in the groin or thigh.[24]

Davis et al. analyzed 129 patients for late radiation morbidity in an RCT.[19] At two years, there was a trend toward greater fibrosis following postoperative XRT ($p = 0.07$; OR = 0.49; 95% CI: 0.24–1.02). Moderate degrees of fibrosis and stiffness correlated with significantly worse patient reported outcomes (Toronto Extremity Salvage Score [TESS] scores) as well as objective assessments (Musculoskeletal Tumor Society [MSTS] scores). There was also increased edema (23% vs 15%; $p = 0.26$; OR = 0.59; 95% CI: 0.24–1.43), and joint stiffness (23% vs 18%; $p = 0.51$; OR = 0.72; 95% CI: 0.30–1.70) in the post- versus preoperative XRT groups. Large field size is typically associated with postoperative XRT and was predictive of increased fibrosis ($p = 0.002$), joint stiffness ($p = 0.006$), and edema ($p = 0.06$) in logistic regression analysis. The Musculoskeletal Tumor Society (MSTS) score and Toronto Extremity Salvage Score (TESS) were not significantly different between both treatment arms but were adversely affected by radiation morbidity.

Stinson et al. retrospectively reviewed acute and chronic postradiation effects in 145 patients and identified tissue induration (57%), decreased range of motion (32%), decreased muscle power (20%), edema (19%), pain (7%), use of walking aids (7%), and fracture (6%).[26] Examining

radiation-associated fractures, Holt et al. noted that patients undergoing thigh STS resection were more likely to sustain a fracture if they received either high-dose postoperative XRT or high-dose combined preoperative XRT and a postoperative boost (60 or 66 Gy) compared to low-dose (50 Gy) preoperative treatment.[27] In this study 24 of 27 fractures occurred in patients who had received high-dose XRT ($p = 0.007$; OR = 0.12; 95% CI: 0.04–0.42).

Resolution of clinical scenario

- Preoperative XRT leads to an increased rate of wound complications relative to postoperative XRT in lower limb tumors (overall quality: high).
- Larger tumors treated with XRT have an increased risk of developing complications (overall quality: high).
- A moderate degree of fibrosis and stiffness leads to significantly poorer patient-reported outcomes (overall quality: high).
- Postoperative XRT leads to diminished long-term functional outcomes, when measured with MSTS and TESS scores, than preoperative XRT (overall quality: moderate).

Summary of answers

- XRT plus limb-sparing surgery is as effective as amputation for the local control of extremity STS.
- XRT plus limb-sparing surgery is superior to surgery alone for the local control of high-grade extremity STS.
- XRT does not impact overall survival.
- Preoperative XRT utilizes smaller treatment volumes and lower overall radiation dosages than postoperative

XRT.

- Pre- and postoperative XRT have equivalent efficacy in terms of overall survival.
- Preoperative XRT leads to an increased rate of wound complications relative to postoperative XRT in lower limb tumors.
- Larger tumors treated with XRT have an increased risk of developing complications.
- A moderate degree of fibrosis and stiffness leads to significantly poorer patient-reported outcomes.
- Postoperative XRT leads to diminished long-term functional outcomes, when measured with MSTS and TESS scores, than preoperative XRT.

Note: in this chapter, the odds ratio (OR) reported in italics has been calculated by the authors and is not reported as part of the manuscripts referenced. Table 168.1A provides an overall review of studies cited and includes either the reported or calculated hazard ratio (HR) or OR for overall survival as related to chemotherapy administration.

Introduction

The two staging systems used to describe soft tissue sarcoma (STS) are the American Joint Committee on Cancer (AJCC) and the Enneking System (Surgical Staging System of the Musculoskeletal Tumor Society). The AJCC is based upon the tumor–node–metastasis (TNM) system, but also includes histologic grade as a measure. The Enneking system is based upon histopathologic grade, anatomic site and extent, and presence or absence of metastases.

Doxorubicin (Adriamycin) is an anthracycline antibiotic used as a chemotherapeutic agent. It works by intercalating DNA. Toxicities can include nausea, vomiting, and heart arrhythmias. Cumulative doses can lead to cardiotoxicity including congestive heart failure and dilated cardiomyopathy.

Ifosfamide (Ifex) is an alkylating agent whose mechanism of action includes the formation of covalent bonds with DNA, RNA, and proteins thereby impairing cell function. Dosing is limited by genitourinary and neurologic toxicity and is usually administered in conjunction with mesna to reduce the genitourinary toxicity.

Synovial sarcoma comprises 10–15% of adult STSs. Synovial sarcomas contain a characteristic translocation (X;18; p11;q11) representing the fusion of SYT (18q11) with either SSX1 or SSX2 (both at Xp11) resulting in the fusion genes SYT-SSX1 or SYT-SSX2.

Clinical scenario

- A 38-year-old vending machine repairman presents for evaluation of left groin pain. Physical examination reveals asymmetric thigh girth (left 67 cm vs right 55 cm).
- Imaging studies demonstrates a 12.5 × 15 × 20 cm mass within the adductor compartment of the left thigh.
- There is no evidence of lung parenchymal disease.
- Open biopsy of the mass is performed.

- Final pathology is reported as pleomorphic high-grade sarcoma (Figure 168.1).

Table 168.1A Efficacy of neoadjuvant chemotherapy in the treatment of STS.

Literature Reference	Study Design Quality of evidence	No. of Patients	Results	Conclusions	Statistical Significance: Overall Survival Related to Intervention
Gronchi et al.[3]	RCT	328	3 cycles NeoCT not inferior to 3 cycles NeoCT plus 2 adjuvant cycles	No control arm of no chemo to compare chemo arms with Study could not evaluate NeoCT compared to no chemo	N/A – cannot compare NeoCT to no chemo control
Gronchi et al.[4]	RCT	287	3 cycles of standard NeoCT compared to 3 cycles of histology-specific chemo regimens for high-grade myxoid liposarcoma, leiomyosarcoma, synovial sarcoma, malignant peripheral nerve sheath tumor, undifferentiated pleomorphic sarcoma	At 1-year follow-up the histologic-specific chemo group had statistically worse OS (38% vs 62% in standard NeoCT group, p = 0.006) so the study was halted early	Histology-specific chemo regimens for high-grade myxoid liposarcoma, leiomyosarcoma, synovial sarcoma, malignant peripheral nerve sheath tumor, and undifferentiated pleomorphic sarcoma are worse than standard NeoCT regimen (epirubicin, IF)

Literature Reference	Study Design Quality of evidence	No. of Patients	Results	Conclusions	Statistical Significance: Overall Survival Related to Intervention
Issels et al.[5]	RCT	329	Regional hyperthermia and NeoCT compared to NeoCT alone had better OS (p = 0.04) and better LRFS (p = 0.002)	No control arm of no chemo to compare NeoCT arm and Neo CT plus hyperthermia arms to Study could not evaluate NeoCT compared to no chemo	N/A – cannot compare NeoCT to no chemo control
Pennington et al.[6]	Retrospective Low	116	IF-based NeoCT and radiotherapy for extremity STS Median follow-up 5.9 years	No control group of no chemo to compare to	OS at 3/6 years was 82/67% Age over 60 years (p = 0.03; HR = 2.34; 95% CI: 1.10–4.98) and tumor size over 10 cm compared with tumor size ≤5 cm (p = 0.03; HR = 3.32; 95% CI: 1.15–9.61) were associated with worse OS

Literature Reference	Study Design Quality of evidence	No. of Patients	Results	Conclusions	Statistical Significance: Overall Survival Related to Intervention
Mullen et al.[7]	Retrospective Low	73	48 extremity STS patients treated with NeoCT and radiotherapy followed by three cycles of adjuvant chemo and 16 Gy postoperative radiotherapy was compared to a historical matched-control 25 patient population at a single center Median follow-up was 9.3 years in NeoCT group, 13.2 years in control group	NeoCT plus adjuvant chemo and pre- and postoperative radiotherapy conferred significant survival benefits	7-year DSS and OS rates were 81 and 50% (p = 0.004) and 79 and 45% (p = 0.003) for the NeoCT and control groups, respectively

Literature Reference	Study Design Quality of evidence	No. of Patients	Results	Conclusions	Statistical Significance: Overall Survival Related to Intervention
Meric et al.[12]	Retrospective Low	65	Reviewed records of patients treated with NeoCT to determine radiographic response: 34% partial, 9% minor, 31% stable, 26% progressive In 13%, NeoCT *downstaged* the operation, 78% had no change, and 9% progressed However, radiographic response was the most significant predictor of overall survival	Although only a few NeoCT patients had smaller surgery, radiographic response did correlate to improved survival	N/A – correlates radiographic response to survival
Eilber et al.[8]	Retrospective Low	496	The percentage of patients who achieved ≥95% necrosis increased from 13% to 48% with the addition of IF to doxorubicin. 5-year survival in patients with >95% necrosis = 80% vs 62% in patients with <95% necrosis	In patients who received neoadjuvant therapy and had evidence of treatment induced necrosis, patients with >95% necrosis demonstrated improved OS and LRFS	N/A – correlates % necrosis to overall survival

Literature Reference	Study Design Quality of evidence	No. of Patients	Results	Conclusions	Statistical Significance: Overall Survival Related to Intervention
Menendez et al.[9]	Retrospective Low	82	The overall five year survivorship for patients with <95% or >95% necrosis were 20 and 33%, respectively	Tissue necrosis from NeoCT did not seem to predict outcome	N/A – correlates % necrosis to overall survival
Gortzak et al.[10]	RCT	134	Chemotherapy did not interfere with planned surgery and did not affect postoperative wound healing Trial closed after phase II because of poor patient accrual Median follow-up of 7.3 years, five-year disease-free survival was 52% for no neoadjuvant chemo and 56% for neoadjuvant chemo groups, and 64 and 65%, respectively, for overall survival	Although chemotherapy did not compromise surgical intervention, there was not a major survival benefit observed with administration of neoadjuvant chemotherapy	*Calculated OR overall survival at mean of 7.3 years: OR = 0.68; 95%CI: 0.34–1.38; p = 0.29*

Literature Reference	Study Design Quality of evidence	No. of Patients	Results	Conclusions	Statistical Significance: Overall Survival Related to Intervention
Pisters et al.[11]	Retrospective Low	76	Responding patients had rates of LRFS, DMFS, DFS, OS similar to nonresponders	NeoCT associated with response, DFS, OS rates similar to reported adjuvant chemotherapy Responding patients had rates of LRFS, DMFS, DFS, OS similar to nonresponders	N/A – correlates radiographic response to survival
Italiano et al.[24]	Retrospective Low	237 (SS)	Median follow-up 58 months Neither neoadjuvant or adjuvant chemotherapy (IF-containing regimen) had significant impact on DSS, LRFS, DRFS	Wide surgical excision of SS with adjuvant radiotherapy are accepted treatments Chemotherapy shows no statistically significant benefit	Reported: HR = 0.91; 95% CI: 0.56–1.49; p = 0.725

IF: ifosfamide, DSS: disease-specific survival, DFS: disease free survival, DRFS: distant recurrence free survival, LRFS: local recurrence free survival, OR: odds ratio, SS: synovial sarcoma, OS: overall survival, NeoCT: neoadjuvant chemotherapy, Reported: authors reported OR/CI in published manuscripts, Calculated: authors of this review calculated OR/CI to improve statistical validity of analysis, N/A – did not address overall survival reported between control (no chemo) and experimental (chemo group), DMFS: distant metastasis-free survival

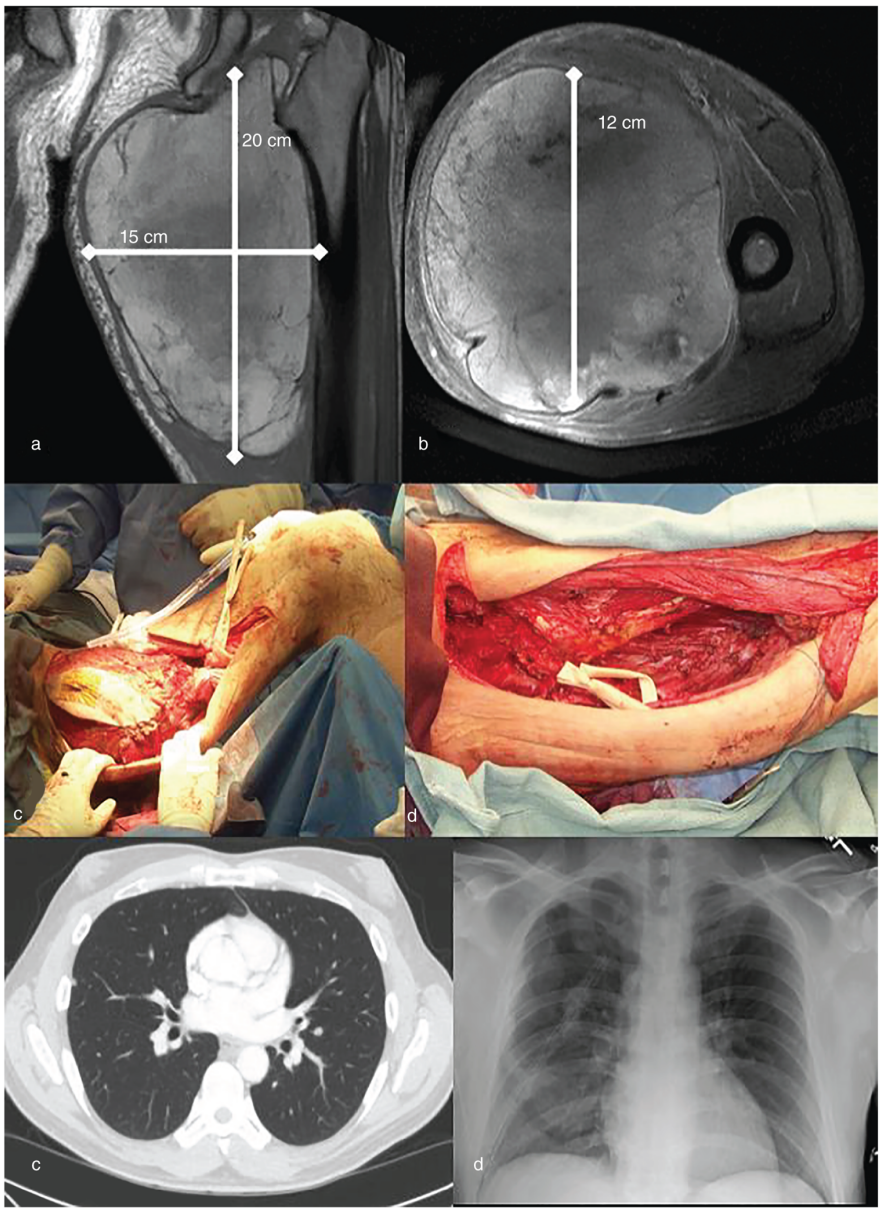

Figure 168.1 Clinical images of patient presented embody the inherent difficulty in treatment of high-risk STS. Pretreatment MRI scans revealed a large 20 × 15 × 12 cm mass in the left medial thigh (A, B). Following neoadjuvant radiation therapy, the patient is taken to the operating room for a wide excision of the tumor (C). Post resection, the sciatic nerve is skeletonized, tagged with a vessi-loop (D). Despite negative margins, no prior evidence of lung involvement on staging studies, and no evidence of local recurrence, the patient developed radiographically detectable lung metastases on CT scan nine months following definitive resection (E). Following treatment with adjuvant chemotherapy (adriamycin and ifosfamide/mesna), the patient underwent pulmonary metastatectomies (F). Source: Robert J. Wilson, Jennifer L. Halpern, Jill Gilbert, Ginger E. Holt, Vicki L. Keedy, Herbert S. Schwartz.

Table 168.1B Efficacy of adjuvant chemotherapy in the treatment of STS.

Literature Reference	Study Design Quality of evidence	No. of Patients	Results	Conclusions	Statistical Significance: Overall Survival Related to Intervention
Sarcoma Meta-analysis Group[16]	Meta-analysis High	1568	HRs of 0.73 for LRFS, 0.70 for DRFS, 0.75 for DFS correspond to absolute benefits from adjuvant chemotherapy of 6, 10, and 10%, respectively at 10 years For OS, the hazard ratio of 0.89 was not significant	Adjuvant doxorubicin-based chemotherapy (statistically) significantly improves time to local and distant recurrence and overall recurrence-free survival	Reported: HR = 0.89; 95% CI: 0.76–1.03; p = 0.12
Frustaci et al.[17]	RCT High	104	Median follow-up of 59 months Median DFS 48 months in treatment group and 16 months in control group DSS was 75 months for treated group and 46 months for control Absolute benefit in OS was 13% at two years and 19% at four years	Intensified adjuvant chemotherapy had a positive impact on DFS and OS in patients with high-risk extremity STS	*Calculated OR overall survival to four years: OR = 0.54; 95% CI: 0.25–1.18; p = 0.12*

Literature Reference	Study Design Quality of evidence	No. of Patients	Results	Conclusions	Statistical Significance: Overall Survival Related to Intervention
Frustaci et al.[18]	RCT High	104	Further follow-up of prior experimental group showed that DFS and OS differences in treatment arm vs control group no longer statistically different	The previously observed overall survival benefit loses statistical significance at later time points Therefore, time to recurrence may be lengthened, but overall survival at further follow up is the same	*Calculated OR overall survival to 89.6 months: OR = 0.538; 95% CI: 0.25–1.17; p = 0.12*
Cormier et al.[19]	Retrospective Low	674	Median follow-up 6.1 years Use of chemotherapy is associated with time-varying clinical effects	Clinical benefits associated with doxorubicin-based chemotherapy are not sustained beyond 1 year	Reported HR DSS at 12 months: HR = 0.37; 95% CI: 0.20–0.69; p = 0.002 Reported HR after 12 months: HR = 1.36; 95% CI: 1.02– 1.81; p = 0.04

Woll et al.[21]	RCT	351	Adjuvant doxorubicin, IF vs no chemo, equal numbers received radiotherapy Median follow-up 7.99 years	Adjuvant chemotherapy with doxorubicin, IF in resected STS showed no benefit in relapse-free survival or OS	OS did not differ significantly between groups (HR = 0.94; 95% CI: 0.68–1.31; p = 0.72) nor did relapse-free survival (HR = 0.91; 95% CI: 0.67–1.22; p = 0.51) 5-year OS was 66.5% in the chemotherapy group and 67.8% in the control group
Le Cesne et al.[22]	Pooled analysis of 2 RCTs	819	Adjuvant chemotherapy vs no chemo Median follow-up 8.2 years	“Adjuvant chemotherapy for STS remains an investigational procedure and is not a routine standard of care”	Adjuvant chemotherapy did not improve OS but improved DFS, HR = 0.74; 95% CI: 0.60–0.92; p = 0.0056

Literature Reference	Study Design Quality of evidence	No. of Patients	Results	Conclusions	Statistical Significance: Overall Survival Related to Intervention
Vining et al.[25]	National Database Review	544 (SS)	131 patients (24% of cohort) received adjuvant chemotherapy in the National Cancer Data Base Median follow-up was 4.1 years OS was the primary endpoint	Adjuvant chemotherapy prolonged OS only for stage III SS patients	Chemotherapy, overall cohort: 0.95; 95% CI: 0.63–1.44; p = 0.811 Stage I: 4.80 (95% CI: 0.91–25.3) p = 0.065 Stage IIA: 1.32 (95% CI: 0.54–3.20) p = 0.541 Stage IIB: 0.36 (95% CI: 0.07–1.76) p = 0.205 Stage III: 0.56 (95% CI: 0.33–0.93) p = 0.028

IF: ifosfamide, DSS: disease-specific survival, DFS: disease free survival, DRFS: distant recurrence free survival, LRFS: local recurrence free survival, OR: odds ratio, SS: synovial sarcoma, OS: overall survival, NeoCT: neoadjuvant chemotherapy, □1568: number of patients pooled from 14 trials, Reported: authors report OR/CI in published manuscripts, Calculated: authors of this review have calculated OR/CI to improve statistical validity of analysis, N/A – did not address overall survival reported between control (no chemo) and experimental (chemo group)

Top two questions

1. In patients with STS, is there a role for neoadjuvant chemotherapy in the treatment of the disease?
2. In patients with STS, is there a role for adjuvant chemotherapy in the treatment of the disease?

Question 1: In patients with STS, is there a role for neoadjuvant chemotherapy in the treatment of the disease?

Rationale

A multimodal approach utilizing radiation and surgery achieves excellent local control. Using successful osteosarcoma treatment regimens as a model, the question raised was whether pretreatment of STS with chemotherapy would result in significant

tumor necrosis thereby facilitating wide resection, and would also decrease the incidence of distant disease.[1,2]

Clinical comment

Current opinion suggests that administration of neoadjuvant chemotherapy does not improve overall survival, except in specific subtypes of STS known to be chemo-sensitive.

Available literature and quality of the evidence

- Level I: 3 randomized controlled trials (RCTs).
- Level IV: 0 prospective case series and 1 retrospective review.

In general, level I evidence still does not exist to justify administration of neoadjuvant chemotherapy in the setting of localized, high-risk STS. Since the prior edition, three RCTs have been performed involving neoadjuvant chemotherapy. Gronchi et al. looked at three cycles of epirubicin and ifosfamide (EI) neoadjuvant chemo compared to three cycles of neoadjuvant chemo followed by two cycles of adjuvant chemo. The three neoadjuvant cycles alone were not inferior to the five cycles. However, a control arm of no chemotherapy was not used to establish baseline survival.[3] The question of the efficacy of histologic subtype-specific chemo regimens was investigated in an RCT as well. Patients were randomized to either standard neoadjuvant EI chemo or histology-specific regimens for the following five subtypes: high-grade myxoid liposarcoma, leiomyosarcoma, synovial sarcoma, malignant peripheral nerve sheath tumor, and undifferentiated pleomorphic sarcoma. Unfortunately, the trial was stopped early due to significantly worse results ($p < 0.006$) in the histology-specific regimen group.[4] This trial did not have a control arm of no chemotherapy either to establish baseline survival. In a study by Issels et al. patients were randomly assigned to either neoadjuvant chemotherapy consisting of doxorubicin, ifosfamide, and etoposide alone, or combined with regional hyperthermia. Mean follow-up was 11.3 years. Regional hyperthermia plus neoadjuvant chemotherapy had statistically significant prolongation of survival ($p = 0.04$) and local progression-free survival ($p = 0.002$). Unfortunately, again, this study lacked a control arm of no chemotherapy to establish baseline survival.[5]

Pennington et al. reported long-term retrospective results of neoadjuvant chemoradiotherapy for 116 extremity STS patients with a median follow-up of 5.9 years at a single center. Local control was deemed *acceptable* in this study, but the overall survival was unfortunately found to be similar to randomized studies treating STS with surgery and radiotherapy only.[6]

A retrospective review of 48 extremity STS patients treated with neoadjuvant mesna, doxorubicin, ifosfamide, and dacarbazine (MAID) and radiotherapy followed by three cycles of adjuvant MAID and 16 Gy postoperative radiotherapy was compared to a historical matched-control patient population at a single center. Median follow-up was 9.3 years. Disease-specific and overall survival were significantly better in the intensive chemotherapy group.[7]

Eilber et al., in small group of patients, demonstrated that complete response to chemo (≥95% necrosis), translated clinically into an improved 10-year local recurrence free rate of 11% versus 23% and 10-year overall survival of 71 versus 55%.[8]

However, most prior studies reported no difference in oncologic outcome in patients treated with neoadjuvant chemotherapy. This may or may not be because these studies were underpowered. Menendez et al. showed no statistical significance in recurrence free or overall survival in patients who received 3–4 cycles of neoadjuvant doxorubicin, ifosfamide, and cisplatin.[9] However, power analysis indicated that the necessary sample size to show an improvement in recurrence-free or overall survival would be 532 patients, and that study reviewed only 82 patients after exclusion criteria were considered. The European Organization for Research and Treatment of Cancer (EORTC) organized an RCT comparing neoadjuvant doxorubicin and ifosfamide in high-risk adult STS. No difference in overall or disease-free survival was noted and the study was closed early due to poor patient accrual.[10] Pisters et al. reported a retrospective review of 76 patients with stage IIIB STS, treated with neoadjuvant chemo with doxorubicin regimens.[11] They found that there was no statistically significant difference in local recurrence-free survival, distant metastases-free survival, disease-free survival, or overall survival between responders and nonresponders (characterized radiographically). The implication was that even the purported advantage of neoadjuvant chemotherapy administration (decrease in tumor size and increase tumor kill) did not correlate to improved oncologic outcomes.

The value of neoadjuvant chemotherapy to aid in margin-negative resection has been further investigated. Previously, Meric et al. showed that out of 105 patients treated with neoadjuvant chemotherapy, only 12% responded enough to simplify their surgical procedure, and in addition 9% required a larger surgery because the tumor progressed while the patient was on chemotherapy.[12] Despite that result, in the group that did demonstrate radiographic response, there were an increased number of margin-negative resections, fewer local failures, and improved overall survival when compared to patients with no radiographic response.

O'Donnell et al. analyzed 28 high-grade extremity STS sarcomas larger than 5 cm that were treated with neoadjuvant chemotherapy and surgery compared to 47 matched controls treated with surgery alone. Histologic evaluation of the pseudocapsules of the tumors were performed and compared between the groups. The neoadjuvant chemotherapy treated tumors more frequently had well-defined pseudocapsules that were more frequently continuous and thicker than the surgery alone group. The neoadjuvant chemotherapy treated tumors also had less malignant cells identified within and beyond the pseudocapsule. No clinical comparisons looking at local recurrence rates or survival were performed between the two groups.[13] An additional study with similar methodology had similar results with the combination of neoadjuvant chemotherapy and radiotherapy having the highest capsular integrity and the thickest capsule. However, no clinical comparison looking at local recurrence rates or survival was performed between the two groups in this study either.[14]

Ultimately, the evidence still does not support a definitive survival benefit in patients treated with neoadjuvant chemotherapy. As shown in Table 168.1A, reported and calculated ORs show no statistical significance in a correlation between neoadjuvant chemotherapy administration and overall survival.[3–12] In addition, it remains unclear whether there is even a survival benefit difference observed between chemotherapy responders and nonresponders.

Resolution of clinical scenario

- Administration of neoadjuvant chemotherapy is not beneficial in the treatment of localized high-risk STS, as there is no difference in overall survival or disease-free

survival, and surgical resectability has not been definitively improved by its administration (overall quality: very low).

Question 2: In patients with STS, is there a role for adjuvant chemotherapy in the treatment of the disease?

Case clarification

Another treatment option for the patient presented would be to initiate treatment with a combination of radiation and wide surgical resection, and then refer for adjuvant chemotherapy. The theoretic benefit of adjuvant chemotherapy would be to improve disease-free survival rates by eliminating micro-metastases.

Clinical elevance

A multimodal approach utilizing radiation and surgery achieves excellent local control. However, despite local control, distant metastases are not controlled. Adjuvant chemotherapy potentially could address unrecognized micro-metastases in high-risk patients.

Clinical comment

Current opinion suggests that administration of adjuvant chemotherapy has marginal efficacy, and its benefits may be outweighed by the significant associated toxicities.

Available literature and quality of the evidence

- Level I: 1 systematic reviews/meta-analyses/database analysis and 2 RCTs.

Findings

The best prior evidence, summarized in the Cochrane review from 2000, suggested that doxorubicin-based adjuvant chemotherapy improves time to local and distant recurrence and overall recurrence-free survival in adults with resectable sarcoma. A trend toward overall improved survival was also observed.[15]

The Sarcoma Meta-analysis Collaboration (SMAC) formed and reported in 1997 on 1568 with localized, resectable disease treated in a series of 14 doxorubicin-based trials. With a median follow-up of 9.4 years, they reported statistically significant treatment effects including decreased risk of local recurrence (27% decrease, absolute benefit of 6%), decreased risk of distant disease (30% reduction in risk, absolute benefit of 10%) at 10 years. There was a trend toward improved overall survival which was not statistically significant (HR = 0.89; 95% confidence interval [CI]: 0.76–1.03; p = 0.12). However, in a specific subgroup (high grade, large, extremity sarcomas) there was a clear survival advantage (7% at 10 years).[16]

Based on that meta-analysis, an RCT designed to assess the clinical efficacy of combined doxorubicin and high-dose ifosfamide therapy was initiated by the Italian Sarcoma Group.[17] Initial results comparing outcomes of patients with extremity and pelvic sarcomas treated either with resection and adjuvant radiation, or with resection, radiation and adjuvant 4'-epidoxorubicin and ifosfamide demonstrated a statistically significant difference between the treatment and control groups. There were observed improvements in median disease-free survival (48 months vs 16

months), median survival (75 months vs 46 months), and an absolute survival benefit of 13% at two years and 19% at four years *(calculated OR overall survival to four years: OR = 0.539; 95% CI: 0.247–1.177; p = 0.12)*. The study was stopped, based on the conclusion that chemotherapy afforded improved oncologic outcomes. However, the same 140 patients were subsequently evaluated in 2003.[18] Now with longer follow-up (89.6 months), the previously observed survival benefit was no longer statistically significant (*calculated OR overall survival to 89.6 months: OR = 0.538; 95% CI: 0.247–1.172; p = 0.11)*.

Additional studies also failed to find a treatment benefit. A retrospective review of 674 patients out of Sloan Kettering and MD Anderson reported that positive treatment effects from adjuvant doxorubicin were not sustained for greater than one year (reported HR disease-specific survival (DSS) at 12 months: HR = 0.37; 95% CI: 0.20–0.69; p = 0.002. Reported HR after 12 months: HR = 1.36; 95% CI: 1.02–1.81; p = 0.04).[19]

However, a systemic meta-analysis of RCTs in 2008 identified a total of 18 trials (1953 patients).[20] That meta-analysis revealed a marginal efficacy with regards to local recurrence, distant recurrence, overall recurrence, and overall survival (OR = 0.8; 95% CI: 0.68–1.03; p = 0.09) that is slightly enhanced with combination doxorubicin and ifosfamide therapy. This is considered strong evidence supporting the efficacy of ifosfamide, but the marginal improvement must be weighed against potential toxicity.

The 2000 Cochrane review determined that adjuvant chemotherapy slightly improved the time to local and distant recurrence, and overall recurrence-free survival in adults with localized, resectable STS, with a trend toward improved overall survival (14 trials including 1568 patients: reported HR = 0.89; 95% CI: 0.76–1.03; p = 0.12).[15]

Since 2000, the evidence supporting adjuvant chemotherapy remains poor. Two RCTs have been published since 2000. The EORTC 62931 trial randomized 351 patients to either five cycles of doxorubicin, ifosfamide, or lenograstim, or no chemotherapy. Equal numbers of patients in each group received radiotherapy. Overall survival, relapse-free survival, and five-year overall survival rate were not statistically different between the groups. The authors concluded adjuvant chemotherapy provided no benefit.[21] A pooled analysis of two phase III trials (Soft Tissue and Bone Sarcoma Group [STBSG], EORTC) was performed which analyzed 819 patients with a median follow-up of 8.2 years receiving doxorubicin-based chemotherapy (CT) found no benefit in overall survival and stated “adjuvant CT for STS remains an investigational procedure and is not a routine standard of care.”[22]

The above analysis primarily focuses on adult STS without further delineating subtypes. Within the heading of STS, there are specific tumors that have characteristic genetic translocations which potentiate more accurate classification. Improved classification translates into better evidence because of more homogeneous study populations. One example is synovial sarcoma.

In the case of synovial sarcoma, there is some evidence to suggest that adjuvant chemotherapy might improve oncologic outcomes, and therefore chemotherapy may be a reasonable intervention in those patients. In a recent prospective study of 101 patients, ifosfamide-based therapy was associated with an improved DSS in adult patients with high-risk, primary, extremity synovial sarcomas.[23] In that study, 67 patients were treated with IF and 33% received no therapy (NoC). The four-year DSS of the IF-treated patients was 88% compared with 67% for the NoC patients (p = 0.01) (*calculated OR overall survival to 48 months: OR = 0.262; 95% CI: 0.102–0.674;*

p = 0.005). Smaller size (HR = 0.3 per 5 cm decrease; p <0.0001) and treatment with IF (HR = 0.3 compared with NoC; *p* = 0.007) were independently associated with an improved DSS. Treatment with IF was independently associated with an improved distant recurrence-free survival (HR = 0.4; *p* = 0.03) but not associated with an improved local recurrence-free survival (*p* = 0.39). However, even with synovial sarcoma there is conflicting evidence. A retrospective analysis of 237 patients with a median follow-up of 58 months, neither neoadjuvant nor adjuvant chemotherapy has a significant impact on overall survival, local recurrence-free survival, or distant recurrence free survival.[24]

A 2017 review of the National Cancer Data Base identified 544 patients with Synovial Sarcoma of which 131 received adjuvant chemotherapy. After stratification of patients by sarcoma stage, prolonged overall survival was found in stage III patients only (p = 0.033).[25]

Therefore, synovial sarcoma in adults is often treated like other STSs, and chemotherapy is reserved for high-risk tumors or metastatic disease at presentation. If adjuvant chemotherapy is offered, combination doxorubicin and ifosfamide is prescribed in appropriate patients.

Resolution of clinical scenario

- Administration of adjuvant chemotherapy in the setting of high-grade, large extremity sarcomas may result in a longer time intervals until local or distant recurrences. There is a trend, and perhaps statistically significant marginal improvement, in survival in those patients, and therefore in patients who can tolerate chemotherapy side effects, chemotherapy could be offered as an adjuvant (overall quality: high).
- There is not overwhelming evidence of a significant oncologic benefit in treating synovial sarcoma with adjuvant chemotherapy. There is evidence of increased tumor sensitivity to ifosfamide, and therefore synovial sarcoma should be treated with meticulous surgical resection and neoadjuvant or adjuvant radiation. Chemotherapy, utilizing doxorubicin and ifosfamide, may be indicated in the treatment of high-risk patients or patients with metastatic disease at presentation (overall quality: low.)

Summary of answers

- Administration of neoadjuvant chemotherapy is not beneficial in the treatment of localized high-risk STS, as there is no difference in overall survival or disease-free survival, and surgical respectability is not definitively improved by its administration (overall quality: very low).
- Administration of adjuvant chemotherapy in the setting of high-grade, large extremity sarcomas may result in a longer time interval until local or distant recurrences. There is a trend, and perhaps statistically significant marginal improvement, in survival in those patients, and therefore in patients who can tolerate chemotherapy side effects, chemotherapy could be offered as an adjuvant (overall quality: high).
- There is not overwhelming evidence of a significant oncologic benefit in treating synovial sarcoma with adjuvant chemotherapy. There is evidence of increased tumor sensitivity to ifosfamide, and therefore synovial sarcoma should be treated

with meticulous surgical resection and neoadjuvant or adjuvant radiation. Chemotherapy, utilizing doxorubicin and ifosfamide, may be indicated in the treatment of high-risk patients or patients with metastatic disease at presentation (overall quality: low).

Conclusion

Despite excellent strategies in STS local control, adjuvant chemotherapy offers only marginal efficacy in the treatment of STS. The evidence supporting this marginal efficacy is considered to be high quality (Table 168.1A). Chemotherapy administered in the neoadjuvant setting does not definitively result in easier resections, but the pseudocapsule of the tumor is likely better defined and thicker when chemotherapy is given. The addition of neoadjuvant regional hyperthermia may improve STS outcomes. Adjuvant chemotherapy may result in improved survival in patients with large, high-grade isolated extremity sarcomas. The inherent difficulty in achieving adequate statistical power in this patient population has resulted in studies that are poorly powered to determine the presence of true statistical significance.

Possible advances in systemic treatment for STS are ongoing with several trials looking at new medicines, which hopefully can offer more effective treatment with less toxicity than doxorubicin-based regimens. New treatment modalities such as immunotherapy have shown benefit in metastatic sarcoma in phase II trials,[26,27] but are outside the scope of this chapter. A current phase II trial of immunotherapy in histologic subsets of localized STS is actively recruiting.[28] Unfortunately, at this time, no systemic therapy regimen currently has shown superior efficacy to doxorubicin-based chemotherapy regimens

[3] Orthopaedic Service, Memorial Sloan Kettering Cancer Centre, New York City, NY, USA

Clinical scenario

- A 48-year-old woman has had a 6 cm mass in the anterior compartment of the leg for about three months (Figure 169.1). She requests that it be removed during the same anesthetic as an elective abdominal procedure. The leg tumor is removed with positive margins. The diagnosis is benign angiomyxoma.
- Sixteen months later there is progressive enlargement of a mass in the same area. Surgical excision is performed, removing 15 cm of fascia and tissue, with an intended clinical margin of 2 cm.
- Pathology shows that the tumor was a 5 cm recurrent high-grade myxofibrosarcoma (MFS). The margins are focally positive. Re-excision is done. No tumor is found on final pathology review. Systemic staging is negative for metastases. Chemotherapy is declined by the patient. Adjuvant 50 Gy radiotherapy is given. Follow-up shows no local or systemic recurrence.

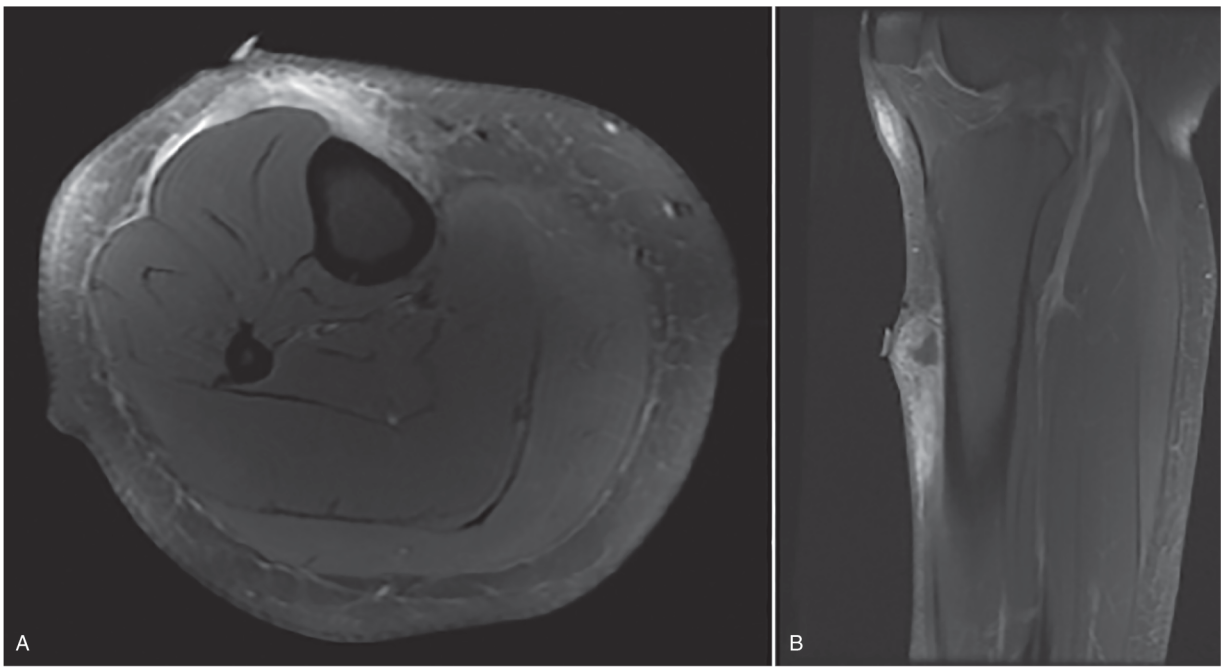

Figure 169.1 T2 weighted images in axial (A) and sagittal (B) view. A hyperintense enhancing signal is extending over 11 cm in the muscle, subcutaneous tissue, along the fascia, and over the tibial periosteum. Source: Eugenia Schwarzkopf, Tomohiro Fujiwara, John H. Healey.

Top three questions

1. Is surgical tumor excision with narrow margins associated with a higher rate of local recurrence than wide margins in patients with localized soft tissue sarcomas (STS)?
2. Does the use of pre- or postoperative radiation therapy (XRT) alter the impact of surgical margins on local recurrence in patients with localized STS?
3. How does the histological subtype affect the relationship between surgical margins and local recurrence among patients with localized STS?

Question 1: Is surgical tumor excision with narrow margins associated with a higher rate of local recurrence than wide margins in patients with localized soft tissue sarcomas (STS)?

Rationale

A balance between adequate surgical margins and preservation of important anatomical structures is required for optimal patient outcomes.

Clinical comment

Oncologically sufficient surgical excision of STS remains indispensable for the cure of patients.

Available literature and quality of the evidence

Level IV studies are available to answer this question.

Findings

Local management of STS requires a surgical margin including a cuff of normal tissue to minimize the risk of local recurrence. The impact of margin status on rate of local recurrence in extremity STS patients is the objective of several studies, but the findings differ.

In a retrospective analysis of prospectively collected data, Potter et al. evaluated the impact of margin status and local recurrence on survival in 363 patients who underwent resection of localized primary extremity STS. Positive margins (hazard ratio [HR] = 1.99; 95% confidence interval [CI]: 1.15–3.45) were significantly associated with worse overall survival on multivariate analysis. For disease-specific survival, positive margins (HR = 1.95; 95% CI:

1.05–3.63) were independent adverse prognostic factors. However, margin width was not discussed.[1] Bonvalot et al. evaluated margin adequacy in the local treatment of extremity STS and assessed the relationship between local control and overall survival. The authors reviewed 531 patients who underwent surgery with or without (neo)adjuvant treatment. In a multivariate analysis, specific subtypes such as epithelioid sarcoma and MFS and surgical margin size <1 mm were correlated with a higher rate of local recurrence. However, neither margin status nor local recurrence affected overall survival in this study.[2] In a retrospective review of 997 patients, Gronchi et al. obtained different results. Ten-year mortality estimates (95% CI) were 0.19 in R0 cases and 0.38 in R1 cases (p = 0.0003). Size, grade, depth, and histologic subtype were also significant predictors of mortality. Furthermore, surgical margins independently predicted local control and survival.[3] In a retrospective multicenter study, Willeumier et al. investigated the effect of surgical margins and radiotherapy on survival in 687 patients with primary high-grade STS of the extremities. Wide surgical margins decreased local recurrence risk but had little effect on survival.[4] Ahmad et al. analyzed the significance of resection margin status and quantitative margin width on outcomes of 382 patients with localized extremity or truncal STS who underwent limb-sparing surgery and XRT. A total of 235 patients had reported quantitative negative margin widths of ≤1 mm (n = 128), >1 mm and ≤5 mm (n = 79), and >5 mm (n = 28). There were no differences in rates of local or distant recurrence nor of any survival outcome based on negative surgical margin width. However, these conclusions must not be applied to patients who undergo surgery alone.[5] In a large retrospective study, Harati et al. assessed the relationship between local recurrence-free, disease-specific, and metastasis-free

survival and potential prognostic factors in 643 patients. Microscopically negative margins (R0) were associated with better local recurrence-free, disease-specific, and metastasis-free survival regardless of whether adjuvant radiation was administered. Within the R0 subgroup, univariate and multivariate analyses of categorized (≤1 mm vs 1–5 mm vs >5 mm) and noncategorized margin widths revealed that close and wide negative margins led to similar outcomes.[6]

To summarize, surgical margins were associated with local recurrence-free survival in localized STS of the extremity. However, the impact of the specific width of the surgical margin has not been sufficiently investigated.

Resolution of clinical scenario

This case exemplifies the so-called whoops procedure, where a lesion is removed in a nononcologic way, often with positive surgical margins. A re-resection was necessary to achieve negative margins and reduce the risk of tumor recurrence and distant metastasis.

Question 2: Does the use of pre- or postoperative radiation therapy (XRT) alter the impact of surgical margin on local recurrence in patients with localized STS?

Rationale

XRT is used to facilitate local control in multidisciplinary treatment of STS.

Clinical comment

XRT can be administered pre- or postoperatively. The relevance of the timing of administration remains open to debate.

Available literature and quality of the evidence

Level I studies and level IV studies are available to answer this question.

Findings

Local management of extremity STS consists of surgery combined with adjuvant treatment modalities in a multidisciplinary setting. The aim of this strategy is to have maximum local control while preserving function. However, the timing of XRT remains open to debate.

In a randomized prospective study, Yang et al. assessed the impact of postoperative external-beam XRT on local recurrence and overall survival. Ninety-one patients with high-grade sarcomas and 50 patients with low-grade lesions were randomized for postoperative XRT or surgery alone. A highly significant decrease in the probability of local recurrence was seen in patients with high- and low-grade lesions who received radiation ($p = 0.0028$ and $p = 0.016$, respectively), but no difference in overall survival was shown.[7] However, this study should be interpreted with caution since preoperative XRT was not included. Another randomized controlled trial was done by O'Sullivan et al. The authors randomized 190 patients for pre- or postoperative XRT. In this study, the rates of local recurrence ($p = 0.7119$), regional/distant recurrence ($p = 0.7911$), and progression-free survival ($p = 0.8349$) did not differ significantly between the two groups. Overall survival was slightly better in patients who had preoperative XRT ($p = 0.0481$).[8]

However, several studies have obtained different results. In a multi-institutional analysis of 821 patients, Sampath et al. evaluated 821 STS patients. Preoperative XRT was associated with significantly improved overall and disease-specific survival compared with postoperative XRT. Furthermore, preoperative radiation was associated with a reduced risk for local and distant relapse compared with postoperative administration.[9] A National Cancer Database (USA) analysis by Gingrich et al. compared the impact of XRT on rates of R0 resection and overall survival in extremity STS patients undergoing surgery; patients who received preoperative, postoperative, and no XRT were included in this study. The rates of R0 resection were 90.1% for the preoperative, 74.9% for the postoperative, and 79.9% for the no-XRT cohort ($p < 0.001$). Preoperative XRT independently predicted higher rates of R0 resection (odds ratio [OR] = 1.83; 95% CI: 1.61–2.07). Both R0 resection and pre-/postoperative XRT were associated with improved overall survival. However, the impact of XRT on local recurrence was not reported.[10] Al Yami et al. retrospectively reviewed extremity STS patients with a positive surgical margin after preoperative XRT. Fifty-two patients were treated with preoperative XRT alone (50 Gy), whereas 41 received preoperative XRT plus a postoperative boost (80% received 16 Gy postoperatively for a total of 66 Gy). The authors found that including the postoperative radiation boost after preoperative radiation and a margin-positive excision did not provide an advantage in preventing local recurrence. Five-year estimated local recurrence-free survival with and without postoperative radiation boost was 73.8% and 90.4%, respectively ($p = 0.13$).[11] Müller et al. performed a large retrospective study and analyzed 769 patients with high-grade STS of the extremities, who underwent a limb-sparing surgery. Eighty-nine patients were treated with neoadjuvant XRT, 315

patients with adjuvant irradiation, and 365 patients with surgery alone. Neoadjuvant XRT provided the best local recurrence-free rate for five years (90.0%), whereas after 10 years (78.3%) adjuvant irradiation showed better local control. The metastatic-free rate was independent from achieved surgical margins ($p = 0.179$).[12] Regarding the timing of administration of XRT, another relevant factor must be considered: wound healing complications, which occur twice as often after preoperative XRT. They are particularly common in the lower extremities of older patients, perhaps due to poorer vascularity in those locations.[13]

In conclusion, there are insufficient data to establish that preoperative XRT is favorable compared to postoperative XRT for local control and overall survival in extremity STS patients.

Resolution of clinical scenario

New technology is needed to identify residual cancer cells in the tumor bed so they can be removed at the time of surgery and not depend on adjuvant therapy. However, (neo)adjuvant XRT can be a useful tool to eradicate residual sarcoma and give the highest chance for achieving a negative surgical margin, as discussed in our clinical scenario.

Question 3: How does the histological subtype affect the relationship between surgical margins and local recurrence among patients with localized STS?

Rationale

The impact of surgical margin on outcome varies depending on the histological subtype of the STS.

Clinical comment

To reduce the risk of local recurrence, surgeons should take into consideration the histological subtypes and their biological features.

Available literature and quality of the evidence

Level IV studies are available to answer this question.

Findings

STS are a heterogeneous group of more than 50 different histological subtypes with a variety of biological behaviors.[14] Decision-making about adequate margins should incorporate any available data on whether the specific histological subtype is infiltrative in nature.

MFS and undifferentiated pleomorphic sarcoma (UPS) frequently exhibit an infiltrative growth pattern, which has been associated with inadequate/positive margin rates of 29–67% and local recurrence rates of 20–62%.[15–18] The infiltrative growth pattern in malignant fibrous histiocytoma (MFH) was first reported in 1999 by Fanburg-Smith et al., who observed pathological infiltration in 83% of patients with superficial MFH and in 24% of deep MFH.[15] Since then, this growth pattern has been documented on magnetic resonance imaging (MRI), and correlation between radiological and pathological infiltration ranges from 87 to 100%.[15,17] In a retrospective review of 89 patients diagnosed with MFS or UPS, Iwata et al. observed an infiltrative growth pattern in 36% of MFS and 22% of UPS on preoperative MRI, which was described as a tail-like extensive lesion along the normal fascial plane.[16] Although their surgical protocol was to excise 2–3

cm from the edge of the tumor extension on imaging studies, the surgical margin was positive in 48% (n = 43/89) and five-year local recurrence-free survival was 81%. These outcomes collectively underscore the difficulty of achieving wide margins for infiltrative subtypes. In a recent retrospective review of 18 patients with superficial MFS and UPS who were treated with preoperative XRT and surgery, Imanishi et al. reported that 60% of UPS (n = 6/10), but no MFS patients were classified as nearly complete-response (≥95% nonviable area) with the nonviable proportion of the remaining 12 cases ranging from 0 to 90%.[18] Tail sign was pathologically confirmed in 13 patients, eight (62%) of which remained viable. They observed that these patients with viable residual tumor cells in the tail were associated with a relatively high ratio of positive margins (25%, n = 2/8) and local recurrence (38%, n = 3/8), concluding that wider surgical margins, safely including the tail sign based on preoperative MRI before XRT if combined, should be chosen. Gronchi et al. described that wide surgical margins with 2–4 cm beyond the clinical boundaries of the palpable mass should be the goal of surgery for these subtypes.[19] The rationale could be supported by the observations of Imanishi et al.; there was no major differences in the tail length between on the glass slides and on the T1 postcontrast (mean 23.6 mm; range 5–36 mm) and fat-saturated MRI (mean 26.0 mm; range 7–79 mm).[18]

In contrast, atypical lipomatous tumor (ALT)/well-differentiated liposarcoma (WDLS) is a relatively common subgroup of liposarcomas and marginal margin for this subtype is allowed by several guidelines.[20],[21] However, Mussi et al. described that simple resection, which consists of a *shell-out* procedure without inclusion of a muscle/soft tissue cuff around the mass, should be avoided, because this procedure was associated with a higher risk of

intraoperative tumor rupture, which was an independent prognostic factor for local recurrence (HR = 4.37; 95% CI: 1.23–15.56).[22]

In conclusion, surgeons should be mindful of the histological subtype and associated biological behavior in surgical planning. Although the ideal margin of excision remains debatable, a wider margin is advisable, especially for infiltrative STS, and the use of intraoperative frozen sections may be helpful as an additional guide for the extent of tissue excision.

Resolution of clinical scenario

Margin assessment of different types of sarcoma is difficult to evaluate. Hyperintense signal commonly spreads along the fascia, creating so-called tails. These may or may not contain cancer cells or be just inflammatory reactive tissue. The best oncologic treatment is to resect the questionable tissue to give the lowest risk of local recurrence and distant metastasis.

Summary of answers

- Positive surgical margins were associated with worse local recurrence-free survival in localized STS of the extremities.
- There are insufficient data to establish that preoperative XRT is favorable compared to postoperative XRT for local control and overall survival in extremity STS patients.
- A wider margin (>4 cm) is advised for histologic subtypes of STS with infiltrative growth.

Clinical scenario (proximal humerus)

- A 13-year-old female presents with a three-month history of left shoulder pain that awakens her at night.
- Open biopsy is consistent with Ewing's sarcoma. Resection and reconstruction are planned.

Clinical scenario (proximal tibia)

- A 45-year-old female presents with a six-week history of knee pain.
- Open biopsy is consistent with high-grade dedifferentiated chondrosarcoma. Resection and reconstruction are planned.

Rationale

An estimated 3600 new primary bone cancers will be diagnosed in the United States in 2020, causing 1720

deaths.[1] With advances in chemotherapy and imaging, it is now possible to provide limb salvage surgery in 90–95% of patients.[2–5] With longer patient survival, it is important that a durable reconstruction follows tumor resection.

Clinical comment

Three common means of reconstruction have been used after periarticular tumor resection: osteoarticular allograft, allograft-prosthetic composite (APC), and endoprosthesis. An osteoarticular allograft reconstruction utilizes a matched cadaver bone that is affixed to host bone via plate/screw construct or intramedullary nail fixation. APCs combine an osteoarticular allograft that is skewered with a joint replacing prosthesis. Endoprostheses replace resected bone with a metal implant cemented or press fit into remaining host bone.

There are many advantages and disadvantages of each method of reconstruction. An important advantage of an osteoarticular allograft is the ability to repair host soft tissue to donor tendon/ligament attachments. Disadvantages of osteoarticular allografts include allograft fracture, host-allograft nonunion, infection, and secondary osteoarthritis. Advantages of endoprostheses include immediate use, modularity, and ease of reconstruction while disadvantages consist of aseptic loosening and wear. APCs provide donor soft tissue attachments for repair and prevent late osteoarthritis by resurfacing the joint, but carry the risk of allograft fracture and nonunion, infection, and the technical challenge of the reconstruction.

Although any anatomic location may be subject to tumor invasion requiring reconstruction, currently the most controversial sites of reconstruction are the proximal humerus and proximal tibia as choices of reconstruction are largely based on individual surgeon experience and

preference without universal agreement on optimal care. Thus, this chapter will focus on these two anatomic locations. The following questions will be addressed in each section.

Available literature and quality of the evidence

Literature review found nine articles meeting the criteria for osteoarticular allografts in the proximal humerus, seven articles for APCs, and 16 articles for endoprostheses.[6–32]

Literature review found seven articles meeting the criteria for osteoarticular allografts in the proximal tibia, four articles for APC, and 17 articles for endoprostheses.[6,8,9,33–54]

Top three questions

1. In patients receiving allograft megaprosthesis, what is the comparative risk of postoperative complications between osteoarticular allografts, APCs, and endoprostheses?
2. In patients receiving allograft megaprosthesis, what are the comparative functional outcomes between osteoarticular allografts, APCs, and endoprostheses via Musculoskeletal Tumor Society (MSTS) score or range of motion, if applicable?
3. In patients receiving allograft megaprosthesis, what is the comparative success of limb salvage and implant survival at 5, 10, and 20 years between osteoarticular allografts, APCs, and endoprostheses?

Question 1: In patients receiving allograft megaprosthesis, what is the comparative risk of postoperative complications between osteoarticular allografts, APCs, and endoprostheses?

Proximal humerus

Pooled data showed 1.3% deep infection in proximal humerus endoprostheses, 6.7% in osteoarticular allografts, and 6% in APCs. The rate of deep infection is significantly lower in endoprostheses when compared to osteoarticular allografts (relative risk [RR] = 0.19; 95% confidence interval [CI]: 0.07–0.47, p <0.001) and APCs (RR = 0.21; 95% CI: 0.08–0.58, p = 0.001).

Local recurrence occurred in 7.3% of endoprostheses, 10% of osteoarticular allografts, and 6% of APCs. These differences were not statistically significant.

Aseptic loosening occurred in 5.5% of endoprostheses and in 4.7% of APCs. These differences were not statistically significant.

Implant fractures occurred in 1.0% of endoprostheses. Periprosthetic fractures occurred in 0.2% of endoprostheses, 1.8% of osteoarticular allograft studies, and in 0% of APCs. Allograft fracture occurred in 30.8% of osteoarticular allografts and only 6.7% of APCs, reaching statistical significance (RR = 0.22; 95% CI: 0.1–0.48, p <0.001).

Nonunion occurred in 10.5% of osteoarticular allografts, as well as 14.3% of APCs. These differences were not statistically significant.

Dislocation occurred in 5.7% of endoprostheses, 20.8% of osteoarticular allografts, and 10.3% of APCs. Thus, endoprostheses had a significantly lower rate of dislocation than osteoarticular allografts (RR = 0.27; 95% CI: 0.17–0.44, p <0.001). Endoprostheses had a lower rate of dislocation than APCs that was close to statistical significance (RR = 0.55; 95% CI: 0.29–1.03, p = 0.06). APCs had a significantly lower rate of dislocation than osteoarticular allografts as well (RR = 0.5; 95% CI: 0.26–0.94, p = 0.03).

Proximal tibia

Pooled data showed a deep infection rate of 15.0% in proximal tibia endoprostheses, 22.3% in osteoarticular allografts, and 16.5% in APCs. Endoprostheses had a significantly lower rate of infection compared to osteoarticular allografts (RR = 0.67; 95% CI: 0.49–0.91, p = 0.01). The differences in infection rate between endoprostheses and APCs and APCs and osteoarticular allografts were not statistically significant.

Local recurrence occurred in 5.4% of endoprostheses, 7.4% of osteoarticular allografts, and 5.9% of APCs. These differences were not statistically significant.

Aseptic loosening was similar between endoprostheses and APCs, occurring in 7.8% of endoprostheses and 9% of APCs, a difference without statistical significance. Within the endoprosthesis group, independent analysis of fixed versus rotating hinge designs was unable to be performed as studies including rotating hinges did not report separate aseptic loosening rates in this subgroup of their analysis. When comparing cemented versus uncemented prostheses, there was a significantly higher rate of aseptic loosening in cemented prostheses (RR = 8.53; 95% CI: 1.16–62.7, p = 0.035). Eleven percent of cemented endoprostheses had

aseptic loosening (five studies, 19 of 168 patients) versus 1.2% of uncemented endoprostheses (three studies, 1 of 83 patients).

Bushing failures requiring re-operation occurred in 7.1% of endoprostheses when recorded.

Implant fractures occurred in 2.7% of endoprostheses and 0% of APCs. Periprosthetic fractures occurred in 2.8% of endoprostheses. No periprosthetic fractures were reported in APCs. Allograft fractures occurred in 30.9% of osteoarticular allografts and in 10.9% of APCs which was statistically significant in favor of APCs (RR = 0.35; 95% CI: 0.2–0.62, p <0.001).

One of the unique challenges of reconstruction after resection of proximal tibia tumors is reconstruction of the extensor mechanism. Of the papers that reported on extensor mechanism failures, they were reported in 6.6% of endoprostheses and in 13.4% of APCs and 0% in osteoarticular allografts (0/97 patients). Osteoarticular allografts were significantly less likely to have extensor mechanism failure than endoprostheses (RR = 0.93; 95% CI: 0.9–0.97, p = 0.01) or APCs (RR = 0.87; 95% CI: 0.81–0.93, p <0.001). Endoprosthesis also had a statistically significantly decreased failure rate compared to APCs (RR = 0.49; 95% CI: 0.25–0.96, p = 0.03).

Three studies on endoprostheses looked at mean extensor lag, with means of 6, 18, and 30° reported. Thirty percent of patients with endoprostheses had an extensor lag >5° (24 of 79 patients, two studies, range 25–37%) as compared with 26% patients with APCs (10 of 38 patients, two studies, range 25–27%). Unfortunately, the articles on osteoarticular allografts did not comment on extensor mechanism failure or extensor lags.

Question 2: In patients receiving allograft megaprosthesis, what are the comparative functional outcomes between osteoarticular allografts, APCs, and endoprostheses via Musculoskeletal Tumor Society (MSTS) score or range of motion, if applicable?

Proximal humerus

The mean 1993 revised MSTS score was 73.6% (22 out of 30) in the endoprosthesis group, 72% in the osteoarticular allograft group, and 77% in the APC group.

Range of motion was infrequently reported. Endoprostheses had an overall mean of 40° abduction and 47° forward flexion Mean range of motion in osteoarticular allografts was abduction of 59° and forward flexion 47°. In APCs, a mean abduction of 55° and a mean forward flexion of 48° was reported.

Proximal tibia

The mean 1993 revised MSTS score was 76% (23.8 out of 30) in the endoprosthesis group, 77% in APCs, and 90% in osteoarticular allografts.

Question 3: In patients receiving allograft megaprosthesis, what is the comparative success of limb salvage and implant survival at 5, 10, and 20 years between osteoarticular allografts, APCs, and endoprostheses?

Proximal humerus

Amputation for any reason was required in 5.1% of patients with endoprostheses, in 10% of patients with osteoarticular allografts, and in 1.7% of APCs. These differences were not statistically significant.

Five-year survival based on Kaplan–Meier survival analysis in endoprostheses showed a range of 83–100%. The range in osteoarticular allografts was 56–78%, and was 90–91% in APCs. Mean 10-year survival rate in endoprostheses was a range of 42–93%. It was not reported in osteoarticular allografts, and was 88% in APCs based on one paper. Only the endoprosthesis group had a 20-year survival rate reported as 66.7–70%.

Mean revision rate for any reason for the endoprosthesis group was 12.8%, 37.2% for osteoarticular allografts, and 10% for APCs. Endoprostheses and APCs had a significantly lower rate of revision than osteoarticular allografts (RR = 0.34; 95% CI: 0.23–0.52, $p < 0.001$; RR = 0.27; 95% CI: 0.14–0.53, $p < 0.001$). There was no significant difference between endoprostheses and APCs. Re-operation rates were infrequently tabulated in the included studies and thus was not analyzed specifically.

The overall five-year survival appears similar between endoprostheses and APCs, both of which have a trend toward improved survival when compared to osteoarticular allografts. Follow-up studies are needed to better predict the 10- and 20-year survival rates of these reconstructions.

Osteoarticular allograft reconstructions have a statistically significant higher rate of revision operations when compared to endoprostheses and APCs.

The rate of deep infection is significantly lower in endoprostheses when compared to osteoarticular allografts and APCs.

Allograft fracture occurred in a high percentage of osteoarticular allografts (30.8%). This, along with the higher rate of deep infections, may account for the significantly higher rate of revision operations.

Interestingly, despite the common belief that osteoarticular allografts offer improved stability due to the ability to repair donor tendon/ligament attachments back to what remains of host soft tissue, osteoarticular allografts had a significantly higher rate of dislocation without any apparent improvement in range of motion or MSTS score. Endoprostheses had the lowest dislocation rate (6%) and APCs fell in between with 10.3%. Range of motion was similar in all groups and overall poor, with no reconstruction obtaining a mean abduction greater than 60° or forward flexion greater than 50°.

Proximal tibia

Amputation for any reason was required in 15.1% of patients with endoprostheses, in 7.5% of patients with APCs, and in 12.7% of patients with osteoarticular allografts. Amputations in the endoprosthesis group were

higher than APCs and it almost reached statistical significance (RR = 2.0; 95% CI: 0.97–4.15, p = 0.05).

The range of five-year survival rate based on Kaplan–Meier survival analysis was 54–84.5% in the endoprosthesis group. It was 45–78% in osteoarticular allografts and 68–73% in APCs. The 10-year survival rate range was 30–63%, 20–68% in osteoarticular allografts, and 33% in APCs. Only the endoprosthesis group had 20-year survival rates reported as 20.7 and 27% in two papers.

Mean revision rate for any reason for the endoprosthesis group was 35.7%, 36% in the osteoarticular allograft group, and 35.1% in the APC group. These differences were not statistically significant. Re-operation rates were infrequently tabulated in the included studies and thus were not analyzed specifically.

Resolution of clinical scenario

Proximal humerus

Though it is difficult to make strong recommendations as to the type of reconstruction that should be performed in the proximal humerus, it should be noted that osteoarticular allografts performed the worst in every outcome examined, with the exception of mean abduction. Endoprostheses and APCs performed quite similarly, with each appearing to be a viable reconstruction option.

Proximal tibia

Overall, proximal tibia reconstructions have the highest rates of amputation, the highest revision rates, and the shortest overall survival when compared to reconstructions in any other part of the body.

Five-year survival rates and revision rates were similar between the three methods of reconstruction; however,

more data are needed to compare the long-term survival of these reconstructions.

Using the data obtained, endoprostheses had a lower infection rate than osteoarticular allografts. APCs trended toward a significantly lower rate of amputation than endoprostheses. Extensor mechanism failure was significantly higher in both APCs and endoprostheses compared to osteoarticular allografts. APCs also had significantly more extensor mechanism failures than endoprostheses. There was no statistical difference between the groups in regards to local recurrence.

Aseptic loosening is similar between endoprostheses and APCs (7.8 and 9%, respectively). Allograft fracture is common, being seen in 30.9% of osteoarticular allografts, and 10.9% of APCs, significantly favoring APCs.

Based on the data points analyzed, it is not possible to definitively recommend one type of reconstruction over the other in the proximal tibia. However, it is important to note the differential risks between the three groups for fractures, deep infection, and extensor mechanism failure. There is a higher risk for fracture in osteoarticular allografts compared to peri-prosthetic fractures for APCs and endoprostheses. We also found a higher risk of deep infection in osteoarticular allografts compared to endoprostheses, and a higher risk of extensor mechanism failure in APCs and endoprostheses compared to osteoarticular allografts. APCs nearly had a statistically significant lower risk of amputation than endoprostheses. Uncemented endoprostheses appear to have a lower rate of aseptic loosening than cemented stems, albeit with small numbers. Certainly, inconsistent reporting of complications and the overall sample size is small, so differences between each reconstruction type may be over- or underestimated due to statistical power.

Summary of answers

- Osteoarticular allografts and endoprostheses perform well in the proximal humerus.
- In the proximal tibia, there is a higher risk of fracture and deep infection in those treated with osteoarticular allografts, while there is a lower risk of extensor mechanism failure in these patients.

171 Biopsy of Soft Tissue Masses

Aaron Gazendam MD, Anthony Bozzo MD MSc, Casey Wang MD, and David Wilson MD MASc
Division of Orthopaedic Surgery, Department of Surgery, McMaster University, Hamilton, ON, Canada

Clinical scenario

- A 70-year-old woman has an enlarging mass in the right axilla. Her primary care physician orders a needle biopsy to be done by a radiologist who carries out a fine needle aspiration (FNA) from 15 different sites around the 4 cm mass in order to obtain adequate tissue. The result is nondiagnostic but suggestive of malignancy, possibly carcinoma with necrosis. The patient is referred to a breast oncologic surgeon, who performs an extensive lymph node dissection and open biopsy of the axillary mass. The entire brachial plexus is carefully exposed and protected during the lymph node dissection. The pathologist finds that the lymph nodes are normal, but the axillary mass is diagnosed as a high-grade sarcoma. The woman is then referred to an orthopedic oncologist, who discusses forequarter amputation for adequate local control.
- The initial needle biopsy contaminated a large area of soft tissue around the sarcoma and was nondiagnostic. The next biopsy was definitive in making the diagnosis, but contaminated further tissue by exposing the brachial plexus at the time of the sarcoma biopsy. A carefully placed biopsy with adequate tissue for diagnosis could have allowed this woman a limb-sparing resection with an excellent chance of local control and probable cure.

Top three questions

1. In patients requiring diagnostic biopsies, does percutaneous biopsy result in different diagnostic accuracy and complication rates compared to surgical biopsy?
2. In patients undergoing biopsy of a soft tissue mass, what are the evidence-based biopsy principles that reduce potential complications and improve outcomes?
3. In patients with soft tissue masses, does biopsy by a specialist at a sarcoma center, compared to a community surgeon in a nonspecialized center, reduce biopsy-related complications and improve survival?

Question 1: In patients requiring diagnostic biopsies, does percutaneous biopsy result in different diagnostic accuracy and complication rates compared to surgical biopsy?

Rationale

There are various methods of biopsy that are available to clinicians when a histologic analysis is required for a patient presenting with a soft tissue mass. The three most common options available are incisional biopsies (IBs), core needle biopsies (CNBs), and FNAs. It is important to understand the advantages and disadvantages of each technique.

Clinical comment

Historically, open biopsies have been considered the gold standard for biopsies of soft tissue masses as provide large volumes of tissue sample which facilitates high diagnostic accuracy. increased morbidity. Percutaneous options, including FNAs and CNBs, have been introduced in attempts to reduce complications and cost while maintaining diagnostic accuracy.

Available literature and quality of the evidence

Level I–III evidence exists to answer this question.

Findings

Kasraeian et al. (level I) prospectively studied 57 patients with palpable soft tissue masses, performing first an FNA, followed by CNB, followed by open biopsy of the same mass.[1] They reported 100% accuracy with regards to the surgical biopsy compared to 80.7 and 75.4% accuracy of the CNB and FNA, respectively. Yang and Damron (level II) compared FNAs to CNBs in the same 50 consecutive patients.[2] CNB was found to have a higher diagnostic accuracy than FNA with respect to nature of the lesion, specific diagnosis, as well as histologic grading and typing. Traina et al. (level IV) performed a systematic review analyzing the accuracy rates of the various biopsy methods.[3] IB has a documented accuracy of 94–100%, CNB a reported accuracy of 72.7–100%, and FNA a wide accuracy range of 21.9–98%.

With regards to complication rates, there is a lack of high level evidence reporting on the differences between open and percutaneous biopsies. Mankin et al. (level III) obtained records from 25 orthopedic oncologists to determine the rates of complications associated with surgical biopsies. Out of 507 patients undergoing for a bone or soft tissue tumor, 15.9% of patients had a

complication associated with the biopsy.[4] Barrientos-Ruiz et al. (level III) retrospectively assessed the number of biopsy tracts that were contaminated with tumor cells at the time of definitive resection in 221 patients with bone and soft tissue sarcomas (STS).[5] They found that significantly more IBs had contamination when compared to percutaneous CNB (odds ratio [OR] = 56; 95% confidence interval [CI]: 7–428; p <0.001). The local recurrence-free survival was shorter with patients who had biopsy tract seeding (mean 11 months; 95% CI: 1–20 months; p <0.001). Adams et al. (level II) reviewed 252 CNBs of bone and soft tissue neoplasms performed in an outpatient setting. They recorded zero biopsy-related complications and a diagnostic accuracy of 91%.[6]

With advancements in interventional radiology and image guided biopsies, there has been an interest in image guided percutaneous biopsies. Narvani et al. (level II) compared nonimage guided CNB with image guided (computed tomography [CT] or ultrasound) CNB in 140 patients with suspected STS.[7] They demonstrated that the diagnostic accuracy of image guided CNB was significantly higher when compared to nonimage guided CNB (95% vs 78%, p <0.025) despite the image guided group having smaller and deeper tumors. However, excellent accuracy results have been published for unassisted CNB in the diagnosis of soft tissue masses. The two methods are difficult to compare as there is likely a bias toward more superficial and larger masses when nonimage guided biopsies are performed.

Overall, level I evidence suggests that incisional surgical biopsies have higher diagnostic accuracy when compared to CNB and FNA. However, IB have significantly higher morbidity than both CNB and FNB.

Resolution of clinical scenario

- Level I evidence suggests that IB has higher diagnostic accuracy when compared to CNB and FNA.
- Level II–IV evidence suggests that open biopsy has higher morbidity than both CNB and FNA.
- Level II–IV evidence suggests that CNB provides higher diagnostic accuracy when compared to FNA.
- Level I evidence that both image guided and nonimage guided CNB can produce acceptable diagnostic accuracy levels; however, for deeper and smaller masses, image guided biopsy is recommended.
- Given the relatively high diagnostic accuracy and low complication rates, CNBs are favored as the first line tool for biopsies of soft tissue masses.

Question 2: In patients undergoing biopsy of a soft tissue mass, what are the evidence-based biopsy principles that reduce potential complications and improve outcomes?

Rationale

Biopsies are a critical step in the timely diagnosis and treatment of soft tissue masses. Inappropriately performed biopsies can result in tumor spread, compromising reconstructive options, and sometimes lead to amputations in order to gain local control.

Clinical comment

Historically, there are several biopsy principles that have been utilized in order to minimize biopsy-related principles. With changes in how biopsies are performed, it is important to revisit these principles to determine if they are the safest options for patients requiring a diagnostic soft tissue biopsy.

Available literature and quality of the evidence

Level III–V evidence exists to answer this question.

Findings

Much of our early understanding regarding the complications of biopsies are gleaned from the landmark study by Mankin et al. (level III) in which data from 25 surgeons on 597 patients with malignant soft tissue or bone tumors were analyzed.[4] 16.6% of patients with soft tissue tumors had their outcomes negatively altered due to errors or complication in biopsies.

All lesions should be treated as malignant until a biopsy proves otherwise. There is expert consensus that meticulous hemostasis must be obtained to prevent postoperative hematoma (level V).[3,8] Postbiopsy hematoma must be considered contaminated by tumor cells, and large hematomas have the potential to contaminate the entire extremity leaving amputation as the only curative option.[8]

The surgeon performing the definitive surgery should be consulted prior to biopsy to determine appropriate placement of the biopsy tract.[8] Historically, the soft tissue tract that the biopsy was performed through was considered contaminated and was excised at the time of definitive surgery.

The literature has supported these concerns in the case of open biopsies. If IB is indicated, the incision should be

performed longitudinally in line with the proposed surgical approach to minimize the amount of soft tissue resection required at the time of definitive surgery.[4] Barrientos-Ruiz et al. (level III) determined that a significant percentage of IB had biopsy tract contamination which was associated with a reduced local recurrence-free survival.[5]

However, in the case of percutaneous biopsies, recent literature and expert opinion have found that excision of the biopsy tract may not affect outcomes.[5],[9],[10] Siddiqi et al. (level III) evaluated 36 patients with STS that did not have biopsy excisions and matched with 36 patients who had resection of the biopsy tract.[11] All patients underwent percutaneous needle biopsy and there was no difference in local recurrence or five-year survival, suggesting excision of the biopsy tract may be less critical after percutaneous biopsy. Barrientos-Ruiz et al. (level III) also examined percutaneous biopsy tracts for contamination and found that only 0.8% of CNBs had evidence of cell seeding.[5]

Historically, expert opinion has also recommended that biopsies occur within one muscular compartment and avoid critical structures including joints and neurovascular structures in attempts to reduce the risk of tumor spill.[12] However, UyBico et al. (level III) retrospectively reviewed percutaneous needle biopsies performed in 363 patients with musculoskeletal tumors.[13] They found 3.6% of biopsies violated the anatomic compartment and 11.6% of biopsies violated critical structures. No cases of recurrences were attributed to seeding along the needle tract.

There is level III evidence that among patients who require IB, there are high rates of biopsy tract seeding.[5] There is level III evidence that, in patients who undergo CNB, resection of the biopsy tract does not alter recurrence or survival rate.[11] There is level III evidence that patients who undergo CNB that violates historically critical structures do

not have higher recurrence rates.[13] There is expert opinion (level V) that meticulous hemostasis is required to reduce the risk of tumor spread secondary to postoperative biopsy.[3]

Resolution of clinical scenario

- There is level III evidence that IB tracts have a significant rate of tumor seeding and thus should be excised at the time of definitive surgery.
- There is level V evidence that meticulous hemostasis is required to prevent tumor spill and postoperative hematomas.
- There is level III evidence that CNB tracts do not need to be excised in the definitive resection.
- There is level III evidence that violation of previously considered critical structures does not increase recurrence in patients who undergo CNB.

Question 3: In patients with soft tissue masses, does biopsy by a specialist at a sarcoma center, compared to a community surgeon in a nonspecialized center, reduce biopsy-related complications and improve survival?

Rationale

Some debate exists on the safety and outcomes of soft tissue biopsies performed in a nonspecialized community setting compared to those performed by experienced

personnel in a specialized sarcoma center. Errors and complications related to the biopsy may influence the clinical course and have a profound impact on survival, quality of life, and cost of care.

Clinical comment

Biopsy is one of the first crucial steps in the diagnosis and management of musculoskeletal lesions. The importance of an accurate and safe biopsy cannot be overstated, as it provides a presumptive diagnosis that will determine management and impact the rest of the clinical course. Delayed or misdiagnosed lesions may lead to inappropriate treatments, greater complications, and decreased survival. There may also be a difference in biopsy-related complications between biopsies performed by community surgeons in a nonspecialized institution compared to those performed by experienced personnel in a specialized sarcoma center.

Available literature and quality of the evidence

Level III–IV evidence exists to answer this question.

Findings

The setting in which soft tissue biopsies take place has been reported to have a direct impact on outcomes in patients with STS. In this context, most of the current literature favors soft tissue biopsy carried out by experts in a specialized sarcoma center over those done by community surgeons in a nonspecialized referring institution.[4,14–18]

The aforementioned paper by Mankin et al. (level III) remains one of the most well-known articles that advocate for soft tissue biopsies to be undertaken at specialized centres.[4] Based on a retrospective evaluation of 597

patients from 25 surgeons across 21 institutions, patients who had a biopsy performed at a nonspecialized institution were more often inaccurately diagnosed (27.4% vs 12.3%), underwent technically poor procedures more frequently (13.9% vs 3.5%), had a greater number of treatment plan alterations (36.3% vs 4.1%), and had a change of clinical course more often as a result of the biopsy (17.4% vs 3.5%) compared to patients who were biopsied in specialized sarcoma centers. The authors suggest that the inherent difficulty level of the biopsy procedures coupled with the inexperience of community practitioners may put the patient at greater risk of complications and change the course of the disease.[4]

The European Cancer Organization (ECCO) published a review detailing updated practice recommendations among European oncology practitioners (level V).[15] Most notably, the ECCO framework discouraged biopsies performed in the community setting and reported that biopsies performed by nonexperts may lead to missed diagnoses, more complications, ineffective subsequent treatments, and possible tumor spread. In line with these recommendations, Bedi et al. (level III) retrospectively reviewed 92 patients with STS who had undergone percutaneous biopsy at either a tertiary sarcoma center or a community hospital.[19] They found that patients undergoing CNBs in the community had significantly higher wound complications after their definitive surgery.

The ECCO framework also highlights the importance of having radiology experts involved in image-guided CNBs as the preferred first method for tissue sampling. This recommendation is reaffirmed in Kubo et al.'s (level IV) systematic review and meta-analysis involving 32 studies and 7209 musculoskeletal lesions.[17] They found that diagnostic accuracy was slightly improved if the CNB

operator was a radiologist compared to if they were a surgeon, likely due to their expertise in interventional radiology techniques.[17]

Care based in specialized sarcoma centers also benefits from improved accuracy in histologic diagnoses from specialized pathologists. Ray-Coquard et al. (level II) performed a population based study in which histologic samples of 1463 sarcoma patients were reviewed by expert pathologists.[18] More than 40% of histological diagnosis made by community pathologists were modified at second reading by a specialized pathologist.

Resolution of clinical scenario

- Level III evidence suggests that patients with STS who undergo biopsy by an expert with multidisciplinary support at a specialized sarcoma center have fewer biopsy-related complications, greater diagnostic accuracy, and more timely treatment.
- There is level IV evidence that CNBs performed by radiologists have higher diagnostic accuracy than those performed by orthopedic surgeons.
- Level II evidence demonstrates that sarcoma-trained pathologists' histologic diagnoses differ significantly from nonspecialized pathologists' diagnoses.

Summary of answers

- CNB is the preferred first-line biopsy in patients with soft tissue masses given their acceptable diagnostic accuracy rates and low morbidity. If nondiagnostic, open biopsy should be considered.
- In the case of IB, the biopsy tract should be made in line with the planned incision and should be excised at

the time of definitive surgery. There is a lack of evidence suggesting CNB tracts require excision.

- Biopsies should be performed by subspecialized personnel, radiologists, or fellowship trained orthopedic oncologists, and should be interpreted by specialized pathologists.
- Care coordinated through a specialized sarcoma center improves outcomes.

172 Denosumab in Giant Cell Tumors of Bone

Michael Parry MD and Robert Grimer MD
Royal Orthopaedic Hospital, Birmingham, UK

Introduction

Giant cell tumor of bone (GCTB) is a primary, intermediate grade tumor with an aggressive local behavior and a rare tendency to metastasize (Ref). The tumor has a preponderance for the meta-epiphyses of long bones, particularly in patients in the third to fifth decade, though it can arise in difficult sites for management, such as the spine and pelvis. Histologically, GCTBs are composed of large, multinucleated giant cells, which resemble osteoclasts in both form and function, and stromal cells which comprise macrophage-like, non-neoplastic cells, and mononuclear spindle cell shaped fibro-osteoblastic-like stromal cells. These neoplastic stromal cells express receptor activators of nuclear factor kappa-B ligand (RANKL), which promote and activate the giant cells, which express RANK, resulting in the characteristic bone resorption seen in GCTB.

Conventional treatment for GCTB comprises surgical removal, either through intralesional curettage, or by en bloc excision or, in extreme cases, amputation. Recurrence following intralesional excision varies but ranges from 12 to 67%. There is no convincing evidence that adjuvants reduce the rate of recurrence following detailed curettage, although a variety are widely used including phenol, liquid nitrogen, cement, etc. The high risk of recurrence and the need for multiple surgical procedures may be associated with a high degree of morbidity. This has prompted the

drive for novel agents to improve local control and maintain function at an acceptable level of morbidity.

Denosumab is a fully human monoclonal antibody that binds with high affinity and specificity to the soluble and cell-membrane forms of human RANKL. Its effect is to effectively switch off osteoclastic activity and, when used for the treatment of GCTB, to stop the lytic effect, pushing bone turnover toward bone formation.

Top three questions

1. In patients with truly inoperable GCTB, is denosumab a safe treatment in the long term?
2. For patients with extensive GCTB, does denosumab allow salvage of the joint where previously the joint would have been sacrificed?
3. How would patients on denosumab benefit from further research?

Question 1: In patients with truly inoperable GCTB, is denosumab a safe treatment in the long term?

Rationale

While denosumab has found a role in the neoadjuvant management of GCTB, it is increasingly being used for tumors where resection presents a significant challenge or risk of mortality, or where the morbidity associated with resection is unacceptable. Such sites include the base of skull or large tumors of the spine and sacrum. In such sites, denosumab is increasingly being used as a definitive treatment option, often with good effect.

Clinical comment

The long-term effects of such prolonged treatment remain unknown or as yet undiscovered. Given the age group most commonly affected by GCTB, many of the acceptable side effects of denosumab applicable to the more conventional use of the drug for the treatment of metastatic bone disease do not apply, and indeed many new side effects have become apparent in the drug's novel application to GCTB. The rate of relapse while on treatment remains uncertain and the risk of relapse after treatment is stopped (for whatever reason) is also not yet known

Available literature and quality of the evidence

Acute side effects of denosumab treatment include bone pain, fatigue, headache, nausea, hypocalcemia, hypophosphatemia, and osteonecrosis of the jaw.[1–3] While the long-term effects of bisphosphonates when used in children and adolescents have been documented,[4,5] the same cannot be said for denosumab. Only 10 adolescent patients were included in the original safety study for denosumab in GCTB,[1] as denosumab is contraindicated in the skeletally immature. The safety of long-term denosumab in the treatment of osteogenesis imperfecta has been shown.[6] However, it should be noted that four juvenile patients developed severe rebound hypercalcemia following cessation of denosumab,[7] a phenomenon reproduced in other applications of denosumab, including GCTB.[8,9] This rebound hypercalcemia has also been reported in the adult population following cessation of denosumab after prolonged treatment for GCTB.[10] Therefore, great caution and hypervigilance for this potentially fatal phenomenon should be exercised after cessation of denosumab.

The effect of denosumab on the human fetus remains unknown. Denosumab was seen to result in increased stillbirths, decreased body weight gain, and decreased growth and development in cynomolgus monkeys,[11] though no case reports exist in the literature to assess the effect on human fetal development. In the absence of such evidence, it is mandatory that female patients avoid pregnancy while undergoing denosumab treatment. This raises a treatment challenge for females of childbearing age with an inoperable GCTB, and patients must be counselled accordingly.

In a multicenter retrospective study on the efficacy of denosumab in unresectable GCTB, Palmerini et al. were able to monitor the long-term effects of prolonged denosumab treatment.[12] The study comprised 97 patients, though 43 went on to have surgical resection after a median time of 12 months. The remaining 54 patients were on denosumab on continuous treatment for the treatment of unresectable GCTB or metastatic GCTB. Twenty patients stopped denosumab treatment for a variety of reasons, and of these 20 patients, further information was available on only 10. Of these 10 patients, four developed recurrent disease after a median of eight months. The incidence of osteonecrosis of the jaw (ONJ) on those on prolonged treatment was 9% with a five-year ONJ-free survival of 92%. Other side effects included mild peripheral neuropathy (11%), skin rash (9%), hypophosphatemia (4%), and atypical femoral fractures (4%). The study supports the long-term use of denosumab in unresectable GCTB with an acceptable safety profile, supporting the findings of others.[1,2] The authors have demonstrated an effective cure following cessation of denosumab in six patients on whom data were available, though it should be noted that only two of these patients have follow-up beyond 12 months.

Rutkowski et al. reported a control rate of 92.3% at almost four years in 48 patients with inoperable disease.[13]

How long and at what dose to continue denosumab remains an area of debate. It would seem logical that, in patients in whom a steady state has been achieved (usually 9 12 months of treatment) and in whom surgery is not possible, reducing the frequency of dosing may reduce the side effect profile. While published data outside of individual case reports are lacking,[14] several reports have been presented demonstrating effective local control at a reduced dose frequency. These findings contradict the findings of Lipton et al., who found that a three-monthly dosing regimen was insufficient to maintain local control in metastatic bone disease, when compared to monthly dosing.[15] However, these findings were in patients who had not yet achieved a steady state of the drug through prolonged monthly dosing.

Concern has been raised around the possibility of malignant transformation of GCTB, which some have speculated relates to the use of denosumab. In an initial safety study on the application of denosumab for GCTB, Thomas et al. report two cases of sarcoma developing while on denosumab.[2] In one case, the patient developed a high-grade sarcoma in the upper limb, and the second developed lung metastases following malignant transformation of a GCTB eight months following discontinuing denosumab. Chawla et al. reported two cases of malignant transformation while undergoing denosumab treatment.[1] However, in one, this was thought to be a misdiagnosis of GCTB, while in the second this was considered malignant transformation of a GCTB. Rutkowski et al. reported 4/222 patients undergoing denosumab developed malignant transformation.[3] However, in two of these cases, this transformation was within the field of previous

radiotherapy, while in the latter two cases the diagnosis of malignant GCTB had not been made due to a sampling error at presentation. Further case series have reported on individuals who have developed malignant GCTB while undergoing denosumab treatment for histologically confirmed GCTB.[16],[17] In all three cases, the malignant transformation occurred in recurrent GCTB having initially undergone a number of previous procedures, in one case en bloc resection.

Evidence is at best level III but in the majority of available literature, it is level IV or V.

Findings

It would appear that the risks of long-term denosumab are offset by the almost universal response of GCTB to denosumab.

Resolution of clinical scenario

It remains to be seen if the risks of recurrence and serious side effects can be reduced by decreased frequency of dosage once control of the primary tumor has been achieved.

Question 2: For patients with extensive GCTB, does denosumab allow salvage of the joint where previously the joint would have been sacrificed?

Rationale

A second application of denosumab in the treatment of GCTB is in the setting of advanced local disease where

extensive bone destruction has rendered the salvage of bone or joint unfeasible either due to pathological fracture or due to extensive infiltration or soft tissue extension.

Clinical comment

Higher-stage lesions (those with extensive bone destruction and soft tissue involvement) are associated with a higher rate of local recurrence following intralesional curettage when compared to Campanacci 1 or 2 lesions.[18] In such situations, sacrifice of the joint may be the only option to achieve an acceptable rate of local recurrence. And the addition of denosumab may allow effective downstaging of the tumor and facilitate joint preserving surgery with an improved rate of local recurrence.

Available literature and quality of the evidence

Denosumab results in the formation of a rim of new bone around the tumor essentially downstaging a Campanacci 3 lesion to a lower grade.[3],[19] An early report by Gaston et al. demonstrated the effective treatment of a Campanacci 3 lesion of the proximal femur with neoadjuvant denosumab, curettage, and autologous fibula grafting that, without denosumab, would have required joint sacrificing surgery.[20] An interim analysis of the phase II study on the efficacy of denosumab in the treatment of GCTB identified patients in whom neoadjuvant denosumab was given in an attempt to downstage tumors and therefore allow less aggressive surgical management.[1],[3] In their study, the authors prospectively recorded the intention to treat at the point of diagnosis. The study population comprised 222 patients, of whom 148 (66.7%) were undergoing treatment for a primary GCTB. High morbidity procedures (e.g. amputation, hemipelvectomy) were avoided in 80%, while 80% of patients in whom an en bloc excision and 37% of

patients in whom an en bloc resection was planned managed to avoid an operation. The native joint preservation rate was 96%. Therefore, in summary, assuming that all 222 patients were intended to have a surgical intervention at the outset in the absence of denosumab, the addition of denosumab has delayed the need for surgery in 48% and a further 38% have undergone a lesser surgery than was planned without the addition of denosumab.

While this is the largest series aimed at answering the question of whether denosumab can downstage GCTB and reduce the morbidity of surgical treatment, it is not without flaws. This was a multicenter study from a number of different countries. The treatment decision at diagnosis was at the discretion of the treating physician and not based on standardized criteria or by peer review. What was deemed only treatable by excision in one institution may have been regarded as treatable by curettage in another. In addition, no details are given of the specific relapse rate for those who underwent a lesser morbid surgery. While the authors state a local recurrence rate of 15% for those who underwent surgery (17/116) at a median time of 13 months (interquartile range [IQR]: 8.5–17.9), the exact details of these recurrences are not given. The question remains, therefore, in the case of those whose disease was downstaged allowing less morbid surgery: was this at the expense of an increase in local recurrence?

Traub et al. reported on 20 patients with GCTB classified as Campanacci 2 (7/20) or Campanacci 3 (13/20), in whom joint preservation at presentation was felt not to be possible or at high risk of failure treated with neoadjuvant denosumab and subsequent intralesional curettage.[21] All underwent intralesional curettage with preservation of the joint in 18/20. At a median follow-up of 20 months (range 20–45), three patients (15%) after curettage.

While providing a detailed analysis of the success in downstaging disease in a group of *high risk* GCTB, the identification of patients deemed unresectable must again be questioned. Discrepancy exists between specialist opinions as to what constitutes a *high risk* tumor, and the potential efficacy of curettage for particular lesions. While the authors felt that the tumors included were likely to recur or go on to jeopardize nearby joints, other experts in the field may disagree with this decision and proceed directly to curettage without denosumab. The success of denosumab in downstaging the GCTB therefore must be questioned as there is the possibility that in other centers these lesions would have been treated with curettage without denosumab with a comparable potential for cure.

In a retrospective assessment of a cohort of patients with GCTB, Rutkowski et al. analyzed the effect of denosumab on local control in 138 patients, a subset of whom (23/138, 17%) were deemed as unresectable.[13] Of the remaining 115 patients, 89 went on to have surgical treatment after neoadjuvant denosumab, with a median duration of six months of treatment. Fifty patients (56%) were treated by curettage, while 39 (44%) underwent excision including prosthetic replacement in 17. The rate of relapse was 21% after surgical treatment, 32% after intralesional curettage, and 7.7% after excision (no patients who underwent prosthetic replacement relapsed).

It is difficult to extrapolate these findings to the GCTB population as a whole in that, again, it is difficult to comment on whether denosumab downstaged tumors and allowed less aggressive treatment. The authors did not state the intention to treat prior to commencing denosumab. Even if these details had been included, it would have been difficult to state categorically that patients had undergone less intrusive surgery as a result of denosumab. However, the authors stated that “all these

tumours were very advanced locally with large soft tissue mass," and if one were to assume that all those treated with neoadjuvant denosumab would likely have required excision, including sacrifice of the joint, then denosumab does offer an attractive alternative.[13]

There is concern that the neo-ossification seen after denosumab treatment may reduce the likelihood of cure following curettage. This rim of new bone may harbor neoplastic stromal cells which are insufficiently removed at the time of curettage and which reactivate the GCTB following cessation of denosumab. Where curettage is planned for local control and denosumab is being used as an adjunct, a shortened course should be considered. While some speculate a reasonable period to be three months,[13] the exact balance between effective consolidation and unacceptable rates of local recurrence remains unclear. Surgeons using denosumab prior to intralesional curettage must be cognizant of the need for a more detailed and rigorous curettage than would be expected for GCTB without prior denosumab. This may account for the increased risk of local recurrence following curettage following denosumab observed by some.[22] The role of adjuvants in this situation to extend the *biological margin* of curettage is again unclear, as it is for primary GCTB.

Evidence is at best level III, but in the majority of available literature it is level IV or V.

Findings

There is increasing, evolving evidence to support the use of denosumab in downstaging GCTB allowing less morbid surgical treatment. Questions still remain about the duration of denosumab prior to curettage allowing an acceptable rate of local recurrence. Surgeons must be cognizant of the effect of denosumab on GCTB when

undertaking intralesional procedures due to the potential for neoplastic cells to remain in the corticated margin of the GCTB and therefore significantly increase the risk for LR.

Resolution of clinical scenario

A clinical trial comparing primary curettage with a group of patients pretreated with denosumab may well be the only way this question can be answered. The use of adjuvants could be another arm of that trial, as could the duration of pretreatment.

Question 3: How would patients on denosumab benefit from further research?

Rationale

While the benefits of denosumab in the treatment of GCTB are immediately apparent, this is clearly an evolving field that requires close scrutiny and further research. The question therefore that follows is in what areas should this research be focused. With our understanding of denosumab evolving with time, it is imperative that we focus our attention on key areas that will benefit patients.

Clinical comment

Questions remain as to the efficacy and application of denosumab for patients with GCTB. These areas of future research should focus on:

- Can denosumab still achieve local disease control at a reduced dose or reduced dose frequency in inoperable cases?

- Is denosumab the best option for local disease control for GCTB?
- Is there an effective way to monitor the response of GCTB to denosumab to try to more accurately predict the risk of recurrence?
- What is the optimum duration of denosumab treatment prior to curettage for operable GCTB?
- Is there a benefit to using adjuvants along with curettage in patients with operable GCTB?

Available literature and quality of the evidence

Conventional treatment algorithms for denosumab when applied to GCTB utilize a dose and frequency of administration based on experience with the drug's application to metastatic bone disease. However, this regimen may well be at an inappropriate dose and frequency for its application to GCTB. Instead, a reduced dose or a reduced frequency may still be effective at achieving local disease control with the added benefit of a reduction in drug-related side effects. While no published evidence exists in this area, small series have been presented at a number of society meetings reporting acceptable rates of disease control using denosumab at a less frequent dose administration than is conventional. This will be the focus of a recently opened multicenter study conducted by the European Organization for Research and Treatment of Cancer (EORTC).

While denosumab is clearly effective at controlling the osteoclastic effect of giant cells, it does not have an effect on the neoplastic stromal cells responsible for giant cell activation. This explains the reactivation of GCTB following cessation of denosumab. Zoledronic acid, a nitrogen-containing bisphosphonate, induces osteoclast apoptosis

through interference with the activation of RAS-related protein, and has demonstrated efficacy in the treatment of benign and malignant lesions of bone.[23] Comparative studies using denosumab or zoledronic acid in the treatment of metastatic bone disease support the use of both agents though with a beneficial effect of denosumab both in terms of efficacy and serious adverse events.[24] In vitro studies on the effect of both agents on osteoclast and differentiation, survival, and cell growth have demonstrated superiority of zoledronic acid over denosumab in terms of osteoclast survival, osteoclast differentiation, and dose-dependent inhibition of neoplastic cell growth. In a comparative study administering neoadjuvant zoledronic acid prior to curettage of GCTB compared to curettage without zoledronic acid, a higher rate of recurrence was seen in those not receiving zoledronic acid (Kundu et al. 2018).[25] However, the potential beneficial effects of zoledronic acid do not appear to have been borne out by clinical studies. In a multicenter study on the effects of adjuvant zoledronic acid, Gouin et al. reported a recurrence rate of 15% which was not affected by zoledronic acid and compares to the local recurrence rate seen following curettage for comparable lesions treated without zoledronic acid.[26]

Treatment of GCTB with denosumab clearly has an effect on the histological appearance when compared to GCTB not conditioned by denosumab. GCTBs treated with denosumab consistently demonstrate ossification, fibrosis, depletion of giant cells, and proliferation of mononuclear cells.[27] While there is often a variable response in terms of viability of giant cells, a consistent feature is one of a reduction in the number of viable giant cells, though of course this will have no reflection on the likelihood of recurrence of the GCTB as this implies a reflection of the inhibition of RANKL activation. Further research should

focus on pathological assessment to the response of GCTB to denosumab treatment prior to resection or curettage to more accurately predict the likelihood of relapse and to guide surveillance.

Findings

While great advances in the understanding and application of denosumab and other anti-osteoclastic agents in the treatment of GCTB have been made, greater focus is still required to assess the response to these agents, to explore the role of alternative agents, and to guide treatment algorithms.

Resolution of clinical scenario

There appears little doubt that the treatment of GCTB has evolved dramatically with the introduction of denosumab. However, as this is an evolving novel application of an existing drug treatment, great efforts are required to more accurately assess its application in the treatment of GCTB. We can expect not only further understanding of this application, but also further awareness of the complications related to the use of denosumab in the neo-adjuvant treatment and definitive treatment of GCTB.

Summary of answers

- It remains to be seen whether risks of recurrence and serious side effects can be reduced by decreased frequency of dosage once tumor control is achieved.
- It is unclear whether pretreatment with denosumab can help promote limb salvage in patients with extensive GCTB.

173 Outcomes in Pediatric Orthopedics

Unni G. Narayanan MBBS MSc FRCS(C)
Departments of Surgery & Rehabilitation Sciences Institute, Division of Orthopaedic Surgery, University of Toronto, Toronto, ON, Canada
Division of Orthopaedic Surgery, Department of Surgery, University of Toronto, Toronto, ON, Canada

Measuring outcomes that matter in pediatric orthopedics

The mandate of *Evidence-Based Orthopedics* is to promote evidence-based practice and to identify areas of clinical uncertainty that would benefit from quality research. The quality of evidence is underpinned by the tenets of *evidence-based medicine* (EBM), a term first introduced by Gordon Guyatt,[1] based on the principles of critical appraisal developed by David Sackett, one of the pioneers of EBM.[2] For each clinical question tackled in this book, authors have used the *PICO framework* to guide their appraisal of the evidence pertinent to that question.[3] The *O* in PICO stands for the *outcome* that should be used to evaluate the effectiveness of the *intervention (I)* of interest relative to the *comparison intervention or control (C)* applied to a specific *patient population or problem (P)*. Fundamental to the practice of EBM is how we choose to define effectiveness, or the *O*. Sacket himself defined EBM "as the conscientious, explicit, and judicious use of current best evidence in making decisions about the *care of individual patients*."[4] The pillars of EBM include (i) using the best available external clinical evidence from

systematic research integrated with (ii) individual clinical expertise. Often overlooked is the third pillar of EBM, which is (iii) the “compassionate use of individual patients' predicaments, rights, and preferences in making clinical decisions about their care.” The emphasis on *patient values and preferences* in evidence based decision-making[5] evolved concurrently with the evolution of the outcomes research movement which set out “to sort out what works in medicine and to learn how to make clinical decisions that reflect more truly *the needs and wants of the individual patient*.”[6] The imperative for patient-centered care as a critical aspect of high-quality healthcare is enshrined in the Institute of Medicine Report in 2001.[7] The outcomes we measure should be meaningful to patients and consistent with their priorities and preferences.

This chapter reviews current concepts of outcome measurement, highlighting frameworks for the conceptualization of outcomes, with an emphasis on patient-reported outcomes (PROs) and the challenges pertinent to measuring these in children. The example of a child with ambulatory cerebral palsy (CP) will be used to demonstrate some of the advances and limitations of outcome measures for pediatric orthopedic patients.

Clinical scenario

- Consider a 10-year-old boy with bilateral spastic CP. He walks on tip toe, legs and feet turned in, and his knees flexed. He finds it difficult to keep up with his friends, trips frequently, tires easily, experiences knee pain, and is relying more on a walker even for shorter distances.
- He undergoes multilevel surgery to improve his gait. Six months after surgery and extensive physiotherapy,

he walks with his heels down and his feet pointing straight ahead. His knees come to full extension during stance.

- He is using a walker at home and at school and a wheelchair in the community. His knee pain has resolved. He experiences some hypersensitivity in his feet and uses ankle foot orthoses (AFOs) for support. His walking speed and endurance declined in the first few months after surgery but has recently improved, but not exceeded, his preoperative level.
- Has the intervention made him better?

What are outcomes?

Outcomes are the consequences of an intervention to treat a condition or what happens over time (natural history) if the condition is untreated.[8] An effective intervention is one which alters the natural history of that condition favorably and achieves the *goal(s)* for which that treatment was intended. The goals of an intervention can be *reactive*, to address a symptom or problem (e.g. eliminate knee pain, tripping, increase walking speed) or *preventative or prophylactic* to prevent some future problem associated with the natural history (e.g. preserves walking, prevents osteoarthritis in adulthood). Some outcomes occur early (e.g. improved gait pattern), while others occur later (e.g. improved walking speed and endurance several months after surgery). An intervention can be associated with many outcomes, some *desirable* (benefits) and others *undesirable* (harms). An undesirable outcome can be *expected* (e.g. postoperative pain, muscle weakness) or *unexpected – complications or adverse events* (e.g. dysesthesias in the feet following nerve stretch injury), which can be transient or permanent.

How does one judge the overall effectiveness of an intervention for an individual patient or a group of patients with a given condition?

Frameworks of health and disease and the evaluation of outcomes

Pediatric orthopedics has a relatively short history of recognizing the importance of measuring outcomes. In 1991, Michael Goldberg proposed a framework of outcomes assessment in which he made the distinction between the more immediate *technical* outcomes of an intervention (e.g. correcting excessive femoral anteversion, normalizing the migration percentage of a displaced hip, reducing the Cobb angle in scoliosis) from *functional* outcomes which were the reasons for which the operation was being done (e.g. decreased tripping, pain relief, improved appearance).[9] He also recommended measurement of patient *satisfaction* to gauge patients' perception of the intervention's success and *cost effectiveness* to measure whether the intervention was worth the costs involved. This framework served the field well with the development of generic and condition-specific patient-reported outcome measures (PROMs) pertinent to pediatric orthopedics.

More recently, the International Classification of Functioning, Disability and Health, or ICF model, introduced by the World Health Organization (WHO),[10] and its pediatric equivalent, the ICF for Children and Youth (ICF-CY),[11],[12] provide a unified language to classify health and health-related domains and a framework to measure health outcomes associated with any health condition.[11]

In the ICF framework, *body structures* refer to the anatomic parts affected by the health condition of interest (e.g. periventricular leukomalacia in CP; spastic muscle;

bone deformity), and *body functions* refer to physiological functions of body systems (e.g. decreased range of motion, lever arm dysfunction). Body functions and structures allow functional *activities* or specific tasks or actions (e.g. sitting, walking, running), which facilitate *participation* or doing the things that one wants to do to engage in life roles (e.g. being independent, going to school, playing sports). Implicit is the assumption that participation contributes to one's quality of life (QOL). The impact of a health condition on the body functions and structures are the biophysical impairments that might lead to activity *limitations* (e.g. inability to run), which might result in participation *restrictions* (e.g. inability to keep up with friends or play sports). The ICF framework incorporates the influence of *environmental factors* (e.g. home/school/community, socioeconomic status, access to health care) and *personal factors* (e.g. demographic characteristics, culture, lifestyle preferences, motivation, personality).[13] These contextual factors can explain the gap between what one *can* do (capacity) and what one actually *does* do in daily life (performance).[14]

Interventions act at the level of body functions and structures. In the management of ambulatory CP, the technical objective of multilevel surgery is to address the impairments such as muscle contractures and bony deformities. Correction of these impairments (technical outcome) is assumed to lead to (functional) outcomes that patients and parents want, which is to achieve activities and participation with fewer restrictions.[15] A technically successful outcome may not necessarily result in a functionally successful outcome. Also, a positive impact on activities and participation can be achieved without an intervention to correct impairments. For example, the use of powered mobility (wheelchair) might provide an

alternative means of efficient locomotion, which may increase participation by allowing an individual to be independent and able to move around faster and with less effort. These gains in participation might be accompanied by a negative impact at the level of body function and structure such as decreased cardiovascular fitness or increased knee flexion contractures. Ultimately, to make meaningful judgments about effectiveness, it is necessary to base these on specific goals that are aligned with the patient's or parents' priorities.

The Priority Framework for Outcomes Evaluation (Figure 173.1)

Patient *priorities* are the concerns, needs, desires, and expectations associated with living with a health condition. Patient and parent *goals* are the product of these priorities and informed by input from clinicians. Understanding priorities and goals is crucial for making decisions about *interventions* that will best address these. There may be multiple perspectives (e.g. the child's or the parent's) which may not be completely concordant.

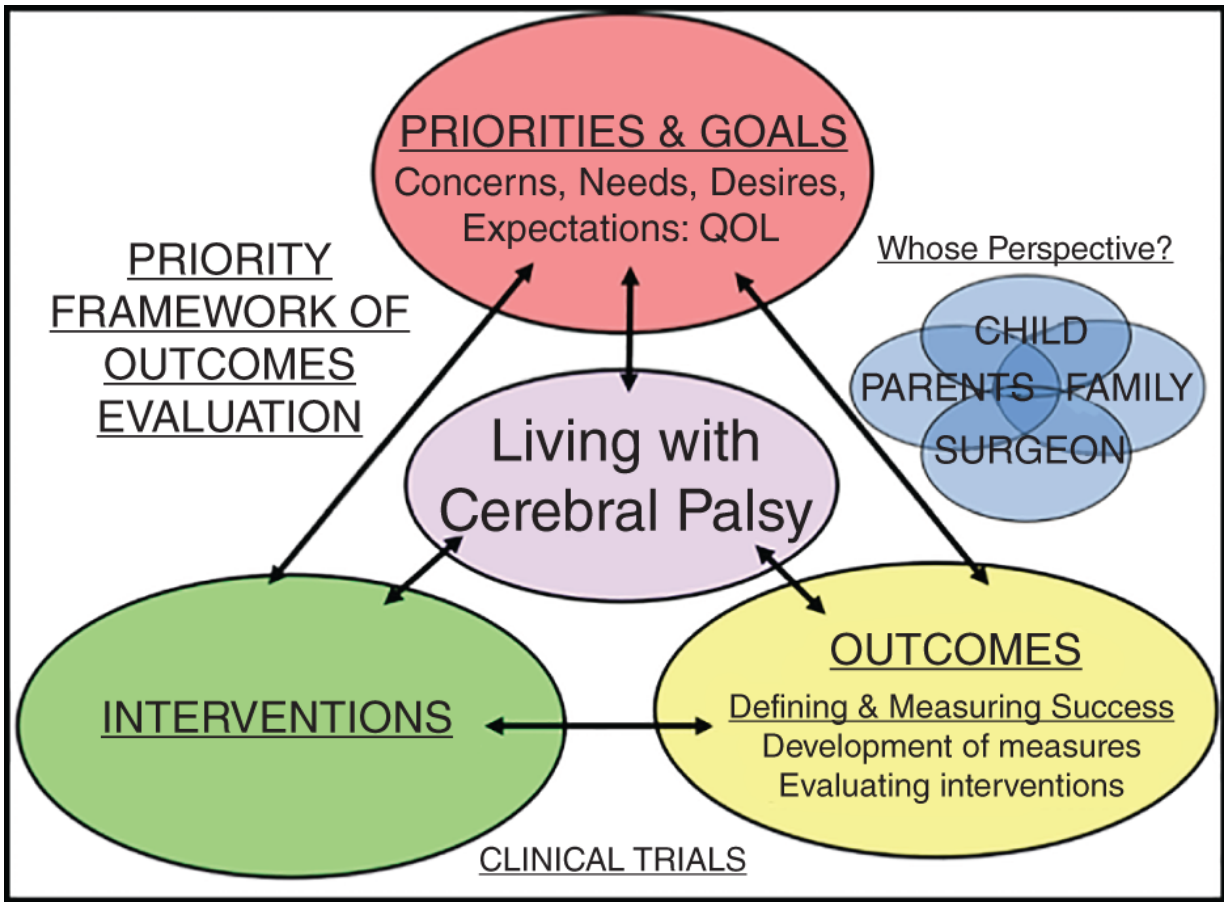

Figure 173.1 The Priority Framework for Outcomes Assessment. Source: Modified from Narayanan.[16]

Outcomes are most meaningful when they are aligned with patient priorities and goals. If our interventions are intended to address these priorities and goals, their effectiveness must be evaluated using *outcome* measures which specifically incorporate the goals and priorities of the patient population.[16]

Outcome measures in pediatric orthopedics: general considerations

Patient-reported outcome measures (PROMs) are the gold standard to evaluate the effectiveness of interventions. The content of PROMs should have been derived from patients

themselves, and in the case of children, parents and caregivers as well. When the perspectives of patients are not accessible because they are very young or cognitively unable, one has to rely on the report of the child's parent(s). The views of older children can and must be taken into consideration, but their perspectives might differ from those of their parents. The level of agreement between parents and children is usually better for domains reflecting physical activity, functioning, and symptoms, but poorer for domains which reflect more social or emotional issues.[17] Whenever possible, both perspectives should be considered during decision-making, and for measuring outcomes as well.

Generic versus condition-specific measures

Generic PROMs evaluate the impact of physical, mental, and social function; health status; and wellbeing across different health conditions. These are useful to policymakers as they can be used to compare outcomes across different clinical conditions and interventions to understand the relative value of some types of interventions over others for purposes of healthcare utilization, planning, and resource allocation. However, generic measures are less sensitive to change than *condition-specific* measures, which focus on issues directly relevant to the condition.

Mortality, health, and quality of life

When the primary goal of an intervention is to save or extend life, measuring *mortality* (survival) must be the primary outcome. However, adding years of life alone is insufficient if the life saved is not worth living. *Quality of*

life (QOL) is defined as “individuals' perceptions of their position in life in the context of the culture and value systems in which they live, and in relation to their goals, expectations, standards and concerns.”[18] *Health-related quality of life (HRQoL)* refers to the health-related factors that contribute to the goodness and meaning of life, where *health* is “a state of complete physical, mental and social well-being, and not merely the absence of disease or infirmity.”[19] HRQoL is multidimensional, encompassing physical, mental, and social domains and their relation to as role attainment, daily functioning, and participation in community life.[20],[21]

Psychometric properties of an outcome measure (See also in Chapter 5)

Reliability is a fundamental requirement and is the property of the measure to produce the same result when no change has occurred.[22] *Internal consistency* refers to a special type of reliability which assesses how well items within a scale correlate with each other to measure a single construct (e.g. physical function).[23]

An outcome measure is valid when it measures the phenomenon it was designed to measure. An outcome measure has face validity when its items appear to be measuring what they are supposed to.[23] Content validity examines the extent to which all relevant and important content or domains pertinent to the attribute of interest are adequately addressed by the items in the measure. Face and content validity represent the sensibility of the measure,[24] and are established by using qualitative research with patients (and their parents) and experts who work with these patients to develop the outcome to ensure it adequately captures what's important to patients and parents. *Criterion validity* is the correlation of an outcome measure with another measure that is regarded as a more accurate measure (gold standard) of the criterion. When such a gold standard measure does not exist, particularly for subjective attributes, *construct validity* requires a process of hypothesis testing to examine the logical relationship that should exist between a measure and characteristics of patients and patient groups.[22] For instance, one can test the hypothesis that the outcome measure should generate different scores when tested on two groups, known to be different in severity of that condition (*known groups* or *extreme groups validity*).

Convergent validity is a type of construct validity demonstrated when the scales of a measure correlate with the related scales of another measure, but not to unrelated scales (*divergent validity*).

A *discriminative* outcome measure is sufficiently sensitive to detect small (but meaningful) differences between patients and is free from *ceiling effects* (i.e. many subjects rate the highest possible score on the measure because it is unable to distinguish higher functioning subjects from each other) and *floor effects* (i.e. less discriminative of lower functioning subjects who are rated at the lower end of the scale). Finally, an outcome instrument that is intended to measure effectiveness is an *evaluative measure*, which must be *responsive* or *sensitive to change* that occurs following an intervention.[25,26]

Outcome measures for ambulatory cerebral palsy

The presenting history of deterioration in gait in a 10-year-old boy with CP is consistent with the functional decline and symptoms that many ambulatory children experience in adolescence. Multilevel surgery is recommended to improve gait or preserve function and a number of outcome measures have been used to evaluate whether these interventions have been effective.

- *Gait Analysis & Gait Analysis Derived Gait Indices:* the (technical) objectives of multilevel surgery are to address the body function and structure impairments (e.g. contractures of the gastrocnemius and medial hamstrings, the lever arm dysfunction and internal rotation gait from increased femoral anteversion). After surgery the range of motion and femoral anteversion

are important to measure but of little direct relevance to the patient. The impact of these impairments on gait can be quantified objectively using three-dimensional (3D) gait analysis to generate temporospatial measures of gait velocity and step length, kinematic and kinetic data, electromyography, and energy consumption. A number of summary indices derived from 3D gait analysis that quantify the overall magnitude of gait deviation from normal, such as the *Gillette Gait (Normalcy) Index (GGI)*[27,28] or the *Gait Deviation Index (GDI)*.[29] The *Gait Profile Score (GPS)* is another index measure that summarizes the overall deviation of kinematic gait data from the norm.[30] The GPS can be decomposed to provide *Gait Variable Scores (GVS)* of nine key component kinematic gait variables, which are presented as a *Movement Analysis Profile (MAP)*.[31] These are valid measures of impairment at the ICF level of activity but may not necessarily correlate with the functional goals at the level of participation that patients want.[32] They may be good summary measures of the overall appearance of gait, in so far as walking on level ground for a few meters in a motion lab is representative of overall gait function in the real world. For that we must rely on functional outcome measures that span the domains of activities and participation.

- *Gross Motor Function Measure (GMFM-66)* is a well-validated, condition-specific measure of gross motor function in children with CP,[33–35] and is evaluated by a trained physiotherapist. The GMFM-66 has been used in numerous trials and has been shown to be sensitive to change following surgery for ambulatory CP.[36] However, the GMFM-66 is a measure of *capacity or capability* (observed under ideal circumstances) rather than *performance* (what one actually does), and does

not necessarily represent the child's activities and participation.

- *Pediatric Outcomes Data Collection Instrument (PODCI)* is a generic measure of musculoskeletal functional health outcomes in children and adolescents, addressing upper extremity function, transfers and mobility, physical function and sports, comfort (pain), happiness and satisfaction, and expectations of treatment.[37] It is reliable and valid for children with CP,[38] but has shown only modest sensitivity to change following surgery for these children.[36]
- *Gillette Functional Assessment Questionnaire (FAQ)* is a reliable, condition-specific functional scale developed for children with CP.[39] It is composed of a 10-level ordinal rating scale of parent report of walking abilities, in addition to the degree of difficulty of 22 higher-level skills. It has been used to evaluate effectiveness of surgery in ambulatory children with CP.[40],[41]
- *Functional Mobility Scale (FMS)* measures the level of walking aid support used for each of three distances: 5 m, 50 m and 500 m, corresponding to walking distances encountered in the home, school and the community, respectively.[42] However, it is limited to six levels of walking aid required for the different distances and does not measure any of the other gait-related domains that are important to patients and their parents.

What were the goals of our patient and to what extent were his goals met? His parents wanted him to walk without any walking aids and to preserve his independence and walking abilities. The patient wanted to trip less, get rid of his knee pain, and feel less tired so that he could keep up with his friends. He wanted to look less different from others. He

wanted to stand up taller and walk with his feet flat on the ground without the use of braces. He wanted his feet and legs to point straight ahead. Six months after surgery he has achieved some of his desired goals. However, many of these goals are not captured by any of the outcome measures that have been used for this population, because the content of all these measures were not derived by asking patients or parents what their priorities and goals are. Consequently, many important domains or items are missing, which might account for the modest improvements demonstrated in clinical trials potentially underestimating the outcomes of multilevel surgery. At the same time, some goals that were realized came at the expense of others. He is disappointed that he remains reliant on a walker, even for shorter distances, and that he is still unable to keep up with his peers. He is also unhappy about the sensitivity in his feet and the fact that he still needs his AFOs for support. This speaks to the need for multidimensional outcome measures that can capture both positive and negative outcomes, when considering overall effectiveness.

Gait Outcomes Assessment List (GOAL) questionnaire

To address these limitations, the *Gait Outcomes Assessment List (GOAL) questionnaire* was developed,[43] with items derived directly from qualitative interviews of patients with ambulatory CP and their parents to capture their gait-related priorities and goals. This newly validated measure is the only goal-based, gait-related PROM. The GOAL has 49 items across seven domains: (i) Independence and Activities of Daily Living; (ii) Gait Function; (iii) Comfort and Endurance; (iv) Sports and Recreation; (v) Gait Appearance; (vi) Use of Mobility Aids and Braces; and (vii) Body Image and Self-Esteem. The GOAL generates a

total and seven domain scores, each from 0 to 100. Unique to this measure is the feature that allows the respondent to indicate for each item whether making an improvement on that item is an important goal for them. This allows patients' and parents' goals to be identified that can inform shared decision-making about the choice of interventions, while serving as a more meaningful goal-based measure of outcomes for gait-related interventions. The GOAL has been shown to have construct and convergent validity with strong correlations between the GOAL scores and the GPS, FMS, and FAQ.[43] It is currently undergoing longitudinal assessment for its responsiveness, following which it has the potential to be a more meaningful and comprehensive functional outcome measure that spans the patient-centered domains of the ICF, including activities, participation, and environmental and personal contextual factors aligned with the priorities and goals of this population, while the technical outcomes at the level of the body's function and structure are best measured by gait analysis. From the patient and parent perspective, the GOAL questionnaire would suggest that the multilevel surgery has made our patient better in some domains but not (perhaps yet) as much in others.[44]

Generic patient-reported outcomes measures of pediatric musculoskeletal function

The *Pediatric Outcomes Data Collection Instrument (PODCI)*[37] has been shown to have good reliability, construct validity, and sensitivity to change when tested in a large sample of children (and parents) over a range of ages (2 to 18 years) and diagnoses and has been used to evaluate pediatric fracture management.[45],[46]

The *Activities Scale for Kids (ASK)* is a reliable and valid, self-reported measure of physical function in children, from 5 to 15 years old.[47,48] The ASK comprises 30 items spanning the dimensions of: locomotion, standing skills, transfers, play, personal care, dressing, and other skills. There is a capability version (ASK Capability) that asks kids what they *could have* done, and a performance version (ASK Performance) that ask kids about what they *did*, in the past week. It has been used in studies of fractures of the upper and lower extremity in children.[49–52]

The *Disabilities of the Arm, Shoulder, and Hand (DASH)* outcome measure (30 items) and its shorter version, the *QuickDASH* (11 items), is a reliable, valid, and responsive self-reported measure of physical function and symptoms arising from musculoskeletal disorders of the upper extremity.[53] Although developed for adults, it has been used for pediatric conditions, including fractures of the upper limb.[54,55]

Generic patient-reported outcome measures of health-related quality of life

The *Child Health Questionnaire (CHQ)* is a generic measure of the physical and psychosocial wellbeing of children. It has been extensively validated in a variety of conditions such as asthma, epilepsy, and attention deficit disorder, and musculoskeletal disorders such as juvenile rheumatoid arthritis and pediatric injury.[56–58] The CHQ has an 87-item child self-reported version (CHQ-CF87) and two parental versions (CHQ-PF50 and CHQ-PF28) comprising 50 and 28 items, respectively, which span 14 unique physical and psychosocial constructs, which can generate a summary score for overall physical and overall psychosocial

health, respectively. Normative values of the parent-reported versions are available for the United States.

The *Pediatric Quality of Life Inventory (PedsQL)* is a generic, multidimensional measure of health-related quality of life of children and adolescents.[59] The 23 items cover the core dimensions of physical, social, and emotional functioning, as well as role (school) functioning. The PedsQL generates a total score, as well as a summary score for physical health and psychosocial health. The PedsQL includes three self-reported children's versions for age groups 5–7 years, 8–12 years and 13–18 years, and separate parent proxy reports for age groups 2–4 years, 5–7 years, 8–2 years, and 13–18 years.[59] The developers of the PedsQL have also developed condition-specific modules for many pediatric health conditions.

Patient Reported Outcome Measurement Information System (PROMIS) is an initiative of the National Institutes of Health to establish a system of reliable, valid, flexible, precise, and responsive PROMs.[60],[61] PROMIS measures cover global health, physical function, fatigue, pain, sleep/wake function, emotional distress, and social health. A number of child or proxy item banks are available for pediatric health domains.[62]–[64] The PROMIS Pediatric Mobility item bank assesses activities of physical mobility. The PROMIS Pain Intensity item pool assesses how much a person hurts. The PROMIS Pain Interference item bank assesses the impact of pain on social, cognitive, emotional, physical, and recreational activities as well as sleep and enjoyment in life. The PROMIS Pediatric Upper Extremity item bank assesses activities that require use of the upper extremity including shoulder, arm, and hand activities. The Peer Relationships item bank assesses the quality of relationships with friends and other acquaintances.

Many of these PROs were developed using *item response theory (IRT)*.[65] Large item banks are created to evaluate the full spectrum of a particular domain or aspect of health. These items are calibrated on a scale using IRT methodology (e.g. Rasch scaling). Statistical models based on IRT allows *computer adaptive testing (CAT)*. The item bank provides a common metric, but each respondent only completes a minimum set of items based on responses to a prior question, which will precisely place them along the continuum of that domain.[22] This increases efficiency and reduces respondent burden. However, CATs only work for unidimensional and hierarchical constructs. Multidimensional constructs, like HRQoL, where individual preferences are important, do not lend themselves to CATs.

Condition-specific patient-reported outcome measures

The *Scoliosis Research Society (SRS) Questionnaire* is an extensively validated patient-reported outcome measure for adolescent idiopathic scoliosis.[66] Since its introduction, various versions of the SRS instrument (SRS-22, SRS-23, SRS-24, SRS-30) have been used to evaluate the effectiveness of nonoperative (bracing) and surgical treatments of idiopathic scoliosis. Although it is psychometrically sound and widely translated worldwide, the major limitation of this instrument is that its content is not directly derived from evaluation of patients' priorities, making it possible that important domains and items relevant to this population are missing or inadequately addressed.

The *Oxford Ankle Foot Questionnaire for Children (OxAFQ-C)* is a child- and/or parent-reported measure of wellbeing for children (aged 5–16) affected by foot and ankle

conditions.[67] In contrast to the SRS questionnaire, the content of the OxAFQ was derived from children to ensure that it covers the issues that are important to them.[67] It has 15 items, 14 of which are used to calculate scores for physical, school and play, and emotional domains. A final item addresses a common concern of many children with respect to their ability to wear footwear of their choice. It is reliable, valid, and responsive, and increasingly becoming the PROM of choice to assess the effectiveness of interventions for pediatric foot and ankle conditions.[68],[69]

Challenges of measuring meaningful outcomes in pediatric orthopedics

Despite advances in our understanding of outcomes assessment, much of the literature on pediatric orthopedic conditions continues to focus on physical examination findings and radiographic measurements (such as range of motion, alignment, length, Cobb angles, migration percentages). These might be sufficient for the assessment of technical objectives of our interventions, but are a far cry from the outcomes that matter to patients. There are many challenges to evaluating meaningful outcomes in pediatric orthopedic conditions, some of which were illustrated in the preceding discussion about ambulatory CP.

- For many pediatric musculoskeletal conditions, PROs are poorly defined and the PROMs to measure them don't exist.
- Some outcome measures might be patient- (or parent-) reported but that does not necessarily mean the content is representative of patients' or parents'

priorities, if their content was not derived from patients' priorities.

- When working with children, whose goals should prevail, those of the child's or of their parents? It is important to measure both whenever possible. For a chronic condition, the perspective of the child, when cognitively able, is important because he or she knows best about their own lived experience. The parents' perspectives are also important as they are often primary decision-makers. When children are young or cognitively impaired, we must rely on the priorities of their parents or the primary caregivers who know the child best.
- Some PROMs have not been adequately validated for use for specific pediatric orthopedic conditions.
- Very few PROMs have been tested for their responsiveness or sensitivity to change. Consequently, it is a challenge to interpret whether the lack of a difference following an intervention is indicative of the ineffectiveness of the treatment or the unresponsiveness of the outcome measure, or both.
- For many pediatric orthopedics conditions our interventions are prophylactic and intended to prevent some problem in the future. A prophylactic intervention will not be associated with a change or improvement in a PROM. In some conditions, patients might be asymptomatic or symptomatic at baseline (e.g. hip displacement in nonambulatory CP, scoliosis in nonambulatory CP). If both these types of patients are analyzed together, the lack of response in the asymptomatic group might dilute any improvements noted in the symptomatic group. This could lead to an underestimation of the true effect unless the asymptomatic and symptomatic groups are identified

and stratified at baseline so that they can be analyzed separately.

- For many pediatric orthopedic conditions, the outcomes of interest are years into the future or much later in adulthood (e.g. treatment of developmental hip dysplasia in infancy to prevent osteoarthritis in adulthood). These are difficult to ascertain, necessitating the use of proxy measures whose association with future good or bad outcomes must be validated with some certainty to justify their use.
- The clinician remains responsible for communicating to parents what is known about the natural history of their child's condition and the evidence based on which an informed decision might be made about whether to intervene (because an intervention has been proven to alter the natural history favorably) or which intervention to choose, if more than one option exists. In some instances, there is strong evidence that one specific treatment is clearly superior. However, for many conditions, there may be more than one treatment strategy that could be expected to accomplish the intended goal, but each strategy has its pros and cons that different patients or parents might weigh differently in making a choice that they believe is right for them. For instance, a closed reduction and immediate application of a spica cast of a femur fracture in a five-year-old might be expected to have just as good an outcome as elastic stable intramedullary nailing (ESIN) of the same fracture. ESIN is minimally invasive and avoids the inconvenience of external immobilization, which can interfere with the care and transportation of the child but does require a second operation under general anesthetic for removal of the nails at a later date. The inconvenience of the spica cast might be outweighed by

the benefits of a single intervention with no scars or retained hardware. Either intervention might be a legitimate choice, and different parents might choose differently based on their circumstances and preferences.[44] Facilitating shared decision-making under such circumstance would only be possible, if they were provided that choice and informed about the relative advantages and disadvantages of each approach.

- In the absence of a meaningful PROM, a clinical trial to measure comparative effectiveness might be premature.

Summary

Pediatric orthopedics encompasses a broad spectrum of musculoskeletal conditions involving a variety of pathologies in different anatomic regions of the axial and appendicular skeleton. There is a wide array of existing and emerging treatments for many of these conditions, the effectiveness of which will need to be established. As the number, diversity, complexity, and costs of treatment options grow, the imperative to evaluate outcomes becomes ever more compelling. This evidence must be generated from high-quality research, clinical trials, and prospective comparative cohort studies. However, these trials will be of little value without the appropriate means to measure effectiveness. Much work remains to improve the status of outcome measurement in our field. This chapter has provided an overview of the principles of outcomes development and measurement, and a framework to define more meaningfully what “works” for patients.[70]

Table of instrument measures

- ICF – International Classification of Functioning, Disability and Health[10]
- QOL – Quality of life[18]
- HRQoL – Health related quality of life[19]
- GGI – Gillette Gait (Normalcy) Index[27,28]
- GDI – Gait Deviation Index[29]
- GPS – Gait Profile Score[30]
- GVS – Gait Variable Scores
- MAP – Movement Analysis Profile[31]
- GMFM-66 – Gross Motor Function Measure[33–35]
- PODCI – Pediatric Outcomes Data Collection Instrument[36–38]
- FAQ – Gillette Functional Assessment Questionnaire[39]
- FMS – Functional Mobility Scale[42]
- GOAL – Gait Outcomes Assessment List[43]
- ASK – Activities Scale for Kids[47,48]
- DASH – Disabilities of the Arm, Shoulder, and Hand[53–55]
- QuickDASH – Quick Disabilities of the Arm, Shoulder and Hand[53–55]
- CHQ – Child Health Questionnaire[56–58]
- PedsQL – Pediatric Quality of Life Inventory[59]
- PROs – Patient-Reported Outcomes
- PROMs – Patient-Reported Outcome Measures
- PROMIS – Patient Reported Outcome Measure Information System

- CAT – Computer Adaptive Testing[22]
- IRT – item response theory[65]
- SRS – Scoliosis Research Society[66]
- OxAFQ-C – Oxford Ankle Foot Questionnaire for Children[67]

174 Cerebral Palsy

Vedant Kulkarni MD
Shriners Hospital for Children – North California, Sacramento, CA, USA

Clinical scenario

- Twin siblings with bilateral spastic cerebral palsy (CP) secondary to prematurity, present at age 7. Twin A walks with ankle foot orthoses (AFOs) and the support of a walker – a Gross Motor Function Classification System (GMFCS, level III evidence). His parents report one year of increasing fatigue with walking, problems with balance and tripping, and decreasing tolerance of his AFOs. He walks with a jump gait pattern, up on his tip toes, with his feet and knees rotated internally, and flexed at his knees. His physical examination reveals bilateral equinus contractures involving the gastrocnemius (but not soleus), medial hamstring contractures, and increased femoral anteversion.
- His brother, Twin B, uses a power wheelchair and is able to stand with assistance for transfers (GMFCS, level IV). His parents note decreased hip abduction over the past few years but this does not interfere with care, and he has no hip pain with sitting, standing, or transfers. An anteroposterior (AP) radiograph of the pelvis demonstrates a hip migration percentage (MP) of 35% bilaterally.

Top three questions

1. Does multilevel orthopedic surgery (MLS) improve gait outcomes for children with ambulatory CP?
2. Is three-dimensional gait analysis (3DGA) essential for surgical decision-making for children with ambulatory CP?
3. Does surveillance for hip displacement result in improved outcomes for nonambulatory children with CP?

Question 1: Does multilevel orthopedic surgery (MLS) improve gait outcomes for children with ambulatory CP?

Rationale

Ambulatory children with CP have gait abnormalities due to tendon contractures, bony torsional malalignments, joint instability, muscle weakness, and abnormal muscle activation patterns, which can limit their independence and participation in activities. The musculoskeletal consequences of CP get worse over time. Left untreated, children with bilateral CP experience deterioration of gait and function as they approach puberty and adolescence.[1–3] This can manifest as a decrease in walking endurance (decreased walking distance and fatigue), poor stability, increasing reliance on walking aids, pain, and reduced physical or recreational activity. The previously common practice of multiple episodes of orthopedic surgery addressing abnormalities at a single level at a time over successive years, has been replaced by simultaneously performed MLS that addresses abnormalities at multiple levels of both lower limbs under a single anesthetic and

episode of hospitalization, followed by an intensive course of rehabilitation.

Clinical comment

The objective of MLS is to optimize lower limb biomechanics – restore muscle length and balance, and bony alignment, in order to preserve or improve gait-related function and appearance and to promote independence and increased participation. Additional surgery may be required in the future as a child grows.[4] The effectiveness of such resource-intensive interventions deserves clarification.

Available literature and quality of the evidence

- Level II: 1 randomized controlled trial (RCT)[5] and1 prospective cohort.[4]
- Level III: 1 retrospective cohort.[6]

Findings

In a small RCT by Thomason et al., patients were allocated to either MLS (n = 11) or progressive resistance strength training (n = 8).[5] At 12 months, the MLS group had a 35% improvement in the Gait Profile Score (GPS), an improvement over 4 times the minimally clinically important difference (MCID) of 1.6°. The patients in the MLS group were followed to 24 months, showing a clinically significant improvement of 4.9% in their Gross Motor Function Measure-66 (GMFM-66) score. The five-year outcomes of the same MLS cohort showed improvements from baseline of 64% in GPS and 3.29% in GMFM-66. The Functional Mobility Scale (FMS) improved in nearly half the children at 50 m and 500 m, and no child had an FMS rated worse than before surgery.[4]

In 2018, Dreher et al. reported the outcomes of a retrospective cohort of 231 patients with bilateral CP who underwent MLS at three high-volume centers that utilized 3DGA for decision-making and outcome assessment.[6] At one year, GPS improved by an average of 5° which was maintained at a mean of nine years after surgery. Seventy-seven percent of children maintained their improvement in the long-term. Up to 40% of children required additional but smaller interventions at a later date.

The outcome measures used in these studies are primarily measurements of gait impairment derived from 3DGA (GPS), and physiotherapist observed functional measures (GMFM-66). The FMS measures the type of walking aid used for different walking distances (5 m, 50 m, and 500 m). Although studies do not adequately evaluate patient-reported outcomes (PROMs) that are aligned with the goals of patients and parents, a recent study has shown a strong correlation between the GPS and the GOAL questionnaire, which is a goal-based PROM derived from the priorities of children with ambulatory CP and their parents.

Resolution of clinical scenario

Evidence from one small RCT and one large multicenter retrospective cohort (without controls) study of prospectively collected data over the long term suggests that Twin A would benefit from appropriately selected MLS, particularly if performed at a high-volume center utilizing 3D gait analysis with access to experienced rehabilitation personnel. The functional outcomes he and his parents seek are likely to be achieved in the short term and maintained in the long term. However, he might require additional surgery before the end of growth.

Question 2: Is three-dimensional gait analysis (3DGA) essential for surgical decision-making for children with ambulatory CP?

Rationale

Although MLS might be beneficial, the question remains whether 3DGA is necessary to inform which operations to include for MLS, and whether this leads to improved outcomes over MLS performed without 3DGA to guide decisions. 3DGA has the potential for such a benefit, since gait deviations in CP are often multiplanar and complex interactions of pathologic and compensatory patterns that are difficult to interpret and quantify with observational gait analysis (OGA) alone. 3DGA in a motion lab is the best technology available to objectively quantify gait deviations and has greatly improved our understanding of the biomechanics of pathological gait patterns in children with CP.

Clinical comment

Surgical decision-making in ambulatory CP involves integrating information from the history of a patient's gait problems, physical examination, including observation of gait, patient goals, and expectations, lower extremity imaging, in addition to 3DGA.[7] In order for 3DGA to be deemed essential for surgical decision-making, the data from 3DGA should be reliable, should alter surgical decision-making at least some of the time, and should lead to improved patient outcomes. This is crucial to establish because there are many centers that perform MLS without access to, or use of, 3DGA.

Available literature and quality of the evidence

3DGA reliability

- Level II: 2 prospective diagnostic studies.[8,9] Level III: 6 retrospective diagnostic studies.[10–15]

3DGA alters decision making

- Level II: 1 RCT.[16]
- Level IV: 1 retrospective cohort.[17]

3DGA improves outcome

- Level I: 1 RCT.[18]

Findings

3DGA reliability

Concerns were raised in 2003 by Noonan et al. about the variability of data generated by different motion labs testing the same 11 patients.[8] Some of this variability can arise from patients themselves and some can be explained by a lack of standardization across different labs. Gorton et al. evaluated the sources and magnitude of kinematic variability of one subject at 12 motion analysis laboratories and found the standard deviation (SD) of mean joint angles of the lower extremity varied from 1.2° to 7.3°.[9] The major source of variability was marker placement by the laboratory staff, and a standardized marker placement protocol improved the SD by 22% in seven of nine kinematic measurements. Pinzone et al. compared the normative data of 81 patients at two well-established pediatric motion analysis centers and found the difference between institutions to be small, with mean SD of

kinematic measurements between 2.2° and 9.7° and mean SD of moments and powers between 0 and 0.3.[10] Several studies in children with CP suggest that 3DGA is reliable when tested at the same institution,[11–13] but summary gait deviation scores can vary substantially between institutions if gait laboratory hardware, processing, and model application are not standardized.[14] OGA using the Edinburgh Visual Gait Score (EVGS) offers an alternative to 3DGA but has high variability and inconsistent reliability. One study found a kappa value for intraobserver reliability of 0.54 (moderate) or below in 11 of 17 scoring items. When compared with 3DGA, complete agreement with EVGS was obtained only 61% of the time.[15]

3DGA alters decision-making

Several case series have shown that the addition of 3DGA does alter decisions first made by OGA. When 3DGA was analyzed, Cook et al. found that 11% of 102 patients did not need the surgery that was proposed by OGA alone.[17] 3DGA concurred with 161 proposed procedures, disagreed with 54 proposed procedures, and added 52 additional procedures. However, are the altered decisions better? Wren et al. randomized patients who were candidates for MLS into two groups, a gait report group where the surgeon received a 3DGA report prior to surgery, and a control group where the surgeon did not receive the 3DGA report.[16] The participating surgeons in this trial did not consistently follow the recommendations of the 3DGA, and more often than not followed their original decisions based on their OGA. When 3DGA recommendation reinforced the surgeon's planned procedures based on OGA, the recommendation was accepted more often in the gait report group (91% vs 71%, relative acceptance = 1.30). When the 3DGA recommended against a planned procedure based on OGA, it was abandoned more

frequently in the gait report group (48% vs 27%, relative acceptance = 1.78). However, when the 3DGA suggested an additional procedure that was not part of the surgeon's plan based on OGA, it was seldom added in either group (12% gait report vs 7% control, relative acceptance = 1.88).

3DGA improves outcome

Wren et al. reported the results of this RCT to examine whether outcomes were better in the patients who were allocated to the gait report group.[18] Unfortunately, this study could not satisfactorily answer the question because of the low concordance between the 3DGA recommendations and the actual surgery that was done (42% gait report, 35% control). They did find that, when concordance between surgery done and gait analysis recommendation was more than 50%, Functional Assessment Questionnaire (FAQ) was more likely to improve (43% vs 23%) and the change in Gait Deviation Index (GDI) was greater (7.5 vs 4.5).

Resolution of clinical scenario

For Twin A there is evidence that the use of 3DGA prior to MLS can influence decision-making by altering decisions made by OGA alone. There is moderate evidence that 3DGA is more reliable that OGA. Although it is believed that 3DGA contributes to better decisions and is widely recommended prior to MLS, there is less evidence that decision-making for MLS by 3DGA directly contributes to improved surgical outcomes.

Question 3: Does surveillance for hip displacement result in improved outcomes for nonambulatory children with CP?

Rationale

Population-based studies in countries with universal healthcare have established that hip displacement occurs in one-third of children with CP, with nonambulatory (GMFCS, level IV and V) children affected in 75–90% of cases.[19] Progressive hip displacement (subluxation to dislocation) can be associated with contractures that interfere with care, including dressing and hygiene, pain, difficulty with seating and mobility, fractures, and a negative impact on the quality of life. Hip displacement can be silent, leading to late presentation. More severe hip displacement might be associated with worse health-related quality of life (HRQoL) and less amenable to effective treatment. Hip surveillance achieved by a schedule of regular physical examinations and radiographs throughout childhood can identify hip displacement before it becomes symptomatic, allowing for earlier or timelier, less invasive, and presumably more effective interventions.

Clinical comment

Twin B is nonambulant and at high risk for progressive hip displacement. He currently has no hip-related symptoms, but radiographs have revealed that he has mild subluxation of both hips with an MP of 35%. The status of his hips would not be known without radiographs. Radiographic measurement of MP is the cornerstone of all hip surveillance programs. Both timing and type of surgical intervention is influenced by MP and other radiographic

findings. Surgery to treat hip displacement can involve (i) soft tissue surgery (lengthening/releases primarily of the adductors iliopsoas, and proximal or distal hamstrings); these are preventive operations which are less invasive but often associated with high rates of recurrence requiring additional future surgery; (ii) reconstructive surgery includes soft tissue releases along with bone operations (femoral varus osteotomy and pelvic osteotomies); these are more invasive and might be associated with higher rates of complications if done for more severe displacement; (iii) salvage surgery, which is less effective, is reserved for when degenerative changes preclude reconstruction (proximal femoral resection, valgus osteotomy, arthroplasty). What is the evidence that a hip surveillance program results in improved hip outcomes for nonambulatory children with CP?

Available literature and quality of the evidence

Hip displacement is associated with poorer HRQoL

- Level III: 3 retrospective cohort studies.[20–22]

Hip surveillance improves clinical outcomes

- Level II: 2 prospective cohort studies.[23,24]
- Level III: 1 retrospective cohort study.[25]

Hip reconstructive surgery improves HRQoL

- Level IV: 1 case series.[26]

Findings

Hip displacement is associated with poorer health related quality of life

Increased hip displacement is associated with poorer HRQoL as measured by the Caregiver Priorities and Child Health Index of Life with Disabilities (CPCHILD) questionnaire, a caregiver-reported measure of HRQoL for children with nonambulatory CP.[27] Jung et al. studied 34 patients with CP and found a decrease in total CPCHILD score with incremental increase in MP (Pearson's r = −0.382).[20] Ramstad et al. found that MP >40% was associated with lower CPCHILD domain scores in Comfort and Emotions and Health in a cohort of 67 patients.[21] In a separate study of 77 patients, Ramstad et al. found that pain as measured on the Child Health Questionnaire (CHQ) occurred in 60% of hips with an MP >50% compared with 14% in an MP <50%. MP >50% was an independent risk factor for pain in multivariate analyses.[22]

Hip surveillance improves clinical outcomes

A 10-year prospective population-based cohort study reported by Hagglund et al. showed that the implementation of a population-based hip surveillance program with prompt referral, treatment, and continued follow-up care essentially eliminated hip dislocation in children with CP in southern Sweden.[23] Hagglund et al. subsequently published the 20-year results of the Swedish hip surveillance program, showing that the population prevalence of hip dislocation had decreased from 8% prior to the implementation of surveillance to 0%, and any need for salvage surgery was eliminated.[25] Every child with a dislocation in their historical cohort had severe hip pain. GMFCS was the strongest predictor of need for preventative surgery (odds ratio [OR] = 12.72 for GMFCS, level III, 18.16 for GMFCS, level IV, and 41.04 for GMFCS, level V), and children with spastic bilateral CP had twice the risk of undergoing surgery compared with those with dyskinetic CP when adjusted for GMFCS (OR = 1.98).

The long-term outcomes of preventative surgeries (i.e. soft tissue releases) as part of the Australian hip surveillance program was evaluated by Shore et al. in a level II prospective cohort trial.[24] GMFCS level and initial MP were the most important predictors of the need for subsequent reconstructive surgery. Overall success was only 32%, with GMFCS levels IV and V having the highest recurrence rates of 73% and 86%, respectively.

Hip reconstructive surgery improves HRQoL

A level IV prospective cohort study by DiFazio et al. of 38 patients found that hip reconstructive surgery increased CPCHILD score from 49.6 points to 58.9 points at 24 months.[26]

Resolution of clinical scenario

There is good evidence that the implementation of hip surveillance enables the early detection of hip subluxation, and if combined with a program of intervention can eliminate hip dislocations and need for salvage surgery. Twin B will benefit from ongoing surveillance to track the progression of his hip displacement and allow timely intervention well before the hip is dislocated. There is less evidence that early preventive surgery (less invasive but high rates of recurrence and repeat surgery) is superior to later reconstructive surgery (more invasive, but less likely to recur) which has been shown to have a positive impact on HRQoL. However, both approach require hip surveillance of the MP to pick the optimal time to intervene and to avoid less effective salvage surgery.

Summary of answers

- MLS improves gait indices and functional outcomes when performed at high-volume centers that use 3D gait analysis for surgical decision-making in collaboration with experienced rehabilitation personnel.
- Use of 3DGA does alter surgical decisions about the specific types of MLS, which has the potential to lead to better outcomes if followed.
- Hip displacement in nonambulatory children with CP is associated with increased pain and poorer HRQoL.
- Population-based hip surveillance programs coupled with timely access to surgical intervention can dramatically reduce the prevalence of painful hip dislocations.
- Reconstructive surgery for hip displacement in nonambulatory children likely improves HRQoL outcomes.

175 Pediatric Osteoarticular Infections

Brice Ilharreborde MD[1], Cindy Mallet MD[1], and Dimitri Ceroni MD[2]

[1] Pediatric Orthopaedic Department, Robert Debré Hospital, AP-HP, Paris Diderot University, Paris, France

[2] Pediatric Orthopaedic Department, Geneva University Hospital, Geneva, Switzerland

Clinical scenario

- A 3-year-old child presents with malaise, low-grade fever (38°), and a limp.
- Physical exam reveals pain with hip motion, limited internal rotation.
- X-rays are negative. Ultrasound shows a moderate hip effusion. Erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) are mildly elevated.
- There is clinical concern for septic hip and/or osteomyelitis of the proximal femur/pelvis, versus transient synovitis/inflammatory arthritis.

Top three questions

1. In children aged less than four years with suspected osteoarticular infection, is oropharyngeal *Kingella kingae* carriage status a viable indirect diagnostic alternative to synovial fluid/bone sample cultures?
2. In children with acute osteomyelitis, is outpatient oral antibiotic therapy equivalent to inpatient treatment

with intravenous (IV) antibiotics?

3. In children with a chronic benign bone lesion, what is the best method to differentiate chronic nonbacterial osteomyelitis (CNO)/chronic recurrent multifocal osteomyelitis (CRMO) from bacterial osteomyelitis (BOM)?

Questions 1: In children aged less than four years with suspected osteoarticular infection, is oropharyngeal Kingella kingae carriage status a viable indirect diagnostic alternative to synovial fluid/bone sample cultures?

Rationale

Osteoarticular infections (OAI) in young children are frequently caused by organisms carried asymptomatically in the respiratory tract, such as *Staphylococcus aureus*, *Streptococcus pneumoniae*, *Streptococcus pyogenes, Haemophilus influenzae* type b, or *K. kingae*,[1],[2] with *K. kingae* currently being the most common pathogen causing osteoarticular infection in children <4 years of age in many regions.[3],[4] Septic arthritis (SA) due to *K. kingae* may be particularly difficult to clinically differentiate from transient synovitis, as *K. kingae* infections are typically characterized by relatively mild symptoms, low-grade fever, and minimally elevated inflammatory markers.[5],[6]

Clinical comment

Standard practice for diagnosis of SA includes arthrocentesis with cell count and culture. Due to inherent difficulties in obtaining positive cultures for *K. kingae*, real-time quantitative polymerase chain reaction (qPCR) assays on synovial fluid, targeting *K. kingae*, are recommended in children <4 years.[7] As acquiring synovial fluid from the affected joint typically necessitates administration of anesthetic and an invasive procedure (arthrocentesis or arthrotomy), the ability to diagnose *K. kingae* SA by alternative noninvasive measures would be highly desirable. The sensitivity/specificity of oropharyngeal *K. kingae* carriage status as indirect evidence of *K. kingae* SA is essential to determining the utility of this potential indirect test.

Available literature and quality of the evidence

- Level II: 2 prospective diagnostic studies.[5],[7]
- Level III: 2 retrospective diagnostic studies.[8],[9]
- Level IV: 3 case series.[3],[4],[10]

Findings

In Switzerland and France, *K. kingae* causes up to 90% of osteoarticular infection in children <4 years of age.[1],[4] *K. kingae* is notoriously difficult to culture on standard culture media, with a false-negative rate of almost 100%.[5],[11] Culturing in liquid medium/blood culture vials improves detection, yet the false-negative rate is still high.[12],[13] Given high rates of false negative cultures, a definitive diagnosis cannot be made in many cases, and it can be difficult to determine appropriate treatment, including whether antibiotics are required, and which antibiotic should be selected. The false-negative culture rate ranges from 24 to 68% for acute hematogenous osteomyelitis (AHO) and 21–

80% for SA.[14–17] It is theorized that *K. kingae* must first colonize the oropharynx in order to subsequently travel by hematogenous spread to a distant osteoarticular location.[18] Obtaining oropharyngeal samples is minimally invasive. Real-time PCR can be performed on these samples, providing results in less than 24 hours. Multilocus sequence typing (MLST; a technique for identifying multiple loci of microbial species using the DNA sequences of internal fragments of multiple housekeeping genes) allows for genotyping of oropharyngeal *K. kingae*, and this has demonstrated that strains carried in the oropharynx of sick children matched with the most frequently invasive strains of *K. kingae* causing OAI, namely ST-6 and ST-25.[8]

A number of studies have investigated the use of oropharyngeal carrier status in the diagnosis of *K. kingae* OAI. A prospective study demonstrated that detection of *K. kingae* in the oropharynx of children aged between 6 and 48 months with suspected OAI had a positive predictive value of 90.5% in diagnosing *K. kingae* osteoarticular infection.[7] A prospective case control study of 77 children admitted for suspected osteoarticular infection and 286 age-matched controls in Switzerland and Canada investigated whether oropharyngeal swab polymerase chain reaction (PCR) could predict OAI due to *K. kingae* in young children with osteoarticular symptoms.[9] The sensitivity and specificity of the oropharyngeal swab PCR assay for *K. kingae* were 100% and 90.5%, respectively. Oropharyngeal testing has also been used to diagnose *K. kingae* in epidemics that occurred in France and Israel.[8,10]

Although detection of K. kingae in oropharyngeal swabs does not mean always that a child has a *K. kingae* OAI, negative oropharyngeal results may exclude *K. kingae* as the cause of their osteoarticular symptoms. Indirect testing has some limitations: it is possible that there could be

multiple organisms causing an infection of which *K. kingae* is only one, or *K. kingae* could be present in the oropharynx but a different bacteria or a nonbacterial process could be responsible for joint inflammation. The technique is also limited by mild discomfort in obtaining oropharyngeal specimens and requires optimal extraction of bacterial DNA. Subsequent investigations focusing on colonization rates of the respiratory tract and test contamination rates may permit more confidence in this indirect diagnostic strategy. PCR assay on oropharyngeal swabs should be added to the standard OAI workup, but at this time synovial analysis is still necessary.

Resolution of clinical scenario

Given 100% sensitivity and 90.5% specificity for nasopharyngeal swab PCR for *K. kingae* in predicting *K. kingae* as the causative organism in a presumed septic joint, this is a reasonable adjunct test in facilities where real-time PCR for *K. kingae* is available.[7] Until further testing confirms sensitivity and specificity, rates of test contamination and rates of respiratory tract colonization, synovial analysis of the involved joint for cell count culture, and PCR are recommended.

Questions 2: In children with acute osteomyelitis, is outpatient oral antibiotic therapy equivalent to inpatient treatment with intravenous (IV) antibiotics?

Rationale and clinical comment

Acute osteomyelitis may occur through hematogenous spread, by contiguous extension of neighboring infection, or through penetration into the bone with direct inoculation.[19] Acute osteomyelitis is typically treated medically not surgically.[19],[20] Patients are admitted and hospitalized, bony/joint biopsy is obtained, and IV broad spectrum empiric antibiotics are initiated, targeted to cover the most likely causative organisms for that region/population. Culture/sensitivity results guide changes to the antibiotic regimen. In cases of suspected bacterial infection with presumed false-negative cultures, empiric antibiotics are continued and are based on regional data on the most common causative organisms and rates of community-associated methicillin-resistant *S. aureus* (MRSA). Historically, patients with acute osteomyelitis would be admitted and receive weeks of IV antibiotics. Over the past decade the length of hospital stay and parenteral treatment has decreased in favor of a less restrictive oral treatment, reducing both the management cost (fewer hospitalization days, less expensive medications) and complications related to IV or peripherally inserted central catheter (PICC) line.[21]

Available literature and quality of the evidence

- Level I: 1 RCT.[21]
- Level II: 1 prospective cohort.[22]
- Level III: 1 retrospective cohort study and 1 case control study.[20],[23]
- Level IV: 3 case series.[4],[22],[24]

Findings

Recent evidence suggests shorter courses of antibiotics (3–4 weeks) and early conversion (day 2–4) from IV to oral administration is safe and effective in acute noncomplicated osteomyelitis that is responding to treatment.[21] Even with prolonged clinical symptoms prior to diagnosis and positive blood cultures, this regimen was successful.[21] Such protocols can even be considered in regions with relatively high rates of MRSA, such as the United States.[22] Large oral doses of well-absorbed antibiotics (such as first-generation cephalosporin or clindamycin), administrated three or four times daily (depending of half-life of the medication), are required to efficiently eradicate noncomplicated cases of osteomyelitis while reducing cost and allowing earlier discharge.[21]

Guidelines for transition to oral antibiotics include: (i) confirmed diagnosis of uncomplicated hematogenous osteomyelitis, (ii) clinical improvement of signs and symptoms, (iii) afebrile at least 48 hours, (iv) CRP decreased from 50% of initial CRP, and (v) received at least 72 hours of IV antibiotics.[20]

The emergence of *K. kingae* in children aged <4 years and the frequent paucity of symptoms have led some authors to question the need for initial IV therapy in Europe.[25] Since early transition to oral therapy has also proved to be a safe option in patients with *S. aureus* OAI (both osteomyelitis and SA), including those due to MRSA, ambulatory treatment might also be considered elsewhere.[22]

To date, only two clinical studies have investigated outcomes following completely ambulatory treatment in pediatric OAI. Roul-Levy et al. treated uncomplicated osteomyelitis in healthy children, with a six-week oral antibiotic regimen and retrospectively reviewed their outcomes.[23] The contraindications for oral treatment at the Emergency Department were (i) patients with severe signs

of infection including CRP rate >50 mg/L, (ii) fever >38.5° or signs of septic shock (hypothermia, hyperthermia, tachycardia, hypotension), (iii) subperiosteal abscesses suspected or diagnosed at admission, (iv) multiple sites of infection, (v) severe immunosuppression or underlying conditions such as sickle cells disease.[23] Since the incidence of clindamycin- and erythromycin-resistant *S. aureus* is increasing, and the necessity to take cephalosporin four times daily, the authors recommended oral amoxicillin + clavulanic acid, despite low bone diffusion. Outcomes were satisfactory at six months follow-up, with only one treatment failure (5%), while three failures were observed in the control group who received initial doses of IV antibiotics before transitioning to oral therapy.

Alcobendas et al. reported a prospective study evaluating a three-week oral treatment in 25 young (mean age 25 months) healthy children with OAI (osteomyelitis, arthritis, and spondylodiscitis), who were compared to 228 hospitalized ones.[25] Patients with a suspicion of OAI and no severe clinical symptoms (no evidence sepsis/shock) were sent home with either cephalosporin, clindamycin, or amoxicillin + clavulanic acid, and received a follow-up appointment within 48 hours. More than half (52%) of the patients treated orally showed fever at some point during the disease course, but all of them had full recovery without sequelae at most recent follow-up. Arthrocentesis and articular lavage were performed in the seven cases of arthritis, but none of them required conversion to open arthrotomy. Of note, MRSA was not found in any patient treated orally. MRSA and a CRP >100 mg/L at presentation were found to be risk factors for complications and sequelae in both groups.

The results of oral only regimens versus traditional IV followed by oral regimens for acute osteomyelitis is limited and evolving. The outcomes of this treatment have not been sufficiently studied to recommend sole oral antibiotic regimens at this time, given the potential severity of OAI and the risk of severe complications in young patients.[24]

Resolution of clinical scenario

In this patient with mild clinical, radiological and biological signs of infection, MRI can diagnose the presence of acute osteomyelitis, and aspiration of the hip can determine whether the effusion is septic. Provided the patient has acute osteomyelitis only, empiric ambulatory antibiotics such as first-generation cephalosporin and/or amoxicillin + clavulanic acid could be considered, but is not standard care. Duration of ambulatory treatment should be at least three weeks. If synovial cell count and clinical signs are suspicious for SA, the patient must undergo irrigation and debridement of the hip with hospitalization, and this same oral antibiotic regimen could still be considered.

Questions 3: In children with a chronic benign bone lesion, what is the best method to differentiate chronic nonbacterial osteomyelitis (CNO)/chronic recurrent multifocal osteomyelitis (CRMO) from bacterial osteomyelitis (BOM)?

Rationale and clinical comment

CNO/CRMO is an idiopathic, auto-inflammatory disorder characterized by multifocal osseous lesions that may mimic

BOM. No diagnostic criteria or biomarkers exist for CNO, and it remains a diagnosis of exclusion. Differentiating between CNO and BOM is paramount, as delayed diagnoses of BOM may result in complications.

Clinical forms of CNO vary from unifocal and time-limited courses to prolonged, chronic and/or recurrent and multifocal forms with severe courses, known as CRMO.[26]

BOM can be classified into three groups (acute, subacute, and chronic) depending on the duration of symptoms. At first presentation, distinguishing a unifocal CNO from a subacute or chronic BOM can be challenging, and requires treatment regimens differ significantly.

Available literature and quality of the evidence

Findings

- Comparison between chronic nonbacterial and bacterial osteomyelitis in children:

  Level III: 1 retrospective cohort.[27]

- Chronic nonbacterial osteomyelitis:

  Level II: 2 prospective cohorts.[26],[28]

  Level III: 2 retrospective cohorts.[29],[30]

  Level IV: 2 literature reviews.[31],[32]

Epidemiology and pathophysiology of CNO

The epidemiology of CNO is not well described. However, it is described as the most common auto-inflammatory bone disorder in central Europe,[31] with an incidence rate estimated at 0.4 per 100 000 children/year in Germany.[27] Although CNO is considered a rare disorder, its incidence is likely underestimated: Schnabel and al. reported CNO

incidence comparable to BOM incidence (4.7 new cases of CNO per year vs 5.4 cases of BOM per year).[27] The exact pathophysiology of CNO remains unknown. Immune dysregulation has been hypothesized as the cause of chronic bone inflammation, bone erosions, and hyperostosis with 38% patients with elevated antinuclear antibodies in one study,[26] and bone biopsies showing chronic bone inflammation and lymphoplasmacytoid infiltrates in another.[27]

Additional inflammatory extra-osteo-articular manifestations have been described in 10 to 25%.[27],[29],[32] The skin (18% acne, psoriasis, palmoplantar pustulosis), and the gastrointestinal systems (5%) (Crohn disease, ulcerative colitis) are most commonly affected.[26]

Existence of extra-osteo-articular manifestations may help to differentiate CNO from BOM.[27]

Demographic data and clinical characteristics

- Sex: no difference in distribution has been reported.[27]
- Age: CNO affects children and adolescent with peak age reported between 7 and 12 years.[26],[27],[31] It rarely occurs in children <3 years old,[27] whereas BOM can affect children at any age.
- Clinical characteristics: clinical presentation of CNO is variable (unifocal or multifocal). Schnabel et al. reported that it is not possible to differentiate CNO from BOM based on clinical findings.[27] Clinical manifestations of CNO include: clinical signs of osteomyelitis (elevated temperature), swelling, pain (92%), redness, and arthralgia (65%).[26] In CNO, noninfectious arthritis is described in 30%.[31],[32]

- Location: children with CNO more commonly suffered from multifocal bone pain.[27] Multifocal lesions have been reported in 78% of patients in the Eurofever (European registry of autoinflammatory diseases) cohort.[27] Both CNO and BOM typically affect the lower limbs (50%)[27],[29] in the metaphyseal part of the long bone.[26]
- Spinal, pelvic, clavicular, and mandibular lesions (especially hyperostosis lesions) are commonly seen in CNO.[26–30],[32]

Radiology

X-rays cannot differentiate CNO from BOM: in both cases, x-rays can initially be normal, or show osteitis or lytic lesions with marginal sclerosis.[26]

Magnetic resonance imaging (MRI) can identify bone edema in the early stages of both CNO and BMO. Other typical findings include cortical thickening, and/or lytic lesions with sclerotic edges.[32] Hyperostotic lesions are more often described in CNO.[27] Abscesses, cutaneous fistulas, and sequestrations are exclusively seen in BOM.[27]

Whole-body MRI is a useful tool to diagnose asymptomatic multifocal lesions in the early stages of the disease in CNO,[28] and thus differentiate CNO and BOM: Schnabel et al. reported unifocal lesion more commonly in the setting of BMO (unifocal lesion: 20% in CNO, 80% in BMO).[27]

Biomarkers

At present, no specific biomarkers exist for the diagnosis of CNO. In CNO, inflammatory markers are typically elevated (67%):[29] mildly elevated CRP (mean 23.6 mg/L) in 50%,[26],[29] mildly elevated ESR (mean 37.7 mm/h) in 86%.[27] Blood cell count is typically normal (77%).[29] Schnabel et al.

reported no differences between CNO and BMO in the inflammatory markers, just a trend to higher CRP in BOM.[27] Biomarkers including antinuclear antibodies and rheumatoid factor and HLA B27 genotyping do not differ between CNO patients and healthy patients.[28]

Jansson score[30]

This score was described to facilitate the diagnosis of CNO and is based on seven criteria:

- Normal blood cell (odds ratio [OR] = 81.5) (13 points).
- Symmetric bone lesions (affecting both sides) (OR = 30.0) (10 points).
- Lesions with marginal sclerosis (OR = 26.8) (10 points).
- Normal body temperature (OR = 20.3) (9 points).
- Vertebral, clavicular, or sternal lesions (OR = 13.9)(8 points).
- Radiologically proven lesions >1 (OR = 10.9) (7 points).
- CRP ≥10 mg/L (OR = 6.9) (6 points).

A score ≥39 had a positive predictive value of 97% and a sensitivity of 68% for CNO.

Bone biopsy

Bone biopsy is an invasive procedure but remains an essential diagnostic tool especially to rule out malignant lesions. Both in CNO and BOM, bone biopsy shows signs of inflammation: Schnabel et al. described differences in the composition of cellular infiltrates with a predominance of neutrophils in BOM and lymphocytes plasma cells in CNO.[27]

Bacteriological cultures or PCR are always negative in CNO,[32] and may be helpful in BOM to identify the causative agent. Nevertheless, identification of the causative agent may be absent in up to 40% of cases of BOM.[16],[27]

Resolution of clinical scenario

In our clinical scenario, in case of culture and PCR-negative results, the differential diagnosis could still include culture negative (false-negative) osteomyelitis with neighboring SA, or inflammatory arthritis, or CNO with inflammatory arthritis. MRI should be used to assess the lesion and scan for potential multifocal lesions.

Conclusion

In case of unifocal lesion, age at diagnosis, clinical and biological findings, nonmusculoskeletal manifestations, x-rays and MRI can help to differentiate subacute or chronic BOM from unifocal CNO (which represent 20% of the CNO), but none is definitively diagnostic. Whole-body MRI is recommended to characterize lesions and may identify asymptomatic multifocal lesions. The Jansson score may help to guide diagnostic and therapeutic decisions:

- if ≤28 points, biopsy and cultures are recommended.
- if ≥39 points, CNO is strongly suspected.
- If 29–38 patients could be clinically monitored and need for biopsy re-evaluated.

Summary of answers

- Indirect diagnosis of *K. kingae* OAI through oropharyngeal culture and DNA detection has high sensitivity and specificity, but has not been fully

validated and is not yet standard of care. Standard work up including serology for CBC, ESR, CRP blood cultures, and synovial fluid analysis including cell count, culture with PCR for detection of *K. kingae* DNA in children aged <4 is still recommended.

- Outpatient antibiotics without an initial IV antibiotic regimen can be considered in patients with acute osteomyelitis, provided they have mild clinical and biological signs without complications. Bone biopsy/arthrocentesis is recommended before starting any antibiotic therapy for any suspected OAI.
- Tumor or CNO can mimic BOM. Localized MRI and biopsy followed by whole-body MRI in culture negative lesions can help to differentiate between these diagnoses.

[2] Department of Pediatric Orthopaedics – Hospital Universitari i Politècnic la Fe, Valencia, Spain

[3] Department of Orthopaedics – Klinikum Stuttgart, Olgahospital, Stuttgart, Germany

[4] Department of Orthopaedics – Leiden University Medical Centre, Leiden, The Netherlands

Clinical scenario

- A five-year-old boy is limping and complaining of thigh pain. He does not have any other symptoms.
- There is no clinical or laboratory evidence of infection. Ultrasound of the hip shows no effusion.
- He has mild tenderness in his inguinal region and slightly decreased hip range of motion (ROM). Radiographs show a lucent lesion at the femoral neck.
- A simple bone cyst (SBC) is suspected.

Top three questions

1. In children with an isolated lucent lesion in a long bone, are radiographs and clinical presentation sufficient to make the diagnosis of SBC?

2. In children with an SBC, which features should prompt treatment of the lesion?
3. In children with an SBC, which treatment yields the most successful results at maturity, considering cyst healing and (re)fracture rate?

Question 1: In children with an isolated lucent lesion in a long bone, are radiographs and clinical presentation sufficient to make the diagnosis of SBC?

Rationale

SBCs are benign fluid-filled lesions of bone, with unknown prevalence, as many are asymptomatic. They are estimated to account for 3% of all bone tumors, with males being three times more commonly affected than females. Bone cysts may be unicameral or contain one or more septations. Although SBCs can affect any bone, the proximal humerus and proximal femur account for 90% of all locations.[1,2] Patients with SBC usually present with a pathologic fracture or pain, although some SBCs are discovered incidentally when x-rays or other imaging is obtained for unrelated reasons. Differentiating between a benign lesion and a neoplastic process is of paramount importance.

Clinical comment

The majority of patients presenting with SBC are children, and as such may have difficulty being still for axial imaging such as computed tomography (CT) or magnetic resonance imaging (MRI). Thus, the question arises: are x-rays sufficient to make the diagnosis?

Available literature and quality of the evidence

- Level IV: 1 study
- Level V:1 study.

Findings

In most cases, plain radiographs and clinical presentation are sufficient to establish the diagnosis of SBC. MRI is indicated in the presence of atypical features: periosteal reaction, eccentric or other atypical location, extension to the articular surface, or soft tissue involvement.[3–6] Cases of pseudocystic osteosarcoma or low-grade central osteosarcoma that were mistaken for SBC have been reported.[3]

When present in a lucent lesion, the fallen fragment sign is pathognomonic of SBC. The fallen fragment is caused by fracture of the cyst wall and dislodgement of fragments into the cyst cavity. Its presence establishes that the cystic contents are not solid, thus distinguishing the unicameral bone cyst from fibrous lesions of bone, which have a solid center.[5] This is particularly helpful in cases where breaches in the cortex secondary to fracture may appear consistent with an intramedullary malignancy with cortical erosion.[3]

In a case series including 51 cases of SBC with 39 cases in patients 17 years old or younger, Struhl et al. identified 10 cases with a fallen fragment sign. All cysts were seen in patients with open growth plates and associated with pathologic fracture through the cyst.[5] Farr et al. surveyed pediatric orthopedic surgeons, members of the European Paediatric Orthopaedic Society, and the Pediatric Orthopaedic Society of North America and found that the preferred diagnostic modalities to confirm the diagnosis of a unicameral bone cyst (UBC) in the humerus were radiographs (88%), MRI in cases of questionable diagnosis

(58%), or CT scan (8%).[6] Only 10% of respondents preferred obtaining an MRI in every single SBC case. In painless, incidental SBCs, advanced imaging (MRI/CT) was never (50%), sometimes (43%), or always (7%) preferred. This rate, however, increased in painful cases to 9, 58, and 33%, respectively, and in fractured UBCs to 36, 54, and 10%, respectively. Bone biopsy was mainly preferred in cases of unclear diagnosis/imaging (64%) or pathologic fracture (3%); 8% of respondents reported they always performed a biopsy. Most common reasons for biopsy were: radiographs unclear (73%), pain (13%), need to establish differential diagnosis (9%), unusual location (9%), and physeal proximity (9%).

Resolution of clinical scenario

In this child with a lucent lesion of the femoral neck, without constitutional symptoms and no clinical or radiological signs of infection or malignancy, plain radiographs alone are typical, yet there is low evidence to guide clinical management at this time.

Question 2: In children with an SBC, which features should prompt treatment of the lesion?

Rationale

Although SBCs are benign lesions, their treatment course may be prolonged and have a significant impact on the patient and family's quality of life, due to relatively high recurrence rates, risk of pathologic fractures,[7] relatively poor efficacy of traditional treatment methods, necessitating activity restrictions to avoid pathologic fractures; evolution to complete healing is rare.[8] Growth

disturbance affects up to 10% of patients, leading to angular deformity or limb length discrepancy.[9–11] Children with SBCs are at risk for continued pain, activity restriction, and anxiety.[12]

Clinical comment

Identifying patients and/or cyst features that predict the risk of fracture in SBCs would help surgeons to select the appropriate treatment for each patient and lesion.

Observation may be a choice for an asymptomatic humeral SBC with minimal cortical thinning. However, for cysts that are large or progressively increasing in size, expansile with progressive thinning of the cortex, and particularly those in lower extremity weight bearing bones, operative treatment may be warranted to minimize the risk of pathologic fracture.

Available literature and quality of the evidence

- Level IV: 1 study[7]
- Level III: 1 study.[13]

Findings

Larger cysts typically have more cortical thinning; the bone is weaker and there is increased risk of fracture.[6] To quantify the strength of the remaining cortex, which is related to the size of the cyst and the size of the involved bone, Kaelin at al. devised the cyst index (cyst index = area of the cyst/diaphysis diameter × diaphysis diameter)[7] to help predict the risk of a pathologic fracture. The authors recommended observation for humeral cysts with an index <4 and for femoral cysts with an index of less than 3.5.[7]

However, others have questioned the usefulness of the cyst index.[13]

Leong et al. investigated the use of CT structural analysis to predict fractures in children with a benign appendicular skeletal lesion.[14] The resistance of the affected bone to compressive, bending, and torsional loads was calculated. Structural rigidity is the product of a material property (modulus of elasticity, or shear modulus) and a cross-sectional geometric property (area, moment of inertia, or polar moment of inertia). For each trans-axial CT image, the axial rigidity (EA), bending rigidity (EI), and torsional rigidity (GJ) were calculated. The ratio of the structural rigidities of the affected bone relative to the normal, contralateral bone was determined at matching cross-sectional levels. Pathologic fracture was predicted if the ratio for EA, EI, or GJ was 65% or less. Both structural analysis with quantitative CT and radiographic analysis were performed. According to the criteria based on the plain radiographs, a skeletal lesion was considered at increased risk of fracture if the defect length was ≥3.3 cm, width ≥2.5 cm, or there was involvement of ≥50% of the cortex as measured on anteroposterior or lateral views.

Of 41 included patients, 34 completed activity questionnaire at least two years after the quantitative CT rigidity analysis. No patient for whom no increased fracture risk was predicted sustained a fracture. Thirty-five patients were predicted to be at risk for a fracture on the basis of the plain radiographs but not on the basis of the quantitative CT rigidity analysis, and the converse was true for one patient. Overall, the specificity of the quantitative CT-based rigidity analysis was 97%, correctly predicting that a bone containing a lytic lesion would not fracture when the patient engaged in activities of daily living, compared with a specificity of 12% for criteria based on plain radiographs. This CT-based analysis has some

limitations: it exposes the patient to relatively large doses of radiation, CT scans are not as readily available as standard radiographs, the application of the algorithm requires sophisticated knowledge of image analysis software to properly align virtual images of right and left bone pairs, and the interpretation of the results requires a background in structural mechanics.

Resolution of clinical scenario

Not all cysts require surgical management or restriction from athletic activities. Although CT structural rigidity analysis has demonstrated success in predicting which cysts are unlikely to fracture, the technique involves significant radiation to the patient and advanced skills and software, making this technique difficult to assimilate into clinical practice. Lucent lesions with a length ≥3.3 cm, width ≥2.5 cm, or involvement of ≥50% of the cortex as measured on anteroposterior or lateral views may be at increased risk of fracture, but these absolute cutoffs may not apply to smaller children. Other radiographic features that should warrant concern for impending pathologic fracture include increasing size, expansion, and progressive thinning of the cortex. In this patient, although not strictly based on evidence, this proximal femoral cyst should be treated to avoid the high morbidity of a pathologic fracture in this region.

Question 3: In children with an SBC, which treatment yields the most successful results at maturity, considering cyst healing and (re)fracture rate?

Rationale

SBCs may be treated nonoperatively (observation, activity restriction, immobilization when a pathological fracture occurs). Conversely, many procedures and surgical interventions have been described: curettage only,[15] curettage and grafting,[16] subtotal resection with and without grafting,[17] percutaneous corticosteroid injection,[18] percutaneous bone marrow injection,[1] drilling holes and continued decompression with a cannulated screw,[19] drilling holes and lavage of the cyst cavity with saline,[20] filling of the cyst cavity with calcium sulphate or calcium phosphate or both,[21],[22] filling of the cyst cavity with demineralized bone matrix,[23] internal fixation and continued decompression with Kirschner wire,[24] internal fixation and continued decompression with elastic stable intramedullary nailing,[25] or a combination of these options.

Clinical comment

Goals of treatment include minimizing the risk of pathological fracture, cyst healing, and pain resolution. Numerous treatment methods have been described for SBCs in children; there is no consensus on the optimal treatment method for SBCs.[26] An RCT historically provided support for injection with steroid, yet this treatment has fallen out of favor due to prolonged cyst resolution time and poor cure rates <50%. Do recent studies provide a potential better solution?

Available literature and quality of the evidence

- Level I: 1 meta-analysis and Cochrane review[26] and 1 randomized controlled trial (RCT).[27]
- Level III: 3 studies.[28–30]

- Level IV: 3 studies.[31–33]

Findings

Wright et al. reported their RCT of 90 patients randomly allocated to treatment with injection of either bone marrow or methylprednisolone with the primary outcome being radiographic evidence of healing. Forty-two percent of those treated with methylprednisolone acetate healed, and 23% of those treated with bone marrow healed ($p = 0.01$). There was no significant difference between the treatment groups ($p > 0.09$) concerning function, pain, number of injections, additional fractures, or complications. However, while superior to simple injection of bone marrow, methylprednisolone still had a very low healing rate (42%) and patients required multiple injections to obtain this result (1.7 ± 1.0 injections under general anesthesia).[27]

Two retrospective studies from the 1980s compared steroid injection with curettage and grafting. Oppenheim and Galleno compared 37 patients with SBC treated operatively (curettage with or without grafting, using autologous or allograft bone) to 20 patients treated with steroid injection with a minimum follow-up of two years.[28] In the operative group the recurrence rate was 40%, rising to 88% in patients under the age of 10 years with active cysts (less than 1 cm from the physis). Major complications occurred in 15% and included infection, refracture, coxa vara, extremity shortening, and physeal damage. In the steroid injected group, the overall response rate to the first injection was 40%, with 50% requiring more than one injection. The injections were done at intervals from 3 to 17 months when no progressive healing was observed in sequential radiographs. Both demonstrated low rates of healing. Due to the simplicity of the procedure and lower morbidity associated with the steroid technique, this was

favored by the authors. Bovill and Skinner reviewed a retrospective cohort of 32 patients with SBC treated in three different ways: 15 patients were treated surgically with diverse procedures, 12 were given steroid injections, and five were treated nonoperatively.[29] The average age at presentation was 8.9 years and average follow-up was 5.6 years. They concluded that steroid injections were as effective as surgical intervention while having lower morbidity. This evidence demonstrating no difference between techniques must be taken in context; the studies were small and likely underpowered, and the surgical procedures were not well documented or standardized, without mention of modern techniques that typically include complete cyst lining excision, breaking through the cyst wall into the medullary canal, and grafting with a material that is slow to resorb.[34]

Roposch et al. reported their results of flexible intramedullary nailing for the treatment of humeral femoral and radial SBCs in 32 patients with mean follow-up of 54 months.[31] Healing ranged from 3 to 105 months. Fourteen cysts healed completely, and 16 healed with residual radiolucent areas visible on radiographs. There was recurrence of two cysts that had healed with residual radiolucency. A change of nails was necessary in nine patients, as the nails had become too short after bone growth. No major complications were observed. They concluded that flexible intramedullary nailing provides early stability, which allows early mobilization and thus obviates the need for a plaster cast, decreases the prevalence of pathological fracture, and also allows for an early return to normal activity.

Wilke et al. completed a multicenter retrospective cohort study to determine whether internal fixation reduces the risk of further procedures for the treatment of SBC and if

radiographic healing is faster with internal fixation.[30] The study included 36 patients treated for SBC of the proximal femur between 1974 and 2014. SBCs were located in the femoral neck (n = 13), intertrochanteric (n = 16), and subtrochanteric (n = 7) regions. Initial treatment included steroid injection (n = 2), curettage and bone grafting (n = 9), and internal fixation with curettage and bone grafting (n = 25). Mean time was to radiographic healing was nine months and time to return to full activity was 15 months. A significant reduction in additional procedures was observed when patients had been treated with internal fixation. There was no difference in time to radiographic healing, but time to return to normal activities was reduced if patients had received internal fixation.

Jamshidi et al. described their experience with surgical reconstruction of pediatric SBCs of the proximal femur using a proximal locking plate and fibular strut allograft, in 14 patients.[32] Complete healing was seen in 10 cysts, while four other cysts healed with residual radiolucent areas. Mean time to healing was 14.1 ± 5.1 (9–24) months. One patient had superficial infection, one heterotopic ossification, and one mild coxa vara, and mean Musculoskeletal Tumor Society (MSTS) score was 99.5%.

Zhang et al. retrospectively evaluated 30 children who underwent curettage and bone grafting combined with elastic intramedullary nailing (EIN) and 32 patients who underwent curettage and bone grafting alone.[33] No statistically significant differences in sex, age, location, activity, pathological fracture, cyst volume, operative time, and intraoperative blood loss were found between the two groups. In the EIN group, 17 cases fully healed, 10 cases were partially healed, and three cases demonstrated persistent cyst. The authors reported an effective rate of 90.0% (effective rate = [cured + partially cured] / total

number of people). In the curettage and bone grafting alone group, 10 cases fully healed, 12 cases were partially healed, and 10 cases were not healed. The effective rate was 68.8%. There was a significant difference in curative effects between the two groups ($p = 0.013$). The authors concluded that, compared to simple curettage and bone grafting, curettage and bone grafting combined with EIN treatment can significantly improve the prognosis of children with bone cysts.

Resolution of clinical scenario

There is still little evidence to guide the management of SBCs in pediatric patients. Historically, steroid injection was favored due to its simplicity and low morbidity, but due to healing rates <50% this technique has been increasingly abandoned in favor of cyst curettage with complete removal of the cyst wall, grafting with synthetic or allogeneic graft, and internal fixation for long bones. The evidence to guide treatment of SBCs is low; recent studies do support treatment of proximal femoral SBCs with curettage, grafting, and internal fixation.

Summary of answers

- In children with an isolated geographical lucent lesion in the proximal metaphysis of the femur or humerus, who have no constitutional symptoms or clinical or radiological signs of infection or malignancy, plain radiographs may suffice (recommendation weak given low evidence).
- In the presence of presumed SBC, MRI is indicated in the presence of periosteal reaction, eccentric location, extension to the articular surface, or soft tissue involvement.

- Lucent lesions with length ≥3.3 cm, ≥2.5 cm, or involvement of ≥50% of the cortex as measured on anteroposterior or lateral views may be at increased risk of fracture and should be considered for potential surgical management.
- There is no role for injection of bone marrow aspirate.
- Historically, steroid injection was favored over curettage and bone grafting, as the technique was simpler and healing was equivalent. However, multiple anesthetics/injections were required, and the overall healing rate was unsatisfactory, <50%.
- Recent series have demonstrated 80–90% cyst healing rates when curettage and grafting is used in combination with internal fixation, and this is currently the favored approach for proximal femoral bone cysts, although the recommendation is weak (evidence is low).

177 Pediatric Clavicle Fractures

Benton E. Heyworth MD[1,2] and Nirav Pandya MD[3]
[1] Division of Sports Medicine, Department of Orthopedic Surgery, Boston Children's Hospital, Boston, MA, USA
[2] Harvard Medical School, Boston, MA, USA
[3] Department of Orthopedic Surgery, Benioff Children's Hospital, University of California San Francisco, San Francisco, CA, USA

Clinical scenario

- A 14-year-old right-hand-dominant football wide receiver sustains a mid-diaphyseal clavicle fracture secondary to a direct shoulder blow during football practice.
- Radiographs in the Emergency Department demonstrate 100% translation with bayonet apposition, with 20 mm shortening.
- The patient is placed in a sling and seeks treatment recommendations in the orthopedic clinic several days later.

Top three questions

1. Does primary surgical fixation of displaced clavicle fractures in the pediatric and adolescent population improve patient function or patient outcomes, compared with nonoperative treatment?
2. What risks are associated with surgical fixation of clavicle fractures in the pediatric and adolescent

population, including risk of secondary surgery, such as removal of implants?

3. Does the amount of shortening influence outcomes in displaced clavicle fractures in pediatric and adolescent patients?

Question 1: Does primary surgical fixation of displaced clavicle fractures in the pediatric and adolescent population improve patient function or patient outcomes, compared with nonoperative treatment?

Rationale

While historical treatment of closed clavicle fractures in the twentieth century consisted almost exclusively of nonoperative measures, management with slings or figure-of-eight braces, studies in the early 2000s suggested that clavicle fracture nonunion[1–3] and symptomatic malunion[4,5] were more common and more functionally debilitating sequalae of nonoperative treatment in adults than previously suspected. Moreover, several studies, including randomized controlled trials (RCTs), suggested superior functional outcomes following operative treatment in adult populations, when compared to nonoperative treatment. A clear trend toward clavicle fracture fixation in adults emerged, with caregivers of adolescent and pediatric patients also following suit[6,7] and increasing the frequency of operative treatment, despite a dearth of comparative studies investigating this concept in young patients.[8]

Clinical comment

The nonunion rate following nonoperative treatment of displaced midshaft clavicle fractures in *adults* is approximately 15%, and the symptomatic malunion rates in *adults* is approximately 9%.[9] The degree to which the clavicle studies of adult populations are applicable to pediatric and adolescent populations remains unclear.

Do children or adolescents have clinically significant rates of nonunion or symptomatic malunion, similar to adults? Is primary open reduction and internal fixation (ORIF) associated with significantly lower rates of nonunion and malunion? Does ORIF in a child or adolescent improve shoulder function, in terms of strength, range of motion (ROM), or scapular kinematics? Does ORIF lead to a faster return to activities of daily life or athletic activities?

Available literature and quality of the evidence

- Level I: 5 RCTs and 1 meta-analysis.
- Level II: 2 systematic reviews and 1 meta-analysis.
- Level III: 3 clinical series.
- Level IV: 6 clinical series and 1 review.

Findings

Several RCTs have emerged comparing operative to nonoperative treatment of displaced diaphyseal clavicle fractures in adult populations. In a landmark RCT conducted by the Canadian Orthopedic Trauma Society,[10] the authors reported a 14% nonunion and 18% symptomatic malunion rate in the nonoperative cohort, with significantly faster time to union, superior appearance scores, and superior patient-reported functional outcome scores in the operative cohort at all time points, including 6, 12, 24, and 52 weeks. In four subsequent similarly

designed RCTs performed in Finland,[11] the United Kingdom,[12] the Netherlands,[13] and Brazil,[14] respectively, nonunion rates ranged from 14 to 24% following nonoperative treatment, but similar functional outcome measure scores between treatment arms were reported at most or all time points in each study, leading the authors of all four studies to conclude that nonoperative treatment was the preferred primary treatment in adults.

Meta-analyses and systematic reviews of multiple level I or II studies have emerged, with varying conclusions. By pooling six level I studies, McKee et al. showed a nonunion rate of 14.5% and symptomatic malunion rate of 8.5% with nonoperative treatment, both significantly higher than those with operative treatment.[9] However, based on pooled outcomes scores that were *not* significantly different, the authors concluded there was little evidence to support a difference in long-term functional outcome between treatments. Xu et al. performed a meta-analysis including eight RCTs and demonstrated superior Disabilities of the Arm, Shoulder, and Hand (DASH) and Constant scores with surgery than nonoperative treatment.[15] In a systematic review, Virtanen et al. demonstrated that superior function associated with operative fixation is present only prior to six months postinjury/surgery.[16] A separate systematic review by Smeeing et al. demonstrated higher nonunion and malunion rates in nonoperatively treated fractures and faster return to work in surgical patients, but in the conclusions cited similar functional outcomes between cohorts.[17]

No RCTs or prospective cohort studies investigating clavicle fracture treatment in pediatric or adolescent patients have been published. Parry et al. retrospectively compared eight operatively treated to eight nonoperatively treated adolescents (mean age 14 years, range 10–16), and

found no difference in functional outcome measures, strength, ROM, or shoulder fatigue between the two groups.[18] Vander Have et al. reported on treatment of 43 clavicle fractures in adolescents (mean age 15.4 years), with no nonunions seen in 17 operatively and 25 nonoperatively treated patients. Symptomatic malunion was reported in 20% of nonoperatively treated patients, with 16% undergoing osteotomy surgery to resolve symptoms, compared with 18% of operative patients undergoing secondary hardware removal surgery. While reported as a level III retrospective study, the comparability of the two cohorts was not assessed, and no functional outcome measures were reported.[19] However, a number of level IV studies have assessed the outcome measures of pediatric and adolescent patients. Namdari et al. reported on 14 adolescents with ORIF and a mean QuickDASH score of 7 at a minimum of 24 months postoperatively, though four patients had undergone plate removal for hardware-related irritation or pain.[20] Randsborg et al. retrospectively analyzed 122 adolescents (mean age 14.4 years) treated nonoperatively with essentially normal functional shoulder scores, one nonunion (0.8%) successfully treated with delayed ORIF, and no cases of symptomatic malunion (0%) requiring surgery.[21] O'Neill et al. reported on 190 pediatric clavicle fractures, 65% of which were completely displaced, and reported no cases of nonunion and no cases of symptomatic malunion requiring intervention.[22] Hagstrom et al. retrospectively compared a series of 46 operatively treated patients (mean age 13.6 years, range 8–18) to 32 nonoperatively treated patients (mean age 10.3, range 10 months to 18 years), finding no difference in time to healing or DASH score, although three operative patients underwent peri-implant fracture and two operative patients underwent secondary hardware removal. No nonunions or

symptomatic malunions were reported.[23] Pennock et al. investigated 25 nonunions treated at nine pediatric hospitals over an 11-year period, underscoring the extreme rarity of this complication, surgical treatment was effective in all cases.[24] Hughes performed a similar study in the form of a systematic review, identifying all 21 previous cases of pediatric clavicle nonunion in the literature (prior to the Pennock study), 16 of which underwent surgery with satisfactory functional outcomes.[25]

Resolution of clinical scenario

While nonunion and symptomatic malunion are relatively common (5–25%) following nonoperative treatment of displaced midshaft clavicle fractures in adults, the most recent evidence suggests no difference in functional outcomes following operative versus nonoperative treatment, and most authors now recommend primary nonoperative treatment for displaced midshaft clavicle fractures in adults.

High-quality evidence to guide the treatment of this 14-year-old's displaced midshaft clavicle fracture is lacking. To date, there are no prospective comparative studies published comparing operative to nonoperative treatment in adolescents and children. Retrospective comparative studies and case series exist, and from these there is no evidence to support improved outcomes with surgical intervention in this population. With pediatric/adolescent nonunion and symptomatic malunions each estimated at <2%,[21] the theoretical benefit of surgical intervention in this population is minimal.

Question 2: What risks are associated with surgical fixation of clavicle fractures in the pediatric and adolescent population, including risk of secondary surgery, such as removal of implants?

Rationale

An increase in the primary surgical treatment of pediatric and adolescent clavicle fractures has emerged,[6,7] despite the absence of evidence supporting this practice.[8] Survey studies have shown that this trend relates to the influence of studies of adult populations on pediatric caregivers. If this trend toward surgeries continues on a national scale, an understanding of the potential risks to which children and adolescents are being exposed, beyond the inherent medical and anesthesia risks of surgery, is critical to insuring patient safety.

Clinical comment

While the risks of nonsurgical treatment in adults sustaining completely displaced clavicle fractures has been elucidated in a body of level I and II studies, nonunions, and symptomatic malunions are extremely rare in children and adolescents, with only one case of each in the largest series of 65 displaced midshaft clavicle fractures followed by Randsborg et al.[21] The risks of surgery for adults with completely displaced fractures includes, in descending order of frequency: painful or irritating hardware, with or without subsequent surgery for hardware removal (19%),[26] neuropraxia or chest wall numbness, wound infection,

implant failure and refracture/peri-implant fracture, nonunion,[9] pneumothorax,[27] and neurovascular injury.

To what degree do the risks of clavicle surgery affect pediatric and adolescent patients? Are they similar to those that affect adults? How common is secondary surgery? Are there unique risks for this younger population?

Available literature and quality of the evidence

- Level I: 1 meta-analysis.
- Level II: 1 meta-analysis.
- Level III: 2 clinical series.
- Level IV: 5 clinical series.

Findings

Higher-level studies investigating complications after clavicle fracture treatment have more frequently been published in the adult literature than the pediatric and adolescent literature. Two meta-analyses effectively report on the breadth of complications that have been reported in high-level adult studies.[9,15] McKee et al. investigated studies accounting for 212 operative patients, 62 (29%) of whom sustained reported complications, most common of which was painful, irritating, or protruding hardware (13%), most of which underwent subsequent surgery for hardware removal. Five cases of delayed union and three nonunions were reported, suggesting this as a rare occurrence, and five cases of nerve injury or neuropraxia. Xu et al. focused on five major complications – symptomatic malunion, delayed union, refracture/implant failure, infection, and secondary surgery – and found no difference in the complication rates between surgical and nonoperative treatment. Leroux et al. performed a population-based study on the administrative database for

the entire province of Ontario, Canada. Surprisingly, 24.6% of patients underwent at least one clavicle re-operation within two years, the most common of which was implant removal (18.8%), but reasons for re-operation also included nonunion (2.6%), deep infection (2.6%), and malunion (1.1%). Pneumothorax (1.2%) and brachial plexus and subclavian vessel injuries rarely occurred (<1%).[26]

In pediatric populations, no cases of subclavian vessel or brachial plexus injury have been reported, but secondary hardware removal is common, with various authors reporting relatively high rates: Vander Have et al. (18%),[19] Namdari et al. (29%),[20] Mehlman et al. (100%).[28] Li et al. reported an overall complication rate of 86% following operative treatment, including 42% implant removal surgery, anterior chest wall numbness (15%), superficial wound dehiscence or infection (5%), peri-implant fracture adjacent to the plate (3%), and refracture following plate removal (3%).[27] Hagstrom et al. also reported on peri-implant fracture in three of the 46 operative patients (7%).[23]

Resolution of clinical scenario

Complications following operative treatment of clavicle fractures are relatively common, based on studies of both adult and pediatric populations. While the most common reported complication is hardware-related pain (approximately 15–20%), frequently requiring secondary surgery for hardware removal, the athletic participation and activity level of the adolescent population may put patients at higher risk for complications that relate to the hardware, either before (peri-implant fracture) or after simple hardware removal surgery (re-fracture through screw holes).

With surgical fixation of his clavicle fracture, this patient has a small risk of potentially life/limb-threatening complications such as pneumothorax or neurovascular injury. Risk of refracture about the plate and infection are estimated at <10%. Eighteen to 100% of patients undergo implant removal, and following implant removal there is a small risk of refracture. Given the considerable risk of minor and major complications associated with surgical treatment of clavicle fractures, the evidence supports primary nonoperative treatment of displaced midshaft clavicle fractures in children and adolescents.

Question 3: Does the amount of shortening influence outcomes in displaced clavicle fractures in pediatric and adolescent patients?

Rationale

Several studies of adult patient populations have suggested that the degree of *shortening* associated with completely displaced clavicle fractures is a critical determinant of patient outcomes.[3–5,29–32] Greater shortening has been linked to higher rates of nonunion and symptomatic malunion, which may relate to altered shoulder kinematics. Shortening has therefore been utilized by surgeons as a threshold in the indications for surgery, or at least a factor in the decision-making process for surgical versus nonsurgical treatment. Specifically, fractures with shortening ≥20 mm are frequently cited as meeting relative indications for fixation. These same thresholds are frequently applied to the pediatric and adolescent populations; younger patients are undergoing more surgical treatment than in decades past.[6–8]

Clinical comment

As the last bone in the human skeleton to complete its ossification process – as late as 25 years old in most people – the clavicle may have enhanced remodeling capacity, compared with many long bones. Therefore, adolescents may be able to accommodate for changes in clavicle morphology following completely displaced fractures, including those with even severe shortening, on both the short- and long-term postinjury periods. To what degree does shortening influence outcomes after adolescent clavicle fractures? How well does the pediatric skeleton recover from a nonoperatively treated, shortened fracture?

Available literature and quality of the evidence

- Level III: 2 clinical series.
- Level IV: 3 clinical series.

Findings

Vander Have et al. reported on 5 of 25 (20%) adolescent clavicle fracture patients who developed symptomatic malunions after nonoperative treatment.[19] The symptomatic malunion diagnosis was made at a mean of 14.6 month postinjury, and four of these five patients (16% overall) elected to undergo osteotomy and plate fixation of the clavicle, which addressed their symptoms in all four cases. Given that the mean fracture shortening in this subset was 26.6 mm, the authors concluded that malunions may be more common in adolescents than previously thought, and cited the 20 mm threshold often referred to in the adult literature, stating that operative fixation restores clavicle length with low complication rates. Randsborg et al. reported on one patient (out of 56 older children and adolescents, ages 10–18) whose completely displaced

fracture with 15 mm of shortening developed a symptomatic nonunion requiring fixation 5.3 months postinjury.[21] While three other patients were reported to have a symptomatic malunion, none required surgery. The authors separately reported a small, but statistically significant adverse effect of shortening on overall functional, cosmetic, and satisfaction scores. However, the authors concluded that conservative treatment should remain the mainstay of management for fractures of the clavicle in this age group. Parry et al. compared eight operative to eight nonoperative patients with ≥15 mm of shortening, citing no cases of symptomatic malunion in the nonoperative group and no clinically significant differences in ROM, strength, or shoulder fatigue between cohorts.[18] Bae et al. similarly investigated two-year results of 16 adolescents with >20 mm shortening in midshaft fractures, reporting outcome scores and pain scores comparable to normative values, and only one of whom developed symptoms requiring osteotomy.[33] Schulz et al. investigated 16 adolescents with completely displaced fractures and a mean shortening of 14 mm (range 11–21 mm). Fifteen patients were satisfied with their treatment, and one was dissatisfied with their clavicle prominence.[34] The authors found no significant difference in the strength, pain, ROM, and outcome scores between the injured and uninjured shoulders in this cohort.

Resolution of clinical scenario

There is no high-quality evidence to guide surgical indications as it relates to clavicular shortening in children and adolescents. The range of 15–20 mm of shortening has been used as a convention in this population, but comparative studies have not demonstrated differences in clinical outcomes at these cutoffs in this age group. Unlike authors of adult clavicle fractures, most authors of

pediatric and adolescent studies have concluded that symptomatic malunion represents an extremely rare event, with minimal to no adverse effects on shoulder strength, ROM, overall function, and patient-reported outcomes, even in the setting of severe shortening. Despite 20 mm of shortening and 100% fracture translation in this 14-year-old football player, there is no clear indication for surgical intervention.

Summary of answers

- Although nonunion and symptomatic malunion are not uncommon in adults, they are rare in children and adolescents (<2%).
- No prospective comparative studies exist between the operative and nonoperative treatment of displaced clavicle fractures in children and adolescents. Results of retrospective comparative studies and case series in this population suggest no functional or patient-reported benefit with surgical treatment.
- Following surgical treatment of clavicle fractures, there is a small risk of limb/life-threatening complications such as pneumothorax or neurovascular injury. Fracture around the plate, or following plate removal may occur 3–7% of the time. Plate removal is common, with some series reporting 100% plate removal.
- There is no magnitude of shortening to constitute a definitive cutoff for indicating surgery in this young population. There is no consistent evidence demonstrating worse outcomes with shortening >15–20 mm in this population. There is no defined threshold of shortening beyond which surgery should be indicated.

- Prospective comparative studies with sufficient sample size are warranted to more clearly elucidate the relative risks and benefits of the operative versus nonoperative treatment of this common injury in children/adolescents.

178 Supracondylar Humerus Fractures

Ravi Brar MD MPH[1], David Skaggs MD MMM[2], and Sanjeev Sabharwal MD MPH[1]
[1] UCSF Benioff Children's Hospital, Oakland, CA, USA
[2] Department of Orthopaedic Surgery, Children's Hospital Los Angeles, Los Angeles, CA, USA

Clinical scenario

- A five-year-old girl sustains a left supracondylar humerus fracture after a fall from the monkey bars.
- In the Emergency Department, she is cooperative with exam and has no neurologic deficits.
- She has no skin puckering and the injury is closed. Her hand is warm and well-perfused with brisk capillary refill.
- A radial pulse is not palpable.

Top three questions

1. In children with a supracondylar humerus fracture, when should an open reduction be performed instead of a closed reduction to ensure optimal outcomes?
2. In a child whose supracondylar humerus fracture needs an open reduction, which surgical approach is best to optimize outcomes?
3. In a child who presents with a supracondylar humerus fracture without a palpable pulse, when should a

vascular, open exploration be performed to optimize outcomes?

Question 1: In children with a supracondylar humerus fracture, when should an open reduction be performed instead of a closed reduction to ensure optimal outcomes?

Rationale

The gold standard in the treatment of displaced pediatric supracondylar humerus fractures is closed reduction with percutaneous pinning. However, there are supracondylar humerus fractures that necessitate an open reduction.

Clinical comment

An open reduction is indicated in the following situations:

- Unable to obtain an acceptable alignment of the fracture fragments using closed reduction.
- Open fracture.
- Compartment syndrome.
- Vascular injury

  Hand is poorly perfused following reduction and fixation.
- Change in neurologic exam or vascular exam (for the worse) following closed reduction of a supracondylar fracture.

Findings

According to Holt et al., nationally 24% of children with supracondylar humerus fractures undergo surgery in the US. Among surgically treated supracondylar humerus fractures, there is a 12.7% rate of open reduction. They also found that, as displaced supracondylar fractures are more often being transferred to tertiary care facilities and being treated by fellowship-trained pediatric orthopedic surgeons, the rates of performing open reductions are trending down.[1] In another study of pediatric closed type III supracondylar humerus fractures, there was a 9.4% rate of conversion following an attempted closed reduction to an open reduction,[2],[3] Novais et al. in their retrospective review found that the incidence of conversion from closed to open reduction was 7%. Among those treated with ORIF, the indication in the majority (93%) of cases to convert to open treatment was secondary to irreducibility of fracture fragments – 40% due to fracture instability, 36% secondary to brachialis interposition, 16% due to periosteal interposition, and 8% secondary to triceps interposition. In those children where the indication to convert to open reduction was secondary to change in vascular status after attempted closed reduction, neurovascular structures were entrapped at the fracture site.[4]

In a retrospective review of 236 surgically treated type III supracondylar fractures at a single institution, Pesenti et al. noted that the low-volume surgeons (treating less than five type III supracondylar fractures/year) had a higher frequency of performing open reduction and had worse postoperative radiographic alignment than those fractures treated by higher volume surgeons. This same study also demonstrated that there is a learning curve of approximately 20 patients with supracondylar humerus fractures treated surgically (close or open reduction) to

positively impact operative time and radiographic outcomes.[5]

The flexion type supracondylar humerus fracture is less common than extension type, approximately 5% of supracondylar humerus fractures. The ulnar nerve can be entrapped in the fracture site – causing nerve compromise and blocking reduction. Open reduction should be undertaken if there is a persistent gap at the fracture side or when the fracture gap closes down, but then springs back open: the *rubbery* reduction.[6]

A retrospective study done by Flynn et al. found that a flexion-type injury had a 15.4-fold increase in the odds of open reduction. They also found that if a flexion-type supracondylar fracture presented with an ulnar nerve injury, there also was a 6.7-fold additional higher risk of open reduction. This study brought to light the need to counsel patients and families preoperatively regarding the increased rate of performing an open reduction in these specific situations and to prepare the operating room appropriately.[7]

Based on the available evidence, the need for open versus closed reduction techniques is not a predictor of clinical outcome.[2] Studies have failed to demonstrate clinically significant differences in outcome when comparing open reduction to closed reduction of displaced supracondylar humerus fractures. Clinical outcome is most often assessed using Flynn's criteria[8] and are comparable in final radiographic alignment and range of motion.[9],[10] The only differences between the two approaches was a longer surgical time and a larger scar in those who underwent open reduction.[9]

Question 2: In a child whose supracondylar humerus fracture needs an open reduction, which surgical approach is best to optimize outcomes?

Rationale

The “best” approach is controversial. For closed fractures, there is literature to support the use of anterior, medial, lateral, and posterior approaches.

Clinical comment

Open fractures, which account for 1% of supracondylar humerus fractures, obviate the decision of the preferred surgical approach.[2],[11] The zone of injury allows for direct visualization and decompression of the fracture, often utilizing an extension of the traumatic wound.

Findings

A principle to keep in mind is that the incision for open reduction of supracondylar humerus fractures is dictated by the location of the distal metaphyseal spike of the proximal fragment. Make a direct approach that is centered over the prominent metaphyseal spike as this is where the overlying periosteum or muscle (most often brachialis) is most likely entrapped and blocking the reduction[6],[10] By choosing the incision based on the location of the metaphyseal spike, one avoids disruption of the remaining intact periosteum, which acts as a periosteal hinge. Otherwise, one risks further destabilization of the fracture fragment or interruption of blood supply to the distal fragment.[10],[12] We believe that this surgical approach is

logical when the indication for an open reduction is an inability to obtain an acceptable close reduction.

In general, the anterior approach (of Henry) is the best used in cases of possible vascular injury since it allows for exploration of the brachial artery. The fracture site can be exposed with a transverse incision in the cubital fossa along the flexion crease of the elbow. The incision can then be extended to a *boat race* incision with the medial limb extending proximally to follow the median nerve and brachial artery. If an anterior approach is used primarily due to inability to achieve an acceptable closed reduction in an extension type injury, one can often make a very small incision directly over the anterior spike, in order to use a finger to sweep out an entrapped brachialis muscle.

After removal of any interposed tissue from the fracture site, place a thumb on the anterior metaphyseal spike and index finger on the olecranon posteriorly to obtain a reduction. The anterior incision allows for palpation of both, the lateral and medial epicondyles to evaluate for any malrotation at the fracture site.[13] It is the authors' experience that an anterior incision is rarely needed secondary to irreducibility if a *milking maneuver* is performed.[14],[15]

A medial approach to the elbow allows for direct visualization of the medial column of the distal humerus, as an aid for restoration of rotation and alignment at the fracture site. It also facilitates placement of a medial Kirschner wire (K-wire), if necessary, minimizing the risk for iatrogenic injury to the ulnar nerve. A medial approach is most often used in a flexion-type injury. The advantages of this approach are direct visualization of the ulnar nerve, and a cosmetic incision.

The lateral approach often affords a more familiar approach to most surgeons, and is similar to the one used

for the open reduction and percutaneous pinning of lateral condyle fractures. The disadvantage of this approach is a very visible scar.

A direct posterior approach can also be performed with a triceps-splitting technique versus triceps tendon transection and proximal reflection. Both approaches allow adequate visualization of the medial and lateral columns. However, the triceps transection technique has been associated with a significant decrease in triceps strength. Some studies also demonstrate that posterior approaches lead to restriction in range of motion, specifically extension. Transection of the triceps tendon has not been found to benefit fracture reduction.[16]

With the posterior approach to a supracondylar humerus fracture, there is also an increased risk of avascular necrosis secondary to disruption of the posterior blood supply to the trochlea. Avascular necrosis of the trochlea remains a known risk for the lateral approach as well.[17] These authors recommend against a posterior approach due to the risk of avascular necrosis (AVN). In an immature elbow subperiosteal dissection should be avoided posteriorly over the capitellum and trochlea.

Question 3: In a child who presents with a supracondylar humerus fracture without a palpable pulse, when should a vascular, open exploration be performed to optimize outcomes?

Rationale

If a child with a supracondylar humerus fracture has a pulseless, poorly perfused hand, undoubtedly the child should undergo emergent reduction and fixation. Hand perfusion may be assessed by arterial capillary refill, warmth, and color of the hand.[18]

Patients presenting with a pulseless and poorly perfused hand (sluggish capillary refill, cool, and pale) are at highest risk for compartment syndrome and needing vascular repair.[19] Preoperative ischemia is the primary factor that has been shown to significantly increase the need for vascular surgery.[20]

If, after closed reduction, there is no pulse and the hand is still poorly perfused (hand is cool and white), one should open the fracture anteriorly and explore the brachial artery. The artery may have been caught at the fracture site and need to be untethered from the fracture site. There also may be a thrombus or an arterial laceration. A surgeon trained in vascular repair should be consulted for thrombolysis or repair of the injured artery.[21],[22] We recommend consulting vascular surgery when a child presents with a pulseless, cold, white hand and having them on standby if vascular status is not improved with reduction and fixation.

Clinical comment

The area of controversy is the warm, well-perfused hand without a pulse. Debate exists as to whether *pulseless* refers to simply not palpable or not palpable and not Dopplerable radial pulse. Still, the presence of a pulse either by palpation or Doppler should be established and documented preoperatively, intraoperatively, and postoperatively. To access a pulse postoperatively for close monitoring, one can place the patient in a posterior splint.

This will also allow the surgeon to assess for compartment syndrome.

Another layer of the controversy is also the optimal postoperative management for the pulseless, well-perfused supracondylar humerus fractures after operative reduction and fixation.

Findings

If a pulse is not palpable, but there is a Dopplerable signal, there is no evidence to support delaying treatment.[23] In other words, these authors recommend urgent treatment of the pulseless supracondylar humerus fracture, whether a pulse signal is dopplerable or not.[18] There is also no indication for prereduction angiography in a pulseless limb.[23–25] Angiography often unnecessarily delays definitive treatment. If the brachial artery is injured, the injury is almost always at the fracture site, in the absence of some highly unusual conditions such as a concomitant proximal humerus fracture,[26] Duplex ultrasound can also be used to map the arterial flow in the arm, determining if there is a defect in the course of the artery and if there is sufficient flow distally, with or without collateral circulation.

A pulse oximeter on the affected limb can be used as another objective assessment tool for distal perfusion. After operative stabilization of the supracondylar fracture, the presence of waveform on the pulse oximeter is highly sensitive (95.6%) in determining vascular perfusion. Soh et al. used the presence and quality of waveform using a pulse oximeter to support or reject the decision for surgical exploration. In their study, four patients with type III supracondylar humerus fractures did not have pulse oximeter waveforms postoperatively. These four patients

underwent exploration of the brachial artery with significant findings.[27]

After fixation of a supracondylar humerus fracture in a well-perfused pulseless hand, if there is return of a pulse (palpable or Dopplerable), we observe the patient for at least 24 hours before discharge. Additionally, if after fixation there is no pulse but the hand is warm and well perfused, the child should be observed closely for at least 48 hours, with regular clinical checks, staying vigilant for an evolving compartment syndrome.[18,19]

If there is a decrease in limb perfusion postoperatively, the child should be taken back to the operating room for emergent vascular exploration.[18–20] In these cases, the majority of the time the artery itself may not trapped be in the fracture site, but tissue surrounding the artery is trapped in the fracture site, tethering the artery at an acute angle. When this tissue is released, the pulse and perfusion usually return.

Even with interruption of the brachial artery at the level of the fracture there can still be distal flow secondary to rich collateral circulation. This can manifest with a well-perfused hand without a palpable or consistently Dopplerable pulse. At that point, whether the artery should be explored should be a discussion between the orthopedic surgeon and the vascular surgeon. Color flow Doppler ultrasound, which is noninvasive and often readily available, may help surgeons better determine the adequacy of distal flow.[26] Still, the question of how much arterial flow distally is sufficient is not well documented in the literature and is a judgment based on physical exam and shared clinical experience.

Surgeons need to have a heightened suspicion of brachial artery injury in a supracondylar humerus fracture with a median nerve deficit. These two structures travel together

in the cubital fossa. The artery can be lacerated or kinked by the metaphyseal spike of an extension type III supracondylar humerus fracture.[18,28] Additionally, median nerve injury can mask the typical clinical signs of compartment syndrome.

To summarize, for a patient who presents with a pulseless supracondylar humerus fracture with poor perfusion, the first-line treatment is an urgent attempt at fracture reduction under general anesthesia. Surgeons, however, should have a low threshold for open exploration and possible vascular repair if perfusion is not improved following fracture reduction or an adequate reduction cannot be obtained by closed means.[19] Anticipation of open reduction and/or vascular repair should be heightened if the patient presents with a pulseless, ischemic hand or has a pulseless hand with a median nerve deficit (Figure 178.1).

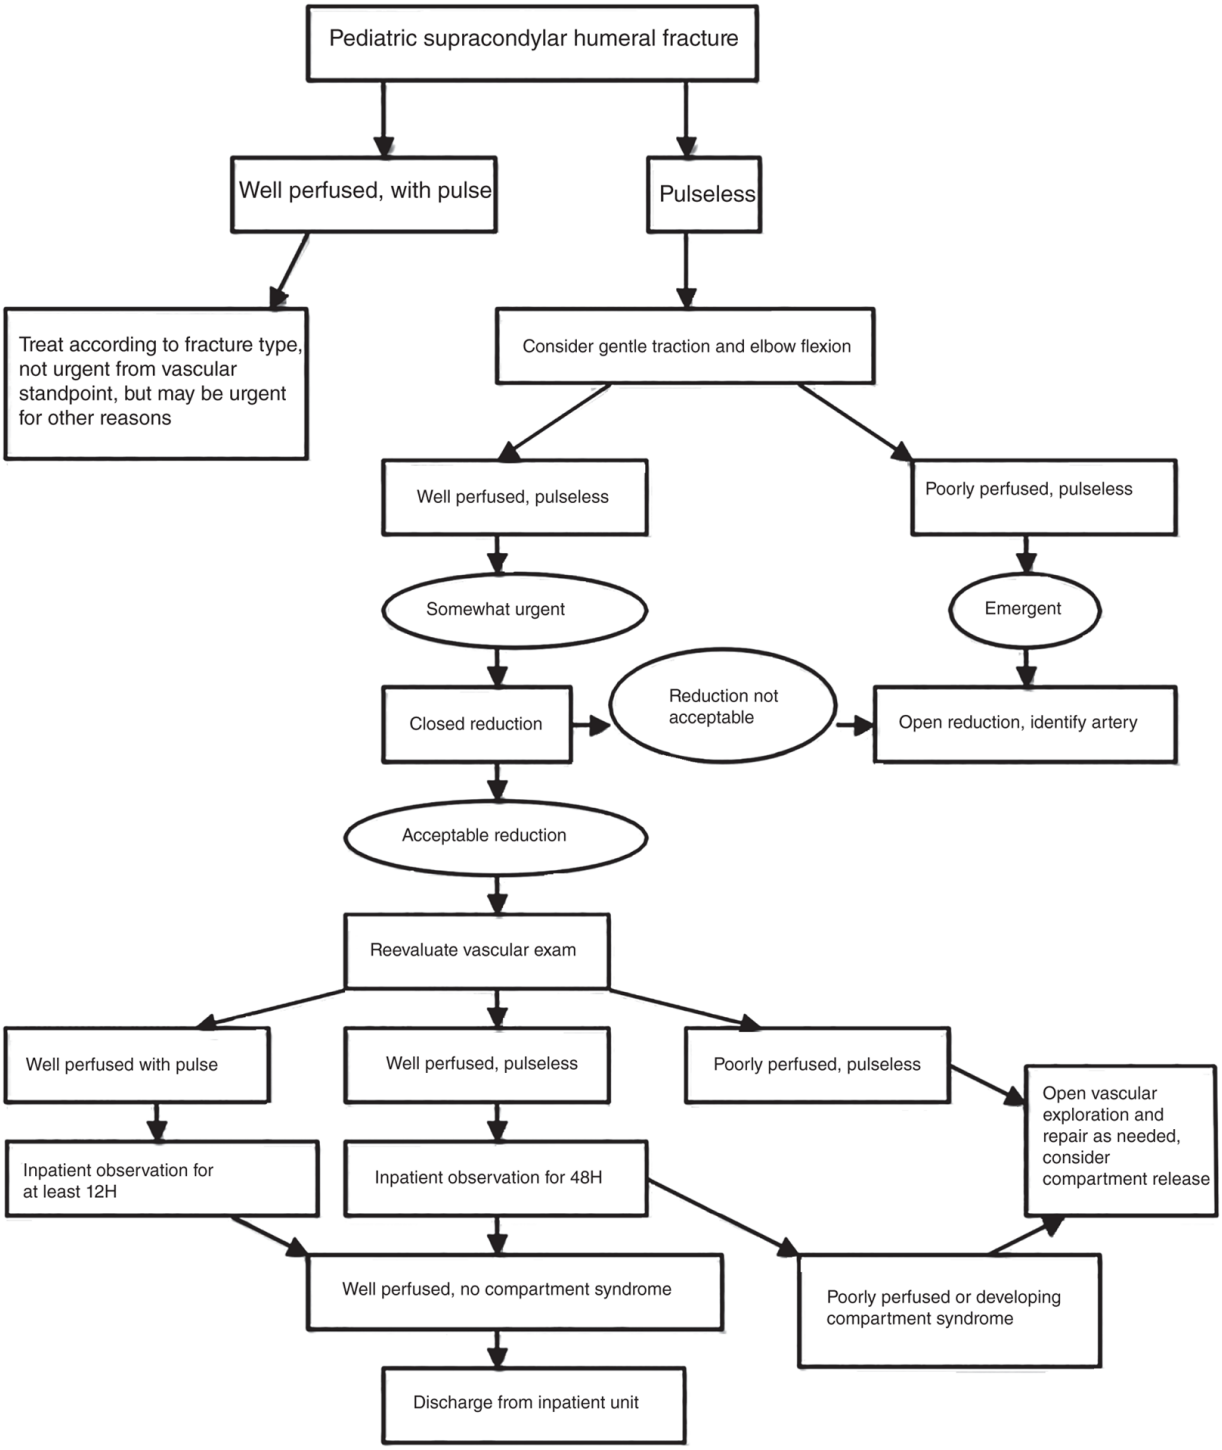

Figure 178.1 Supracondylar humeral fracture treatment algorithm. Source: Badkoobehi et al.[18]

Summary of answers

- The gold standard for operative treatment of supracondylar humerus fractures is closed reduction with percutaneous fixation. However, some supracondylar humerus fractures cannot be treated with closed reduction secondary to irreducibility and soft tissue interposition.
- There is a higher likelihood of open reduction in the flexion type supracondylar humerus fracture.
- According to the available literature, there is no difference in clinical outcomes between children with supracondylar humerus fractures who underwent closed reduction versus open reduction.
- There is no single best surgical approach for an open reduction of a supracondylar humerus fracture. Still, the authors caution against a posterior approach and advocate an anterior approach in a supracondylar humerus fracture that may need vascular exploration.
- The first line of treatment for a pulseless supracondylar humerus fracture with poor perfusion is urgent fracture reduction. There should be a low threshold for performing an open exploration with possible vascular repair if the fracture cannot be reduced or the perfusion does not substantially improve with fracture reduction.
- A median nerve deficit can mask compartment syndrome. Since the median nerve runs is in anatomic proximity to the brachial artery, a median nerve deficit should prompt more suspicion for vascular injury and the need for open exploration in a pulseless supracondylar humerus fracture.

[1] Children's National Health System, Division of Orthopaedic Surgery and Sports Medicine, Washington, DC, USA

[2] Department of Orthopaedic Surgery, Boston Children's Hospital, Harvard Medical School, Boston, MA, USA

Clinical scenario

- A 12-year-old female presents with recurrent low back pain despite six weeks of rest from gymnastics.
- The pain is reproduced with hyperextension of the lumbosacral spine.
- Her popliteal angle measured 30° on the right and 30° on the left. Motor and sensory exam are normal.
- The patient would like to compete in the regional gymnastic competition in four weeks' time. Radiographs are performed at an outside office but are not available for review at the time of the visit.

Top three questions

1. In adolescent patients with acute low back pain, what is the ideal diagnostic imaging to assess for spondylolysis?
2. In adolescent patients with a radiographic diagnosis of acute lumbar spondylolysis, what is the natural history of this condition?

3. In adolescent patients, what is the ideal treatment for low-grade versus high-grade spondylolisthesis?

Question 1: In adolescent patients with acute low back pain, what is the ideal diagnostic imaging to assess for spondylolysis?

Rationale

Diagnostic imaging is essential for establishing a distinct diagnosis for back pain with hyperextension. Patients who present with classic history and physical examination consistent with spondylolysis may be treated with a presumptive diagnosis for six weeks. However, if pain persists then diagnostic imaging should be performed. The ideal imaging modality providing the best accuracy with the least radiation exposure to assess for spondylolysis in adolescent patients is unclear.

Clinical comment

Diagnosis of spondylolysis in adolescent patients with persistent low back is challenging. Imaging is needed, but the ideal imaging modality must be accurate and minimize ionizing radiation exposure in the assessment, diagnosis, and treatment of this condition.

Available literature and quality of the evidence

Systematic reviews and retrospective cohort studies exist to answer this question.

Findings

The difficulty in the assessment of pediatric spondylolysis lies in the desire to choose an imaging study with the best diagnostic accuracy while limiting radiation exposure to the patient. Plain radiographs are readily available and relatively low radiation, but controversy exists as to whether two (anteroposterior [AP] and lateral) versus four views (AP, lateral, and obliques) are needed for optimal diagnostic accuracy. Beck and colleagues investigated this issue with a retrospective cohort study looking at the diagnostic value of these two types of radiographic imaging studies. They found no significant difference in either imaging technique in regards to the test characteristics. Two view radiographs had an accuracy of 0.81, sensitivity of 0.59, a specificity of 0.96, and positive and negative predicative values of 0.91 and 0.78. Four view radiographs demonstrated comparative values of 0.78, 0.53, 0.94, 0.85, and 0.76, respectively.[1]

While computed tomography (CT) scanning is thought to be more accurate then magnetic resonance imaging (MRI) in the assessment of pediatric spondylolysis, Campbell and colleagues assessed the diagnostic accuracy of CT and single-photon emission computerized tomography (SPECT) imaging to that of MRI in 72 pediatric patients with acute low back pain. These authors found MRI was able to diagnose pars abnormalities in 98% (39/40) of pars defects found on CT/SPECT. Concordant defect grading between MRI and CT/SPECT was seen in 73% (29/40) of cases.[2] While both normal anatomy and complete pars fractures were readily identified on both CT/SPECT and MRI, incomplete fracture identification remained challenging with MRI. Similar findings were found by Masci and colleagues in their investigation of 71 subjects with acute low back pain. They found 80% of the pars abnormalities identified by bone scan to be seen on MRI and 95% of pars fractures identified on CT to be seen on MRI.[3]

Two recent systematic reviews of the literature investigating imaging for pediatric spondylolysis have been performed.[4],[5] Both studies indicate that it is difficult to reach any conclusions based on review of the literature because of the lack of high level evidence and variation in outcomes reporting in the studies reviewed. Despite this, both studies recommend screening for pediatric spondylolysis should start with a two-view plan radiograph. Advanced imaging in cases of indeterminate radiographs or persistent symptoms can be done with either CT or MRI scan. While CT scan is associated with more radiation exposure, this modality may be more accurate in detecting incomplete pars fractures.

Resolution of clinical scenario

- Despite a reported low sensitively with plain radiographs, due to the availability of this imaging and the relatively low radiation exposure, screening for spondylolysis in this patient with persistent low back pain is best done with two-view lumbar radiographs.
- Advanced imaging for detection of lumbar spondylolysis can be performed by CT or MRI scan when back pain persists and radiographs are negative or indeterminate. While both modalities are comparable, CT may be considered in longer courses of symptoms when incomplete fractures are more prevalent, whereas MRI should be considered in shorter-duration cases when pars stress reaction is more likely. If the plain radiographs are normal, an MRI should be ordered to assess for pars injury in this patient.
- Use of SPECT bone scan in the diagnosis of extension-induced back pain in the adolescent athlete does not seem to be supported by any evidence in light of the high radiation dose of this imaging modality.

Question 2: In adolescent patients with a radiographic diagnosis of acute lumbar spondylolysis, what is the natural history of this condition?

Rationale

Following diagnosis of acute lumbar spondylolysis in pediatric patients, questions exist as to the natural history of this condition. Understanding the effects of lumbar spondylolysis found in childhood in regards to the healing of the underlying pars fracture, expected symptoms in the future, and progression of the defect to spondylolisthesis significantly impacts informed decisions on appropriate treatment and follow-up.

Clinical comment

A clear understanding of the natural history of acute lumbar spondylolysis, in regards to defect healing, long-term symptoms, and progression of the defect to spondylolisthesis is critical to determine appropriate treatment in pediatric patients presenting with this condition.

Available literature and quality of the evidence

Systematic reviews, as well as prospective and retrospective cohorts, exist to answer this question.

Findings

The expectation of healing of pediatric spondylolysis appears to depend on the morphology of the pars defect. Two studies investigating the long-term natural history of pediatric spondylolysis have demonstrated healing in only

unilateral defects.[6,7] Despite this, other studies have demonstrated healing of some bilateral defects, depending on the presences of specific prognostic findings. Fujii and colleagues evaluated 134 patients with pediatric lumbar spondylolysis at a mean follow up of 3.4 years and found the following factors to be predictive of defect healing: vertebral level of the defect, degree of lumbar lordosis, slipping of the affected vertebral body, location of the defect, and condition of the contralateral pars.[8] Sairyo and colleagues developed a grading system of lumbar spondylolytic defects on CT scan and found this was predictive of eventual defect healing.[9]

Less information is available in regards to the natural history of symptoms in patients with acute lumbar spondylolysis diagnosed in childhood. Beutler published a follow-up study on the natural history of a cohort of 30 patients at 45 years following diagnosis of this condition. They found no statistical differences in the reported function and pain domains of the Short Form 36 (SF-36) survey in these patients with spondylolysis as compared to age-matched norms.[6] Similarly, Miller and colleagues reported on 32 patients with a mean follow-up of nine years following diagnosis of spondylolysis. They reported 91% of patients had good or excellent scores on the Low Back Outcome Score (LBOS) survey.[7]

Finally, progression of a spondylolytic defect in pediatric patients to spondylolisthesis seems to be associated with laterality of the defect and maturity of the patient. In numerous studies, authors have found only bilateral spondylolysis are at risk of progressive deformity. Additionally, Sairyo and colleagues showed progression is dependent on the skeletal maturity of the patient, with those patients presenting with less maturity having a higher risk of progressive deformities.[10]

Resolution of clinical scenario

- The natural history of pediatric spondylolysis appears to be most related to the morphology of the pars defect and skeletal maturity of the patient.
- Healing of a spondylolytic defect and progressive deformity are inversely related, with bilateral defects and less mature patients being more likely to have persistent defects and progressive deformities.
- Despite the low incidence of pars defect healing, long-term symptoms of pain and disability appear to be rare as compared to age-matched norms.

Question 3: In adolescent patients, what is the ideal treatment for low-grade versus high-grade spondylolisthesis?

Rationale

Low back pain, restricted range of motion, and performance anxiety are symptoms that drive patients to seek medical care. The high prevalence rate of 6% of spondylolysis/listhesis in the asymptomatic adolescent population requires clinicians to establish a causative relationship between the clinical presentation and the imaging. Restoration of function and reduction of pain are the goals in treatment of low-grade spondylolisthesis. High-grade patients have proven instability of the vertebral column with risk for nerve root injury.

Clinical comment

Adolescent patients with spondylolytic defects and their parents often are anxious to return to their activities as quickly as possible. However, they need to be informed about the potential for recurrent injury limiting their immediate athletic participation as well as potential long-term effects that will extend into adulthood. Therefore, often the “ideal” treatment plan is a shared decision to balance the short- and long-term goals of the patient and their parents.

Available literature and quality of the evidence

Systematic reviews and diagnostic studies exist to answer this question.

Findings

The systematic structured reviews of the literature were unable to find any level I or II studies of comparative treatment for spondylolisthesis.[11,12]

Nonsurgical treatment of spondylolysis has included restricted activity, nonsteroidal medications, physical therapy, and bracing. A systematic review of the treatment of pediatric spondylolysis did not find any comparative studies of natural history to nonoperative treatments. Both natural history and various nonoperative treatments report return to activity of 80–85% of patients. There was insufficient evidence to favor a specific treatment modality.[11,12]

Operative repair of spondylolysis and low-grade spondylolisthesis has been performed by several methods. A meta-analysis of 46 studies reported on 900 patients from retrospective observational studies with the majority of the patients in their second decade of life. The best fusion rates (90.21 and 83.53%) and lowest complication rates (12.8

and 13.41%) were found in the pedicle screw and Buck screw groups, respectively.[13]

Comparative studies on the surgical results of high-grade spondylolisthesis have mixed results possibly due to poor preoperative classification systems. Pathologic posture of the lumbosacral junction can be distinguished from compensatory stance based on radiographic measurements. A radiologic classification based on standing sagittal images of the total spine and pelvis (C7 to femoral heads) was validated by Mac-Thiong et al. Outcomes measures of surgical treatment based on the severity scale have not yet been published.[14]

Systematic reviews which focus on treatment of high-grade spondylolisthesis by in situ fusion versus reduction and fusion have identified eight retrospective comparative series (level III).[15],[16] No comparative series of operative or nonoperative treatment of high-grade spondylolisthesis were identified. The mean reduction in anterior translation of L5 on S1 was 27.8% ± 13.2%. Slip angle mean reduction 20.9° ± 1.7° (four studies). Pseudarthrosis rate was 5.5% in the 165 patients in the reduction groups, while the 101 patients in the fusion in situ groups had a rate of 17.8% ($p = 0.004$). The standardized risk ratio for a pseudarthrosis in the pooled reduction group was 0.4 (95% confidence interval: 0.19–0.81) compared to the patients with in situ fusion.

Neurologic deficits, a concern with surgical treatment, were found in 13 (7.9%) of the 165 in the reduction group patients in the reduction group and in nine (8.9%) of the 101 patients in the arthrodesis in situ group ($p = 0.8$). Instrumentation failure leading to revision surgery was reported in eight (4.8%) of the 165 patients in the reduction group and none in the in situ group. The analysis concluded that reduction and fusion of high-grade

spondylolisthesis lowered the risk of nonunion and there was no difference in rate of neurological injury between the surgical groups.[15,16]

Resolution of clinical scenario

The patients radiograph showed Meyerding grade I spondylolisthesis with lumbosacral angle of 95° (normal 110°). A discussion of the treatment options of observation, nonoperative treatment, or surgical treatment was had with the patient and her family. The patient and family agreed on a treatment plan to initially withdraw from sports activity for six weeks, the use of lumbosacral orthosis, and undertaking a physical therapy program. This plan gave her an 85% chance to return to her sport after three months of consistent brace wear. She would progress out of the brace and back to gymnastics based on her clinical improvement as imaging studies would most likely not change over this period.

Summary of answers

- Initial imaging should be performed using two-view lumbar radiographs. If symptoms persist following a course of nonoperative treatment in the setting of normal radiographs, an MRI or CT scan should be performed (modality dependent on the length of symptoms) to assess for pars defect.
- Healing and progression of spondylolysis are related to the skeletal maturity of the patient and pars defect morphology with unilateral pars injury and more mature patients being more likely to heal the defect and have less progression. Long-term symptoms of pain and disability in this condition are rare.

- Treatment of low-grade spondylolisthesis is similar to the plan for spondylolysis. Restricting activity has rates of success equivalent to lumbosacral orthosis use. The evidence supports the reduction of high-grade spondylolisthesis to reduce the rate of pseudarthrosis. Neurological injury rate attributed to surgery was not different between surgical techniques.

[2] Department of Orthopaedics and Rehabilitation, University of Rochester, Rochester, NY, USA

[3] Department of Surgery, IWK Health Centre, Halifax, NS, Canada

Clinical scenario

- An otherwise healthy two-year-old boy with syndromic scoliosis presents with a 45° right thoracic scoliosis and 40° kyphosis.
- At the age of 2.5 years, his scoliosis has progressed to 55° and he is treated with Mehta casting.
- Despite initial success with casting, at the age of six years his curve progresses to 65° and he is treated with magnetically controlled growing rods.

Top three questions

1. In patients with nonidiopathic early onset scoliosis (EOS), does serial casting control curve progression as compared to idiopathic EOS?
2. In patients with EOS, do magnetically controlled growing rods (MCGRs) result in fewer complications as compared to traditional growing rods (TGRs)?

3. In patients with EOS, does treatment with traditional spinal growing rods result in greater spine growth compared to rib-based distraction?

Question 1: In patients with nonidiopathic early onset scoliosis (EOS), does serial casting control curve progression as compared to idiopathic EOS?

Rationale

The resurgence of serial casting as a viable treatment option for EOS is one of the greatest changes in the past decade for the management of early onset spinal deformity. The work by Mehta and Sanders et al. showed serial elongation de-rotation flexion casting could result in complete curve correction in infantile idiopathic scoliosis.[1–3] The idea that serial casting can be utilized to delay growing instrumentation in EOS of all etiologies is appealing.

Clinical comment

Management of EOS remains a challenging problem for the pediatric orthopedic surgeon. Progressive curves during early life can negatively impact the development of the lungs, spine, and chest wall and are potentially fatal. Managing these with growing instrumentation allows delay of formal fusion until around 10 years of age due to the detrimental effects of pulmonary function when fusion is performed earlier.[4] However, growing instrumentation is not without complications and limitations. Compelling findings such as a 13% decrease in the likelihood of

experiencing complications for each year of increase in age at initial implantation of TGRs,[5] unintended auto-fusion,[6,7] and diminishing returns after repeat lengthening of growing instrumentation[8,9] make delaying growing instrumentation appealing as long as progression of deformity can be controlled. Thus, use of serial casting has expanded to include multiple etiologies of EOS with even larger curves. Whether serially casting for early onset nonidiopathic scoliosis can control curve progression, delay surgical intervention, and allow for growth of the spine without increased complication is not well delineated.

Available literature and quality of the evidence

No level I or II evidence was identified pertaining to serial casting outcomes, control of curve progression, or delay of growing instrumentation. The majority of the evidence comes from case series and retrospective studies. To compare outcomes, results were summarized from recent studies that included heterogeneous populations as well as single etiology EOS patients (Table 180.1).

Table 180.1 Level of evidence (LOE) of included articles.

Serial casting articles	LOE
Sanders et al.[3]	IV
Fletcher et al.[12]	IV
Baulesh et al.[13]	III
Waldron et al.[14]	IV
Johnston et al.[16]	III
Gussous et al.[15]	IV
Demirkiran et al.[11]	IV
Cao et al.[10]	IV
Iorio et al.[17]	IV
Hassanzadeh et al.[18]	IV

Findings

There were two papers dedicated to investigating casting in congenital patients,[10,11] with others including mixed etiologies,[3,12–16] or only idiopathic patients.[17,18] Overall, the majority of patients were idiopathic (Table 180.2). In regard to controlling curve progression, although idiopathic patients were the only cases of resolution, as would be expected, nonidiopathic curves were also controlled with casting. Notably a wide range of curve sizes were casted in both idiopathic and nonidiopathic groups. Although spine growth in nonidiopathic cases appears less than in idiopathic groups, there were still cases with comparatively normal growth.

Table 180.2 Number of EOS patients included by etiology.

Etiology	Papers	Patients (N)	Patients (%)	Follow-up (months)
Idiopathic	9	209	61.3	12–91
Nonidiopathic total	8	132	38.7	12–91
Congenital	3*	20	5.9	13–91
Neuromuscular	4*	17	5	12–91
Syndromic	4*	45	13.2	12–91

*Two studies did not sub-classify nonidiopathic diagnoses.

Sanders et al. and Johnston et al. investigated outcomes of serially casting in heterogeneous EOS populations.[3,16] However, the authors did not separate the population by etiology for comparison. Importantly, Sanders's early work echoed that of Mehta's, demonstrating good correction of deformity if treatment was started prior to 13.2 months of age, and full correction was rare in those starting treatment who were greater than 18 months of age. However, the majority of the population (68%) were patients with idiopathic EOS, and 75% of those patients with resolution of the curve were idiopathic.[3] Johnston et al. investigated TGRs versus serially casting in a retrospective matched study including pairs with neuromuscular, syndromic, and idiopathic EOS. They found that overall the curve magnitude was controlled over a mean casting course of 2.4 years, with surgery delayed by a mean of 1.7 years subsequent to that.[16] While more nonidiopathic patients in this review required surgery over the follow-up period than idiopathic patients, studies reported delays in surgery for all etiologies of EOS, up to a mean 52.8-month delay to surgical intervention in idiopathic patients,[17] mean 26.3-month delay in congenital

patients,[11] and up to mean a 39-month delay in mixed etiologies.[12]

While the level of evidence is low, these results suggest that casting may be an initial option for all etiologies of progressive EOS, even congenital cases, without increased complications compared to idiopathic cases. Minor complications were more common including skin irritation, which was reported in all but one study.[17] Respiratory complications that were temporary were reported in four studies,[10],[11],[13],[18] and nausea/vomiting postcasting in three studies.[10],[12],[18] Nonspecific cast intolerance in two patients in one study,[14] intolerance secondary to increase increased seizure activity in one patient,[12] and noncompliance with casting one idiopathic patient were reported.[18] Major complications including subclavian vein thrombosis, cardiac arrest, and one death were reported in a single study;[15] cardiac arrest occurred in an idiopathic patient on induction of anesthesia with negative further cardiac workup, subclavian thrombosis, and the death from presumed asthma attack, six and three weeks after cast application, respectively, in syndromic patients. Importantly, few respiratory complications were noted and all resolved, with only one instance where cast removal was required,[11] and one case where the cast was bivalved;[10] this indicates that serial casting did not pose increased respiratory risk for patients with larger curves or nonidiopathic curves where respiratory function may be more concerning.

The longest reported follow-up in this review was 7.6 years, with most reporting a minimum follow-up of 1–2 years. With the resurgence of serial casting and expanded indications, longer-term follow-up will soon be available that may augment the current evidence, and with the increased use of casting there are opportunities for

prospective investigation. The most recent literature on serial casting has also expanded the indications to include congenital patients. These patients were not included in the initial serial casting literature, although the largest population investigated remains early onset idiopathic patients.

Resolution of clinical scenario

- Serial casting has become common for progressive EOS with recent evidence from relatively short follow-up and largely case series.
- Infantile idiopathic patients remain the EOS population with the largest numbers in the literature, with evidence of resolution of scoliosis for some patients with serial casting, and control of curve progression for up to several years possible with a wide range of curve magnitudes.
- While more nonidiopathic progressive curves will likely undergo surgery, these curves may be temporarily controlled with serial casting without increase in complications compared to idiopathic patients. The delay to surgical intervention may be shorter than for idiopathic patients.

Question 2: In patients with EOS, do magnetically controlled growing rods (MCGRs) result in fewer complications as compared to traditional growing rods (TGRs)?

Rationale

MCGRs have revolutionized the management of EOS, as they provide noninvasive spine lengthening, allowing for more frequent and smaller distractions to better mimic normal physiological growth. However, whether this surgery actually reduces the number of complications as observed with TGRs is unknown.

Clinical comment

TGRs have previously been the gold standard for the treatment of EOS with abundant evidence supporting their use in preventing curve progression and allowing physiological spine growth.[19–21] However, there is increased risk of anesthetic and wound complications due to manual distractions of the rods every six months under general anesthesia.[22] With MCGRs, distractions can be performed in the outpatient clinic with the patient awake. Hence, patients can undergo safe distractions under constant neurological monitoring and avoid the risks with repeated surgery for surgical lengthening. The MCGR has been shown to be effective in controlling curve progression and promoting spine growth.[23–26] It is also useful as a temporary measure for gradual correction of severe deformities.[27] Although frequent distractions require regular imaging for monitoring length gains, the ultrasound has been shown to provide equal accuracy as radiographs but with reduced radiation exposure.[28–30] Despite these improvements, whether MCGRs result in fewer complications and less re-operation risk overall is unknown and requires attention.

Available literature and quality of the evidence

Limited evidence exists comparing the complication rates between TGR and MCGR. There are no randomized controlled trials (RCTs) or comparative cohorts. Most of the

available evidence are based on case series. A total of six TGR studies[5,8,23,31–35] and nine MCGR studies[23,33,36–42] are included in the analysis.

Findings

The main complications to be highlighted include infection/wound complications, implant dislodgement, rod fracture, proximal junctional kyphosis (PJK), law of diminishing returns and medical complications, and MCGR-specific distraction-related complications (distraction failure or rod slippage).

The main TGR article that is the benchmark for comparison was reported by Bess et al.[5] This study reported, from the largest TGR patient population, a breakdown for each complication. Along with several other key articles on TGR complication data, the overall complication rate was 132.6%, suggesting that more than one complication on average will occur in every TGR-treated patient. Of these, implant dislodgement is most common (55.8%), followed by infection/wound complications (27.0%) and rod fractures (17.5%). It should be noted that Bess et al. did not evaluate for risk of PJK.[5] Despite better distraction gains with dual rods, implant and rod fracture complications occur both in single and dual rods. Implant-related complications in MCGR treatment are similarly the most prevalent (19.5%) but MCGR has dramatically reduced infection/wound complications (5.3%). Rod fractures are still common (8.4%) but less so in more recent reports. The overall rate of PJK may be skewed due to limited reporting and follow-up in the MCGR studies. Nevertheless, overall reporting is low as the simple presence of PJK may not warrant revision surgery. Those subjects with proximal junction failure such as proximal implant dislodgement are included in the implant dislodgement complication group for analysis.

There are increasing concerns regarding distraction problems such as failure of distraction and rod slippage, which both affect the degree of length gains. However, it appears that the law of diminishing returns does not occur or at significantly reduced rates as compared to TGR. This may be due to reduced rates of auto-fusion with smaller degrees of distraction and higher distraction frequencies.[36],[37]

Due to the relatively recent introduction of the MCGR, the overall patient population reviewed was much smaller than the TGR and with shorter follow-up duration. Despite having fewer reported complications in general for the MCGR group, our findings will need to be revisited when longer-term follow-up studies are available. In addition, fewer complications may not equate to fewer re-operations, as Kwan et al. reported that up to 46.7% of patients require unplanned re-operations up to a two-year postoperative follow-up.[43] What occurs in MCGR graduates is of interest, as outcomes and complications are variable at skeletal maturity and beyond final fusion surgery.[44],[45] There is a specific concern with regards to the law of diminishing returns as the current available evidence on MCGR is based only on a monthly distraction methodology. Whether the absence of this phenomenon is also present in longer distraction intervals is unknown. It is also important to note that these studies all report unexpected returns to the operating theater. The overall rate of surgery may not be as low for the MCGR if the expected returns for rod exchanges are taken into consideration as the current maximum allowable distractible length of the rod is only 4.8 cm. Moreover, some specific MCGR complications, like actuator pin fracture, have been identified but may be underreported.[46],[47] In addition, distraction-related complications require further examination in future work. The significance of these events on length gain and

correction is currently unknown and requires attention. Preliminary reports suggest that the effectiveness of distractions reduces with use and may result in early rod exchanges.[36,37] This has implications on the overall re-operation rate and has significant cost concerns.

Resolution of clinical scenario

- The overall evidence for MCGR is based on a relatively smaller patient population and shorter follow-up as compared to TGR.
- Based on the available early follow-up, MCGRs may have an overall reduced complication rate as compared to TGRs.
- MCGRs have a significantly lower relative percentage of infection or wound complications.
- Not all complications are comparable as there are specific complications that exist which only concern MCGR, such as distraction failure and rod slippage.
- MCGR appears to avoid the law of diminishing returns due to more frequent distractions and at smaller amounts.
- Distraction failure and rod slippage are major concerns in MCGR as they have been shown to reduce length gains and may require rod exchange. This has implications on clinical effectiveness and costs.

Question 3: In patients with EOS, does treatment with traditional spinal growing rods result in greater spine growth compared to rib-based distraction?

Rationale

As growth-friendly surgery is utilized to promote spine growth for children with EOS, it is important to know whether normal spine growth is achieved utilizing these techniques.

Clinical comment

Fusion has been the gold standard for treatment of progressive scoliosis. For children diagnosed with scoliosis under the age of 10 years (EOS), the spine, thorax, and lungs have significant growth remaining.[48,49] As surgical fusion has been found to halt growth of these structures,[4] it is now common to treat EOS with techniques *that* allow for growth of the spine.[50–52] Only recently has literature been available to assess the effects of these techniques on spine growth.

Available literature and quality of the evidence

Limited reference data exist for normal spine growth. These data are based on two-dimensional (2D) coronal plane radiographs and do not take into account the three-dimensional (3D) nature of spine growth.[53,54] As this is currently the best available literature, it has been used as a reference for assessing spine growth for growth friendly surgeries. There are no RCTs currently published. The available evidence is based on prospective and retrospective case series.

Findings

The landmark paper describing a *law of diminishing returns* for spinal growth during treatment with TGRs was published in 2011.[8] The conclusion of this paper was that total spine height (T1–S1) did not change appreciably after

the seventh lengthening procedure; however, after mean follow-up of 3.3 years, T1–S1 height increased from 24.9 to 33.1 cm. This represented an 8.2 cm, or 33%, increase in spine height. Of note, 3.2 cm of the increase occurred during the implantation procedure and 5.0 cm of the increase occurred during the distraction phase. Although this widely quoted study asserts that growth-friendly surgery is ineffective over time, it is important to recognize that this population achieved significant growth during the study period.

A similar study on spine growth, which focused on rib-based distraction rather than TGR, demonstrated improvement in T1–S1 height from 19.9 cm preoperatively to 22.1 cm postimplantation, to 28.0 cm at minimum five-year follow-up.[55] This 8.1 cm gain in height represented a 41% increase over the study period. This study also evaluated the sagittal plane and determined that kyphosis increased from 40° to 65°. This prompted the authors to evaluate *out of plane* spinal growth that may explain the law of diminishing returns.[56],[57] Since posterior distraction-based surgery may be kyphogenic, lengthening of growth friendly implants may increase spinal length when measured in the sagittal plane (sagittal spine length, or SSL). These increases may not be evident when evaluating spine height purely on a coronal plane radiograph. While some authors are now questioning the accuracy of Dimeglio's original coronal plane spine growth data,[58] Dimeglio and his group continue their significant efforts to define spine growth by now evaluating 3D spine and chest growth.[59]

In 2007, the Children's Spine Study Group embarked upon a prospective, multicenter study on the use of rib-based distraction in children with scoliosis that do not have associated fused ribs.[60] That study demonstrated that

preoperative coronal spine height for T1–T12 (15.7 ± 3 cm) and T1–S1 (25 ± 6 cm) increased significantly after implantation surgery (17.7 ± 4 cm and 28.6 ± 6 cm, respectively) and at two years postoperatively (18.4 ± 4 cm and 29.1 ± 5 cm, respectively). Ninety-four percent of patients were found to have an increase in spine height over the study period. In addition, this study also recognized that SSL and instrumented spine length also increased significantly.

A combined Children's Spine Study Group and Growing Study Group retrospective comparative review compared TGRs to rib-based distraction in patients with idiopathic EOS. With a minimum five-year follow-up, they determined that TGR patients gained a greater percentage of thoracic height (24%) as compared to the rib-based group (12%) during the distraction phase of treatment.[61]

Resolution of clinical scenario

- The overall evidence for spine growth is based on relatively small patient numbers with minimum two- to five-year follow-up.
- Level II evidence is available with only short-term follow-up results. Rib-based distraction significantly increases spine height and length at minimum two-year follow-up.
- Level III evidence is available with longer follow-up time intervals. At minimum five-year follow-up, TGRs were found to achieve greater gains in spine height than rib-based distraction techniques.
- Level IV evidence is also available with a minimum five-year follow-up. Spine height and length for rib-based distraction increases significantly without evidence of diminishing returns.

- Despite higher levels of evidence, a level IV study with only two-year follow-up has been widely quoted and has popularized a law of diminishing returns for TGRs.
- Level II and Level III studies have *not* demonstrated a law of diminishing returns for rib-based distraction or for TGRs.
- Based on the best available evidence, there is no evidence to support a law of diminishing returns for growth-friendly treatment.
- Traditional spinal growing rods may result in slightly greater spine growth compared to rib-based distraction.

Summary of answers

- While more nonidiopathic progressive curves will likely undergo surgery, these curves may be temporarily controlled with serial casting without increase in complications compared to idiopathic patients. The delay to surgical intervention may be shorter than for idiopathic patients.
- Based on the available early follow-up, MCGRs may have an overall reduced complication rate as compared to TGRs.
- Based on the best available evidence, there is no evidence to support a law of diminishing returns for growth-friendly treatment. TGRs may result in slightly greater spine growth compared to rib-based distraction.

[2] Department of Orthopaedic Surgery, BC Children's Hospital, Vancouver, BC, Canada
[3] Department of Orthopaedic Surgery, Children's Hospital of Philadelphia, Philadelphia, PA, USA

Clinical scenario

- A two-day-old female infant receives her newborn clinical hip assessment examination by a pediatrician in the newborn nursery.
- She is first-born and presented breech at birth; there is no known family history of developmental dysplasia of the hip (DDH).
- Barlow and Ortolani maneuvers are both negative and there is no evidence of hip instability upon examination.

Top three questions

1. In newborn infants, what is the evidence to support universal compared to selective ultrasound (US) imaging in conjunction with clinical examination for screening for DDH?
2. For infants with risk factors for DDH, to what extent is clinical and radiologic follow-up required after a normal screening US to ensure optimal outcomes?

3. For infants treated successfully by harness/brace treatment for DDH, what extent of clinical and radiologic follow-up is required to ensure optimal outcomes?

Question 1: In newborn infants, what is the evidence to support universal compared to selective ultrasound (US) imaging in conjunction with clinical examination for screening for DDH?

Rationale

The early diagnosis and treatment of DDH is widely accepted to improve long-term radiographic and functional outcomes for the patient, while decreasing the need for more complex, operative treatment approaches and their potential complications. There is much controversy, however, as to which screening programs best optimize the balance between early detection and potential overdiagnosis or overtreatment. Clinical newborn examination for hip instability remains the universal minimum standard for DDH screening. However, the utility of additional ultrasound (US) imaging in DDH screening is an issue of continuing debate. Some centers or countries employ universal US screening in conjunction with newborn clinical examination, while others employ selective US screening based on the presence of defined DDH risk factors.[1]

Clinical comment

DDH is a spectrum of hip joint abnormalities ranging in severity from mild dysplasia of a reduced and stable hip to an irreducible hip dislocation. The Barlow and Ortolani maneuvers are the standard clinical tests performed on newborns to detect the presence of a dislocated or dislocatable hip. However, these tests for clinical instability cannot detect the presence of stable acetabular dysplasia.[1] US is the primary imaging modality of choice to detect dysplasia in infants under 4–6 months of age, as bony ossification has not yet developed to the extent to allow plain radiographs to be useful. Some natural history studies have shown that up to 70% of cases of neonatal hip instability and 90% of cases of acetabular dysplasia resolve spontaneously as the hip joint matures in the developing infant.[2]

Available literature and quality of the evidence

- Level I: 1 systematic review/meta-analysis.[3]
- Level II: 2 prospective studies.[4],[5]
- Level III: 4 retrospective cohort studies.[6]–[9]

Findings

Shorter and colleagues sought to evaluate and compare screening programs for DDH in order to assess the effectiveness of clinical and US-based screening procedures at preventing late presentation.[3] With strict inclusion criteria of randomized, quasi-randomized controlled trials (RCTs), and cluster randomized trials comparing different types of screening programs, only five studies were ultimately included for analysis. Meta-analysis of two studies comparing clinical examination with universal US to clinical examination with targeted US in unselected infants revealed no significant difference in late-

diagnosed DDH between the two programs with a pooled relative risk (RR) ratio of 0.49 (95% confidence interval [CI]: 0.19–1.26). There was also no significant difference in surgery (pooled RR = 0.36; 0.04–3.48) or incidence of avascular necrosis or osteoarthritis (pooled RR = 0.33; 0.01–8.02). Meta-analysis of two studies comparing treatment guided by US surveillance and treatment guided based on clinical assessment alone for infants with unstable hips likewise revealed no significant difference in late-diagnosed DDH (RR = 1.05; 0.6–1.85). Given the small number of studies included and lack of power within individual studies to detect rare events, Shorter and colleagues concluded that neither US strategy proved more effective at improving clinical outcomes.

Laborie et al. performed a prospective survey of their center's selective US screening program for all infants born in a 15-year period with defined DDH risk factors of clinical hip instability, breech presentation, congenital foot deformities, or a family history.[4] During the study period, 11 539/81 564 infants were identified as at-risk infants, and subsequently received a US scan at 1–3 days of age. In total, 2433 infants received abduction treatment as a result of early screening (21.7% of at-risk infants, 3.0% of entire cohort). Of the 152 infants diagnosed with late-presenting DDH requiring treatment, only three (0.004%) were from the at-risk group. The authors concluded that their screening program resulted in acceptable rates of early treatment and low rates of late-detected DDH.

Choudry and Paton undertook a similar prospective assessment of their neonatal hip instability screening program.[5] Rather than employ selective US screening for risk factors, this program only performed US scans on infants with positive clinical exam findings of hip instability. The primary goal was to assess the positive predictive value (PPV) of the initial screening – a positive

Barlow or Ortolani maneuver performed by a nonexpert – compared with an expert in screening detecting clinical instability or sonographic dysplasia. During the study period, 124 newborns with findings of clinical instability were referred to the authors' institution for clinical and sonographic screening from a birth cohort of 28 241. Overall, they reported a PPV of 4% for the Barlow/Ortolani tests (5/124 hips) and 16.1% for sonographic assessment (20 Graf type IV/124 hips). The authors concluded that referral volume for hip instability appeared to be increasing in conjunction with a decreasing PPV, and thus advocated for limiting DDH screening to a small group of experienced examiners.

Sahin et al. retrospectively reviewed hospital records of 5798 infants who were examined regularly until walking age at their institution over a seven-year period.[6] While 111 infants were found to have DDH risk factors, and 606 infants had physical examination findings suggestive of DDH, 10 infants were ultimately diagnosed with DDH. The authors concluded that the combined sensitivity of risk factors and physical exam findings is high enough to merit acceptance as a screening tool.

Schams et al. investigated the association of risk and protective factors with DDH in a cohort of 11 820 infants receiving universal US screening.[7] While the authors did identify female gender: odds ratio (OR) = 4.07 (3.01–5.51); breech presentation: OR = 4.98 (3.71–6.71); and family history: OR = 5.05 (3.49–7.31), as independent predictive risk factors, they concluded that the strength of these predictive factors to inform selective US screening was limited, and therefore advocate for early universal US screening.

Westacott et al. performed a retrospective comparative study examining a universal US screening cohort of 10 015

infants and a selectively screened cohort of 18 053 infants.[8] Rates of delayed presentation were comparable between the two cohorts (0.5/1000 universal vs 0.28/1000 selective). Treatment rate was higher in the universally screened cohort (0.79% vs 0.23%); however, surgical treatment was found to be higher in the selectively screened cohort (26% vs 12% of those treated in each cohort).

Olsen et al. examined the impact of adding universal US screening to a single-examiner clinical screening clinic at a single institution in Norway over an eight-year period.[9] A total of 4245 infants receiving both clinical and US assessment were compared to a historical cohort of 3594 infants receiving clinical examination alone. The treatment rate increased from 1 to 2.1% in the universally screened cohort, while the number of late-detected cases was halved from 1.0 to 0.5/1000.

Resolution of clinical scenario

While many retrospective studies have been performed, little strong evidence exists to suggest universal US screening provides significant benefit over clinical examination and selective US screening based on particular risk factors for DDH. This infant should be referred for selective US screening between four and six weeks of age based upon the presence of the risk factor breech presentation.

Question 2: For infants with risk factors for DDH, to what extent is clinical and radiologic follow-up required after a normal screening US to ensure optimal outcomes?

Rationale

Late-presenting or late-diagnosed DDH (dislocation, instability, or dysplasia) can lead to the need for more complex corrective procedures, increased potential for complication, and result in long-term debilitation that impacts quality of life. Consequently, US screening for infants with risk factors (breech presentation, positive family history, or history of clinical hip instability) is routinely employed at 4–6 weeks of age. However, dysplasia may still develop later in infancy after initial screening tests and little is known about the extent of follow-up necessary in those infants with risk factors who receive a normal initial screening US examination in order to prevent this occurrence of late dysplasia.

Clinical comment

A great degree of practice variability exists among orthopedic surgeons on the extent to which they follow-up with infants with risk factors after an initially normal screening US. This follow-up may range from immediate discharge after US, to a single radiograph at 4–6 months of age, to serial radiographs at six months, one year, and two years.

Available literature and quality of the evidence

- Level II: 1 prospective study.[10]

- Level III: 2 retrospective studies.[11],[12]

Findings

In a prospective randomized study, Morris et al. sought to identify the rate of late dysplasia after normal screening in a breech infant cohort while also examining the impact of a prophylactic abduction diaper.[10] Infants were prospectively randomized into observational or prophylactic treatment arms following referral for breech presentation and a normal clinical examination and screening US. Routine clinical and US follow-ups were performed, ending with a pelvic radiograph at approximately 13 months. The authors reported a 7.4% overall rate of radiographic dysplasia in the 90 patient cohort (8.3% in the observational arm and 5% in the prophylactic abduction arm), thus they suggested follow-up beyond a normal screening US was recommended for the risk factor of breech presentation.

Imrie et al. retrospectively reviewed the incidence of DDH in breech infants on six-month radiograph after receiving a normal screening US.[11] Out of the cohort of 193 infants with normal USs at six weeks, 131 returned for a four- to six-month radiograph. From those, 38 (29%) infants had abnormal findings that resulted in treatment for DDH.

Similar to Imrie et al., Brusalis et al. performed a retrospective analysis of 94 hips in 47 breech infants with normal screening tests to determine the rate of subsequent acetabular dysplasia at six months.[12] Applying a traditionally used threshold for defining dysplasia (acetabular index [AI] ≥30°), 10/94 hips (10.6%) met diagnostic criteria. Applying a normative AI value stratified by gender and laterality, 4/94 hips (4.3%) were deemed significantly dysplastic. Despite discrepancies in diagnostic definitions, their findings supported a role for observation of breech infants beyond six weeks of age.

Resolution of clinical scenario

Very few studies have been done, prospectively or retrospectively, to determine the appropriate amount and length of follow-up required for infants with DDH to balance detection of late-presenting DDH and radiation exposure. Although high-level evidence is lacking and incidence rates are variable, the existing studies suggest some degree of follow-up is recommended, at least for infants born breech following a normal screening US at six weeks of age. This infant should be followed until at least six months of age with a pelvic radiograph, even if her screening US due to a breech risk factor referral is normal.

Question 3: For infants treated successfully by harness/brace treatment for DDH, what extent of clinical and radiologic follow-up is required to ensure optimal outcomes?

Rationale

When detected early, and/or in mild cases of DDH, a harness or brace can be an effective approach to treatment that avoids complex or invasive operative procedures while still providing excellent long-term outcomes for the patient. Numerous long-term studies have mentioned late sequelae relating to acetabular dysplasia or femoral head deformities and therefore recommend follow-up to skeletal maturity. Follow-up is resource- and time-intensive for both the family and hospital/healthcare system; therefore, understanding the extent of follow-up required to ensure normalization of hip development is important.

Clinical comment

Follow-up to skeletal maturity is often recommended, even for cases in which successful reduction and stabilization of the hip is achieved through early brace treatment in order to detect late acetabular dysplasia. Practice variability does exist, however, and discharge following a normal two-year pelvic radiograph is not uncommon among orthopedic surgeons.

Available literature and quality of the evidence

- Level III: 4 retrospective studies.[14–17]

Findings

Cashman et al. performed a prospective longitudinal follow-up study of 332 infants (546 dysplastic hips) treated by Pavlik harness over a mean period of 6.5 years.[13] While the Pavlik harness failed to reduce 18 hips in 16 infants, no significant difference was found from the normal values of AI for successfully treated hips beyond 18 months of age. Persistent significant late dysplasia was seen in 2.4% of successfully treated hips, all cases of which were identified no later than five years of age by an abnormal center edge angle. The authors therefore recommend radiological surveillance until this age for harness-treated patients.

Allington retrospectively reviewed 109 hips in 83 infants who had been successfully treated for DDH by Pavlik harness and had a normal pelvic radiograph at two years of age.[14] At a mean follow-up of 10.2 years, all hips had a normal clinical examination and a normal pelvic radiograph with no signs of avascular necrosis. Thus, the authors suggested long-term follow-up is not required provided

normal clinical and radiographic findings at two years of age.

Bin et al. retrospectively reviewed the evolution of acetabular dysplasia after hip stabilization by Pavlik harness in a series of 42 hips in 30 patients with a mean follow-up of 6.7 years.[15] Mean acetabular angle and Wiberg's lateral center-edge angle were within normal range for all hips, with one report of recurrent dislocation occurring at five months of age following Pavlik harness treatment. The authors suggested that early, brief treatment by Pavlik harness was sufficient to promote self-correction of acetabular dysplasia, but recommended radiological follow-up at four months, 18 months, and five years.

Fujioka et al. retrospectively reported on 158 hips with >20-year follow-up from an original cohort of 574 hips treated by Pavlik harness in infancy.[16] At final follow-up, mean Sharp angle was significantly larger and mean center-edge angle was significantly smaller than the normal value, and 19% of hips were Severin class III (dysplastic). Although the patient sample is likely enriched for poor outcomes (27.5% follow-up), this is one of the few studies to report radiographic and clinical outcomes on Pavlik-treated hips in the third decade of life, and findings suggest outcomes are not always satisfactory despite early success.

Sarkissian et al. assessed the importance of importance of continued radiographic monitoring following a normalized US in a retrospective series of 115 infants diagnosed with DDH, 79 of whom were treated by Pavlik harness.[17] All included patients had achieved a normal US and clinical examination by 3.1 months of age; however, 17% had radiographic signs of acetabular dysplasia on pelvic radiograph at 6.6 months, and 33% had dysplasia at 12.5 months. Consequently, radiographic follow-up at six and 12

months is recommended to detect residual dysplasia. This study could not comment on longer-term outcomes as follow-up was limited to 12 months.

Resolution of clinical scenario

While few high-level studies with long-term radiographic and clinical follow-up exist, most have reported at least some instances of acetabular dysplasia after successful Pavlik harness treatment. Comprehensive prospective studies will be required to strengthen the evidence in this regard; however, radiographic follow-up in these patients until at least two years of age is recommended to monitor for residual dysplasia.

Summary of answers

- Little strong evidence exists to suggest universal US screening provides benefit over clinical examination.
- Some degree of follow-up is recommended, at least for infants born breech following normal screening.
- There are at least some instances of acetabular dysplasia after successful Pavlik harness treatment.

182 Legg–Calvé–Perthes Disease

Benjamin Joseph MS Orth MCh Orth FRCS Ed[1], and Hitesh Shah MS Orth[2]

[1] Department of Orthopaedic Surgery, Aster Medcity, Kochi, Kerala, India

[2] Paediatric Orthopaedic Service, Department of Orthopaedics, Kasturba Medical College, Manipal Academy of Higher Education, Manipal, Karnataka, India

Clinical scenario

- A nine-year-old boy presents with pain in the left hip and a limp for the duration of one month.
- Radiographs of the pelvis reveal features of Legg–Calvé–Perthes disease in the late stage of avascular necrosis (Stage Ib: Modified Waldenström classification) with sclerosis and minimal loss of height of the capital femoral epiphysis.[1]
- A perfusion magnetic resonance imaging (MRI) scan confirms that over 50% of the epiphysis is avascular.[2]

Top three questions

1. In children with Legg–Calvé–Perthes disease, are the chances of preserving the spherical shape of the femoral head (i.e. preventing the femoral head from getting deformed) greater following surgical or nonsurgical containment than following symptomatic treatment?

2. In children with Legg–Calvé–Perthes disease, are the chances of preventing femoral head deformation greater if containment is achieved early in the course of the disease (by Modified Waldenström Stage IIa) than if containment is achieved later in the evolution of the disease?
3. In children with Legg–Calvé–Perthes disease, which of these methods of containment offers the best chance of preventing femoral deformation: bracing, proximal femoral osteotomy, innominate osteotomy, shelf acetabuloplasty, or combined femoral and innominate osteotomy?

Question 1: In children with Legg–Calvé–Perthes disease, are the chances of preserving the spherical shape of the femoral head (i.e. preventing the femoral head from getting deformed) greater following surgical or nonsurgical containment than following symptomatic treatment?

Rationale

The aim of treatment of children with Legg–Calvé–Perthes disease is to prevent the femoral head from getting deformed.[3] Extrusion of the femoral head predisposes to femoral head deformation and, consequently, prevention or reversal of extrusion (i.e. by containment) should, potentially, minimize the risk of femoral head deformation.[1]

Clinical comment

There are two strategies for achieving containment (ensuring that the anterolateral part of the femoral capital epiphysis is well within the acetabular margin). The first involves keeping the hip abducted and internally rotated or abducted and flexed by bracing or a proximal femoral varus de-rotation (or varus extension) osteotomy. The second entails improving acetabular coverage of the anterolateral part of the femoral epiphysis by an innominate osteotomy (e.g. Salter osteotomy) or a shelf acetabuloplasty.

Available literature and quality of the evidence

- Level II: 3 prospective studies.[4–6]
- Level III: 1 meta-analysis[7] and 3 retrospective cohort studies.[8–10]
- Level IV: 1 retrospective cohort study.[11]

Findings

Saran and colleagues analyzed 14 level II and III studies and reported a pooled odds ratio (OR) of 1.29 (95% confidence interval [CI]: 1.05–1.60; p = 0.02) for a spherical head at skeletal maturity in children who had surgical containment either with a femoral varus osteotomy or a Salter innominate osteotomy when compared with children who were not operated on. Surgical containment did not influence femoral head sphericity in children under six years at onset of the disease (OR = 1.02; 95% CI: 0.45–2.36).[7] Children older than six years at the onset of disease were more likely to have spherical femoral heads at skeletal maturity if they had surgical containment rather than nonoperative treatment (OR = 2.05; 95% CI: 1.28–3.26).

Wiig and colleagues undertook a prospective study of 152 children with Legg–Calvé–Perthes disease.[4] The children were treated by physiotherapy (n = 55), Scottish Rite abduction orthosis (n = 26), or femoral varus osteotomy (n = 71). Sphericity of the femoral head was preserved more frequently following femoral varus osteotomy than following physiotherapy ($p < 0.001$).

Terjesen et al. treated 70 children who were between 6 and 10 years of age at onset of the disease with a femoral varus osteotomy and compared their outcomes with 61 children who received physiotherapy only.[5] Femoral head sphericity was retained in 86% of children who underwent an osteotomy compared to 25% who were treated with physiotherapy.

Herring et al. in a multicenter prospective study evaluated the shape of the femoral heads at skeletal maturity of 345 hips in 337 children and noted that 61% of hips treated by surgical containment had spherical femoral heads as opposed to 46% of hips that were not surgically contained ($p = 0.02$).[6]

Joseph et al. analyzed the outcome, after femoral varus osteotomy, of 48 children between 7 and 12 years of age at onset of symptoms in Stage I or II of the disease and compared them with the outcome in 30 historical controls treated symptomatically.[8] At the time of healing, 62.5% of the operated group had spherical femoral heads compared with 20% of those treated nonoperatively ($p < 0.001$).

Nguyen et al. did a meta-analysis of 23 reports of treatment of Legg–Calvé–Perthes disease which included 1232 children.[11] They observed that among children younger than six years the outcomes of operative and nonoperative treatments were comparable (OR = 1.071; 95% CI: 0.58–1.968; p: 0.828). In children older than six years, operative

treatment was almost twice as likely to result in a spherical femoral head (OR = 1.754; 95% CI: 1.299–2.370; p <0.0001).

Carsi et al., in a retrospective cohort study, noted that the shape of the femoral head at healing was spherical or ovoid in 84% of 44 children who had been treated with a shelf acetabuloplasty performed either during Modified Waldenström Stage I or Stage IIb of the disease.[9]

Rich and Schoenecker in a retrospective cohort study of 213 children, treated by a protocol of restoring and maintaining satisfactory hip abduction with an adductor tenotomy and abduction cast, followed by daily range of motion (ROM) exercises and an A-frame orthosis to facilitate femoral head containment, reported that 79% of hips were spherical at skeletal maturity.[10]

Resolution of clinical scenario

Despite the paucity of high-quality studies related to the treatment of Legg–Calvé–Perthes disease, there is some evidence to suggest that nonsurgical or surgical containment can improve the chances of retaining the spherical shape of the femoral head. In the light of this, the boy should be offered containment.

Question 2: In children with Legg–Calvé–Perthes disease, are the chances of preventing femoral head deformation greater if containment is achieved early in the course of the disease (by Modified Waldenström Stage IIa) than if containment is achieved later in the evolution of the disease?

Rationale

There is some evidence to suggest that if irreversible deformation of the femoral head occurs during the evolution of Legg–Calvé–Perthes disease, it occurs either in the late stage of fragmentation or shortly thereafter (in Stage IIb or IIIa of the Modified Waldenström classification).[1] Consequently, any intervention aimed at preventing the femoral head from getting deformed should be instituted before Stage IIb if it is to be effective.

Clinical comment

In the past, indications for considering containment were dictated, by the recognition of poor prognostic factors on radiographs (collapse of the lateral pillar, head-at-risk signs, and epiphyseal infarction exceeding half or more of the epiphysis).[12],[13] Most, if not all, of these signs become manifest in Stage IIb of the disease; consequently, intervention had to be deferred till then. Recently, there has been a trend to intervene earlier in the course of the disease.[14]

In children over the age of seven years at onset of Legg–Calvé–Perthes disease femoral head extrusion develops almost invariably as the disease evolves,[1,15] and this has led surgeons to consider pre-emptive containment even before extrusion develops in these older children.

Available literature and quality of the evidence

- Level I: 1 meta-analysis.[7]
- Level III: 1 meta-analysis[16] and 1 retrospective cohort study.[17]

Findings

Saran et al. noted, from meta-analysis of data of level II and IIIa studies, that surgery appears to be more likely to be associated with a spherical femoral head if treatment is instituted during or before the fragmentation stage (OR = 1.46; p = 0.02; 95% CI: 1.06–2.01).[7]

Kadhim et al. did a meta-analysis of 11 studies of children who underwent shelf acetabuloplasty either early in the course of the disease (in modified Waldenström Stage Ia, Ib, IIa, or IIb) or late in the course of the disease (in modified Waldenström Stage IIIa, IIIb, or IV).[16] They noted that among those operated on early good results (Stulberg Class I, II, or III) were seen in 85.6% (95% CI: 77.4–93.9; p <0.05) while good results were noted only in 69.9% (95% CI: 55.3–85.5; p <0.05) among those operated late in the disease.

Joseph et al. reported a multivariate logistic regression analysis of 97 children who underwent a femoral varus osteotomy.[17] They compared the outcome of treatment of children operated early (in modified Waldenström Stage Ia, Ib, or IIa) and those treated late (Stage IIb or later) and found that if containment was achieved late in the disease

the OR for a deformed, aspherical femoral head was 16.58 (p <0.01; 95% CI: 2.6–103.13).

Resolution of clinical scenario

There is no high-quality evidence that can resolve the question of whether the outcome of containment treatment is likely to be better if instituted by Stage IIa of the disease. Nevertheless, the OR for a poor outcome following treatment later in the disease noted in the study of Joseph et al. is so high that containment should be offered by Stage IIa.[17] Since extrusion invariably develops in children who are older than seven years of age at the disease onset, pre-emptive containment may be offered straight away in this child who is nine years old with Stage Ib disease involving more than half the femoral epiphysis.

Questions 3: In children with Legg–Calvé–Perthes disease, which of these methods of containment offers the best chance of preventing femoral deformation: bracing, proximal femoral osteotomy, innominate osteotomy, shelf acetabuloplasty, or combined femoral and innominate osteotomy?

Rationale

Improving the coverage of the anterolateral part of the capital femoral epiphysis is the basis of containment treatment for Legg–Calvé–Perthes disease, and this can be achieved by bracing or surgery on the proximal femur, on

the acetabulum, or on both the femur and the acetabulum. The choice of the method of achieving containment has largely been governed by personal preferences without sound scientific evidence. It would, therefore, be desirable to know which one of these methods is most effective in preserving the spherical shape of the femoral head.

Available literature and quality of the evidence

- Level II: 2 prospective studies.[4],[6]
- Level III: 7 retrospective cohort studies[10],[11],[16],[18_21]

Findings

Results of the multicenter prospective study of Herring et al. indicated that the likelihood of preserving the sphericity of the femoral head was higher if surgical containment was performed as compared to nonoperative treatment.[6] Within the nonoperative group, there were no significant differences in outcomes of children who received no active treatment, children treated by bracing, and children treated by ROM exercises ($p = 0.13$). Similarly, within the surgical containment group there was no difference in the outcome between children treated with a femoral or innominate osteotomy ($p = 0.65$). However, among children older than eight years, a higher proportion of children (62%) who had femoral osteotomy had spherical femoral heads as compared to children who had an innominate osteotomy (41%).

Wiig et al. in a prospective study reported that results following proximal femoral osteotomy were superior to those bracing ($p < 0.001$).[4]

Kamegaya et al. in a retrospective study noted that the frequency of spherical femoral heads at final follow-up was greater among children who had combined femoral and

acetabular osteotomies as compared to children who had only a femoral osteotomy (65.6% vs 38.3%; p = 0.031).[18]

Mosow et al. in a retrospective cohort study of children who had undergone combined femoral and pelvic osteotomies observed that the results (spherical femoral heads at skeletal maturity in 51% of patients) were not superior to results reported in the literature of isolated femoral or innominate osteotomies.[19]

Nguyen et al. in a meta-analysis noted that in children under six years the frequency of a spherical femoral head at follow-up was five times higher following a pelvic rather than a femoral osteotomy (p = 0.034; unadjusted OR = 5.20; 95% CI: 1.021–26.471) and in children older than six there was no difference in outcome following the two procedures (p = 0.174; unadjusted OR = 1.329; 95% CI: 0.881–2.004).[11]

Several retrospective studies of children treated by different methods of containment (without a control group of an alternate method for comparison) claim that the respective method is efficacious in preserving the sphericity of the femoral head in a high proportion of children treated. The treatment modalities include weight bearing brace (93% spherical femoral heads),[10] nonweight bearing brace (63% spherical femoral heads),[20] shelf acetabuloplasty (85.6% spherical femoral heads),[16] innominate osteotomy (43% spherical femoral heads),[22] and femoral osteotomy (56% spherical femoral heads).[21]

Resolution of clinical scenario

There is no high-quality evidence to suggest that any one method of containment is superior to others and hence the choice of the method of containment may be based on the surgeon's preference.

Summary of answers

- Containment of the femoral head in children with Legg–Calvé–Perthes disease either by nonsurgical or surgical means can improve the chances of retaining the spherical shape of the femoral head.
- Containment is likely to be more effective in preserving the spherical shape of the femoral head if achieved early in the course of Legg–Calvé–Perthes disease (i.e. by Stage IIa).
- There is no evidence to suggest that any one method of containment is more effective than other methods of containment in preserving the spherical shape of the femoral head in children with Legg–Calvé–Perthes disease.
- None of these answers is based on high-quality studies, because of the paucity of such studies. This highlights the need for level I studies to resolve these issues.

183 Slipped Capital Femoral Epiphysis

Eduardo Novais MD[1] and Randy Loder MD[2]
[1] Department of Orthopedic Surgery, Boston Children's Hospital, Harvard Medical School, Boston, MA, USA
[2] Department of Orthopaedic Surgery, Indiana University School of Medicine, Indianapolis, IN, USA

Clinical scenario

- A 12-year-old boy has sustained an unstable, completely displaced slipped capital femoral epiphysis (SCFE) following a minor fall while leaving the car in the garage.
- He has had prodromal hip pain for the past six months associated with mild limp after running.

Top three questions

1. In adolescent patients with completely displaced unstable SCFE, does an open procedure result in a lower proportion of osteonecrosis compared to in situ fixation?
2. In patients with unilateral SCFE, does prophylactic fixation of the contralateral hip safely reduce the risk of subsequent slip in the initially unaffected hip?
3. In patients with chronic stable moderate and severe SCFE, does subcapital realignment yield improved results as compared to in situ fixation and intertrochanteric realignment?

Question 1: In adolescent patients with completely displaced unstable SCFE, does an open procedure result in a lower proportion of osteonecrosis compared to in situ fixation?

Rationale

Recent studies have reported the importance of hip capsular decompression with gentle repositioning/inadvertent reduction and/or open reduction; however, the ideal treatment to reduce the risk of osteonecrosis after unstable SCFE remains controversial.

Clinical comment

Osteonecrosis of the femoral head is the most common complication associated with unstable SCFE. The outcomes of unstable SCFE are severely compromised by the occurrence of osteonecrosis as there is no definitive treatment for osteonecrosis and typically the hip will deteriorate to osteoarthritis. Osteonecrosis is the most common reasons why patients with a history of SCFE undergo a total hip arthroplasty (THA) in adult life.

Available literature and quality of the evidence

- Level III: 5 therapeutic studies.[1–5]
- Level IV: 3 therapeutic studies.[6–8]

Findings

SCFE is defined as unstable if the child has such severe pain that walking is not possible even with crutches, regardless of the duration of the symptoms.[5] Osteonecrosis

of the femoral head is the most feared complication following treatment of unstable SCFE. According to Loder et al. 47% of unstable SCFEs treated with fixation following reduction developed osteonecrosis of the femoral head.[5] Since Loder and colleagues proposed their classification, there has been persistent controversy about the ideal management of unstable SCFE.[5] Given that closed reduction with subsequent fixation results in a high proportion of osteonecrosis, several studies of open reduction have been reported.

Ziebarth et al. reported the results of the modified Dunn procedure for patients with moderate and severe SCFE.[7] In their series, no patients developed osteonecrosis of the femoral head. However, only four patients were found to have unstable SCFE. However, a multicenter North American series reported a 26% prevalence (seven out of 27 hips) of osteonecrosis after the modified Dunn procedure for unstable SCFE. Parsch et al. reported on 64 consecutive cases of unstable SCFE using a Watson-Jones approach to expose the hip joint and to perform a capsulotomy that allows for the surgeon to place the fingertip in the gap between the metaphysis and the epiphysis while gentle traction is achieved.[6] They reported 4.7% (three out of 64 hips) occurrence of osteonecrosis.

There are very few comparative studies in the literature. In a small series, Alves et al. compared six patients treated with closed reduction and percutaneous fixation versus six patients treated with open reduction using the modified Dunn procedure.[1] They noted osteonecrosis in four (66.7 %) patients after a modified Dunn procedure, while two (33.3 %) patients had osteonecrosis after closed reduction. Similarly, in a small series, Souder et al. reported that three of seven hips stabilized with a percutaneous screw developed osteonecrosis (43%) compared to two of the

seven unstable SCFE treated by the modified Dunn procedure developed avascular necrosis (AVN) (29%).[4]

Two larger comparative studies have also been reported. Walton et al. compared 16 hips that underwent intracapsular cuneiform osteotomy and 30 that underwent fixation after varying degrees of serendipitous reduction.[3] Osteonecrosis developed in four hips (25%) following osteotomy and in 11 (42%) following fixation after serendipitous reduction. The proportion of osteonecrosis was significantly higher following fixation with complete reduction than that following intracapsular osteotomy. Novais et al. evaluated 45 patients with unstable SCFE treated using the modified Dunn procedure (n = 27) or percutaneous pinning after inadvertent reduction (n = 18). Of the 27 patients treated by a modified Dunn procedure, seven (26%) developed osteonecrosis compared to 28% (5/18) patients treated by percutaneous pinning (p >0.999).[2]

Resolution of clinical scenario

In the treatment of unstable SCFE, there is low-quality evidence suggesting that open reduction using the modified Dunn yields better clinical and radiographic results but does not reduce the proportion of osteonecrosis when compared to in situ pinning after inadvertent reduction. Open reduction through an anterolateral approach seems to be a promising technique, but further comparative studies are required.

Question 2: In patients with unilateral SCFE, does prophylactic fixation of the contralateral hip safely reduce the risk of subsequent slip in the initially unaffected hip?

Rationale

The uninvolved contralateral hip in patients presenting with unilateral SCFE is at risk of slip. Prophylactic fixation would avoid a subsequent slip; however, it is controversial whether the risk outweighs the benefits.

Clinical comment

SCFE presents with unilateral involvement in 77–91% of patients.[9–11] However, between 18 and 41% of patients will develop a contralateral slip,[10–15] typically during the first 18 months after the initial diagnosis.[11]

Available literature and quality of the evidence

- Level III: 2 therapeutic studies.[16,17]
- Level IV: 1 case report[18] and 3 therapeutic studies.[19–21]

Findings

Bhattacharjee et al. compared 44 patients who underwent prophylactic fixation to 36 patients managed by observation and observed a higher incidence of sequential SCFE of initially unaffected hips in the observation group compared to those with prophylactic fixation without any cases of osteonecrosis or chondrolysis.[16]

Clement et al. compared the outcomes and cost of 36 patients who underwent prophylactic fixation with 50 who did not.[17] The proportion of a subsequent slip without prophylactic fixation was 46%. Patients in the nonfixation group were more likely to develop a subsequent slip and had inferior functional outcome as assessed by the Short Form 12 (SF-12) physical and mental patient outcome report. Femoroacetabular impingement (FAI) cam morphology was only observed in patients who did not undergo prophylactic fixation. Moreover, prophylactic fixation was found to be a cost-effective procedure.

Kroin et al. reported on two cases of osteonecrosis of the femoral head after prophylactic fixation of the asymptomatic contralateral noninvolved hip.[18]

Sankar et al. investigated 99 patients (mean age 11 years; range 8–15 years) who underwent prophylactic pinning of the contralateral hip after treatment of a unilateral SCFE.[19] They reported two cases of osteonecrosis (2%) but no cases of chondrolysis (0%). Two patients (2%) had femoral fractures around the implant. Three patients (3%) had symptomatic hardware with further surgery for implant removal performed in two of the three. However, no patients developed a subsequent slip on the side of the prophylactic pinning.

Woelfle et al. reviewed 66 patients with unilateral SCFE who underwent prophylactic fixation of the unaffected hip.[20] They did not observe major complications. However, there were minor complications including wound revision (4.6%; three of 65) and loss of fixation with need for repeat fixation (6.2%, 4/65). The authors concluded that prophylactic fixation in SCFE is a safe procedure with no major complications and an acceptable rate of minor complications.

Kumm et al. studied 34 patients who underwent prophylactic dynamic screw fixation with a contralateral SCFE and found no cases of perioperative complication.[21] Further, there was no osteonecrosis or chondrolysis, and no growth disturbance including greater trochanteric overgrowth was noted.

Resolution of clinical scenario

Prophylactic fixation of the initially uninvolved hip in patients presenting with unilateral SCFE prevents the development of further contralateral SCFE. Prophylactic fixation may be rarely associated with complications including osteonecrosis of the femoral head, subsequent growth with *outgrowth* of the screw, and peri-implant fracture. Although further prospective, comparative studies will be important to clarify the risks and safety of prophylactic fixation and to define the best implant, the available literature (level III and IV) favors prophylactic fixation in comparison to observation in those patients at higher risk of further contralateral SCFE.

Question 3: In patients with chronic stable moderate and severe SCFE, does subcapital realignment yield improved results as compared to in situ fixation and intertrochanteric realignment?

Rationale

Severe and moderate stable SCFE are associated with a deformity of the proximal femur that leads to FAI and acetabular cartilage damage. In situ fixation does not allow

for complete restoration of the deformity, and subcapital realignment using a modified Dunn technique has been proposed as an alternative to in situ pinning.[22]

Clinical comment

In situ fixation is a universally available technique that achieves the goal of stabilization of the SCFE with a low rate of complications, while the modified Dunn technique is technically difficult and may result in major complications. Osteonecrosis of the femoral head is a potential complication after the modified Dunn procedure.

Available literature and quality of the evidence

- Level III: 4 therapeutic studies.[22–25]
- Level IV: 1 therapeutic study[7] and 3 case series.[26–28]

Findings

Ziebarth et al. described the modified Dunn procedure for patients with moderate and severe SCFE and reported no cases of osteonecrosis or chondrolysis.[7] Most patients had moderate deformity.

Souder et al. compared an in situ fixation group to that of subcapital realignment with the modified. Dunn procedure: two of 10 patients developed osteonecrosis after the modified Dunn procedure for the treatment of stable SCFE, while no patients developed osteonecrosis after in situ fixation.[22]

Novais et al. compared 15 patients with severe stable SCFE treated with the modified Dunn procedure to 15 patients treated with in situ fixation and demonstrated better deformity correction with the modified Dunn procedure compared with in situ pinning.[23] The odds of good or

excellent clinic results in the modified Dunn group was higher than in the in situ group. There were no differences in the numbers of complications in each group, but there were more reoperations in the in situ pinning group. One patient (7%) developed osteonecrosis of the femoral head after a modified Dunn procedure.

Sikora-Klak et al. compared 12 patients with moderate and severe stable SCFE treated with a proximal femoral intertrochanteric osteotomy with 14 patients treated with the modified Dunn procedure.[24] Postoperative radiographic parameters were similar between the groups except the neck shaft angle, which was better improved in the modified Dunn group. The modified Dunn group had a 29% AVN rate, while no cases of osteonecrosis were observed in the intertrochanteric osteotomy group ($p = 0.1$). However, the overall proportion of complications rate was similar between the groups (33% after intertrochanteric osteotomy and 36% after a modified Dunn procedure; $p = 1.0$).

Abu Amara et al. reported a French multicenter retrospective study of 182 patients (186 hips) with severe SCFE; 94 hips (50.5%) were stable SCFEs and 92 (49.5%) unstable SCFEs. In the stable group, there were six cases of osteonecrosis (6.4%), all of which occurred after reduction by osteotomy.[25]

Aprato et al. reported a case series of hip instability after the modified Dunn procedure and described three potential causes of instability: (i) those directly related to SCFE (acetabular labral damage, severe abrasion of the acetabular cartilage, flattening of the acetabular roof, and a bell-shaped deformity of the epiphysis); (ii) those not related to the SCFE (acetabular orientation and poor quality of the soft tissues); and (iii) those directly related to the surgery (capsulotomy, division of the ligamentum teres, shortening of the femoral neck, trochanteric-pelvic

impingement, previous proximal femoral osteotomy and postoperative positioning of the leg).[26]

Upasani et al. reported that 17 of 406 (4%) patients treated with a modified Dunn procedure developed postoperative hip instability.[27] Fourteen of the 17 patients (82%) with hip instability developed osteonecrosis of the femoral head.

Abdelazeem et al. reported improvement in patient-reported outcomes and radiographic parameters of femoral alignment in 31 patients (32 hips) with moderate and severe SCFE after a modified Dunn procedure with only one case (3%) of osteonecrosis.[28]

Davis et al. compared the results of the modified Dunn procedure for 31 consecutive hips (29 patients) acute, unstable, to 17 chronic, stable SCFEs (15 patients).[29] Two patients (6%) developed AVN in the unstable group, with five patients (29.4%) in the stable group ($p = 0.027$).

Resolution of clinical scenario

Subcapital realignment using a modified Dunn procedure allows for radiographic correction of the deformity after moderate and severe SCFE compared to in situ fixation. However, the proportion of patients developing osteonecrosis remains a concern and to this date there is no high (level I). The potential for iatrogenic instability is also a concern after the modified Dunn procedure.

Summary of answers

- Low-quality evidence suggests that open reduction in the treatment of unstable SCFE yields better clinical and radiographic results but does not reduce the rates of osteonecrosis.

- Prophylactic fixation of the uninvolved hip prevents the development of contralateral SCFE, although it may be associated with some rare complications.
- Subcapital realignment allows for radiographic correction of moderate and severe SCFE; however, the proportion of patients developing osteonecrosis remains a concern.

184 Pediatric Femoral Shaft Fractures

Matthew Winterton MD[1], Shital Parikh MD FACS[2], and Keith Baldwin MD MSPT MPH[1]

[1] Department of Orthopaedic Surgery, Neuromuscular Orthopaedics, and Orthopaedic Trauma, Children's Hospital of Philadelphia, Philadelphia, PA, USA

[2] Division of Pediatric Orthopaedics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH, USA

Clinical scenario

- A pediatric patient sustains a diaphyseal femur fracture after a mechanical fall.

Top three questions

1. In children younger than four years of age with a femoral shaft fracture who are treated with a hip spica cast, does a single-leg cast portend improved clinical and radiographic outcomes when compared with double-leg casting?
2. In children between 4 and 11 years of age with a femoral shaft fracture, what is the ideal management of fracture fixation to optimize outcomes?
3. In children older than 11 years of age with a femoral shaft fracture, what is the ideal management of fracture fixation to optimize outcomes?

Question 1: In children younger than four years of age with a femoral shaft fracture who are treated with a hip spica cast, does a single-leg cast portend improved clinical and radiographic outcomes when compared with double-leg casting?

Rationale

Femur fractures are among the commonest fractures treated by the pediatric orthopedic surgeon, and over 70% of these involve the femoral shaft.[1],[2] Historical treatment included skeletal traction with or without casting, which was complicated by prolonged immobilization, traction injuries to nerves, and skin breakdown. Over the past 20 years, however, the standard of care has evolved to a systematic approach to the evaluation and treatment of pediatric femoral shaft fractures, with consideration given to both patient and injury characteristics, age, and fracture pattern.[2]

Clinical comment

In the young pediatric patient, tremendous remodeling potential exists and treatment modalities that are less invasive are generally preferred and have excellent outcomes.[1]

Available literature and quality of the evidence

- Level I: 1 prospective, randomized controlled trial (RCT).[3]
- Level II: 1 prospective, randomized cohort study.[4]

- Level III: 1 prospective observational cohort study,[5] 1 systematic review,[6] and 4 retrospective cohort studies.[7–10]
- Level V: 2 consensus guidelines.[1,2]

Findings

In a prospective case series of 14 patients with 16 femur fractures, Stannard et al. were the first to demonstrate the use of the Pavlik harness, demonstrating excellent outcomes.[5] Treatment was initiated at <6 months of age, and all fractures united within five weeks without adverse events. Morris et al. later compared the efficacy of the Pavlik harness with traction and traditional spica casting in birth-associated femoral fractures, studying eight femoral fractures retrospectively in 55 296 live births; all went on to heal without limb length discrepancy or angular deformity.[7] A retrospective study in children <1 year of age with a femoral shaft fracture comparing 24 patients treated with Pavlik harness and 16 patients with traditional spica casting found similar results, with no differences in radiographic outcomes between the two groups.[8] However, 38% of the patients treated with hip spica casting were noted to have skin complications from the casting. Despite excellent and equivalent fracture outcomes among these treatment modalities, potential advantages of the utilization of Pavlik harnesses in infants <6 months of age included ease of application without general anesthesia, ease of nursing care and hygiene, and ease of adjustment if the reduction was lost.[5]

Spica casting has generally been advocated for patients between six months and four years of age. Fracture patterns in this age group that are amenable to treatment with immediate spica casting include low-energy mechanism fractures with up to 2 cm of shortening. Flynn

et al. compared the efficacy of a *walking* spica cast (single leg spica with a hip band)[11] with traditional hip spica casting (bilateral leg spica).[4] In this prospective cohort trial in 45 children 1–4.8 years old with low-energy femoral shaft fractures, similar times to initial callus formation (traditional 2.4 weeks, 95% confidence interval [CI]: 2.1–2.7 weeks, vs walking 2.3 weeks, 95% CI: 1.7–2.8 weeks, p = 0.74) and mean time to fracture union (traditional 6.3 weeks, 95% CI: 5.9–6.6 weeks, vs spica 6.0 weeks, 95% CI: 5.7–6.3 weeks, p = 0.37) were observed. Two patients treated with traditional hip spica casts returned to the operating room for loss of fracture reduction, compared with one in the walking spica group (p = 1.0). Traditional hip spica casting was noted to place significantly more burden on family care, as assessed with Impact on Family Scale surveys (traditional 43.3, 95% CI: 38.5–48.0 vs walking 35.6, 95% CI: 28.7–42.4, p = 0.04) and a significant increase in the need for ambulance transportation (traditional 42% vs walking 0%, p = 0.001), costing an estimated $505 per trip with an additional $5 per mile at the time. Additionally, more patients with walking spica casts required wedge adjustments of the cast in clinic (traditional 4% vs walking 26%, p = 0.04). Both groups had similar malunion rates (traditional 8% vs walking 0%, p = 0.38).

Loss of reduction typically occurs in the first three weeks of care, secondary to decrease in swelling of the extremity, which can be corrected in the outpatient clinic setting with cast wedging. It has been recommended that patients with <2 cm of shortening have close surveillance during these first three weeks.[2]

Clinicians can use either single- or double-leg hip spica casting. A prospective RCT of 52 patients between two and six years of age comparing immediate single- and double-

leg hip spica casting found similar clinical outcomes;[3] however, patients with single-leg hip spica casts were more likely to fit into their previous car seat (71% single vs 35% double, p = 0.01), were more comfortable sitting in a chair (as assessed by Visual Analog Scale; single 4.38 vs double 6.26, p = 0.032), and required the caregiver to take fewer days off of work (single 10.38 days vs double 19.00 days, p = 0.049); this study notably suffers from short follow-up time and retrospective recall bias from survey instruments. Jaafar et al. in their retrospective chart review of 59 patients who underwent single-leg hip spica casting and 35 patients who underwent double-leg hip spica casting found that single-leg casting resulted in shorter time to cast removal (4.1 weeks vs 5.3 weeks, p <0.0001), lower rates of clinically significant limb length discrepancies (1.7% vs 20%, p = 0.004), and lower rates of skin complications (10.2% vs 31.4%, p = 0.013).[9] A systematic review corroborated these results.[6]

Some institutions have attempted to compare spica casting with other popular methods of fixation. Heffernan et al. performed a retrospective, multicenter chart review of 141 patients ages 2–6 years old treated with immediate spica casting and 74 treated with titanium elastic nails (TEN) and found that patients treated with TEN were more likely to have higher energy mechanisms of injury (26% vs 8%, p = 0.001), shorter time to unassisted ambulation (29 days vs 51 days, p <0.001), and similar times to radiographic union (45.1 days vs 44.1 days, p = 0.652); however, patients with hip spica casting were younger in this cohort (spica 3.2 years vs TEN 4.5 years, p <0.001),[10] and would have fallen into the present treatment algorithm of spica casting.

Finally, a subset of patients <5 years of age with initial shortening up to 3 cm and a negative telescope test can be

placed in a nonwalking/standard spica cast, with close, weekly follow-up and cast adjustments as necessary.[2]

Resolution of clinical scenario

- Despite excellent and equivalent fracture outcomes with casting, Pavlik harnesses are recommended in infants <6 months of age due to ease of application without general anesthesia, ease of nursing care and hygiene, and ease of adjustment if the reduction is lost.
- In patients between six months and four years of age, given the lower costs, lesser family burden, decreased return to the operating room, and equivalent fracture outcomes, immediate walking spica casting offers a reliable clinical solution.
- Cast wedging may need to be performed during the first several weeks after casting.
- In patients with shortening up to 3 cm with a negative telescope test, a standard/nonwalking spica cast can be used.

Question 2: In children between 4 and 11 years of age with a femoral shaft fracture, what is the ideal management of fracture fixation to optimize outcomes?

Rationale

The pediatric patient between 4 and 11 years of age presents a difficult choice in fracture fixation; a wide variety of patient characteristics and fracture patterns exist. Moreover, the orthopedic surgeon has an array of

options in the treatment toolbox, including titanium elastic nailing, external fixator placement, and submuscular plating. Regional implant use and surgeon comfort with specific implants also direct treatment considerations in this population.[12] Early application of hip spica casts to this group of patients led to inferior outcomes. A multicenter, RCT of external fixation versus early application of spica casts for pediatric patients 4 to 10 years of age with femoral shaft fractures and minimum two-year follow-up demonstrated higher rates of malunion in the hip spica group (45% vs 16%; 95% CI: 12–46%, p = 0.002).[13] No differences were appreciated in RAND physical function child health questionnaire scores (0.34 vs 0.45; 95% CI: −0.57 to 0.34, p = 0.61), parent satisfaction (4.3 vs 4.2; 95% CI: −0.3 to 0.6, p = 0.5), and child satisfaction scores (6.9 vs 7.7; 95% CI: −2.2 to 0.5, p = 0.21).

Clinical comment

The patient presenting in this scenario is seven years of age, under 45 kg in weight, and suffers a low-energy mechanism fracture. What treatment modalities exist for this patient?

Available literature and quality of the evidence

- Level I: 1 RCT.[14]
- Level II: 1 prospective clinical cohort study.[1]
- Level III: 1 systematic review[15] and 1 retrospective cohort study.[16]

Findings

Current treatment philosophy in this broad age range and patient characteristics take into consideration fracture pattern, patient weight, and mechanism of injury.

Generally, low-energy mechanism injuries with length stable fracture patterns (AO class 32D/4.1) in patients under 45 kg are amenable to titanium elastic nailing or submuscular plating. Patients at the lower end of the age spectrum in this category with unstable fractures (AO 32D/4.2, 32D/5.1, or 32D/5.2) can also be treated with titanium elastic nailing.[17] Older pediatric patients with higher body mass indices (BMI) are treated with locked trochanteric entry nails or plating, which is discussed later.

Baldwin et al. performed a systematic review comprising 1128 pediatric femoral shaft fractures treated with TEN.[15] Nearly all patients went on to union (99.5% union rate). Complications included infection (2%, ranging from superficial to deep requiring surgical debridement), hardware irritation (23.4%; noted to be as high as 60% in one series), and a 0.9% rate of refracture following hardware removal. Notably, the rate of malalignment was noted to be >15%; however, the authors noted that there was little consensus on malalignment criteria among the studies included in the systematic review and these results cannot be interpreted properly. Importantly, when compared with traction and casting, titanium elastic nailing was less expensive, had lower rates of complications (18.9% vs 34.3%, $p = 0.047$), but had only a trend toward decreased malunion (10.0% vs 18.0%, $p = 0.236$). Finally, in terms of patient satisfaction and quality of life, children treated with TEN were able to return to independent ambulation and school sooner than children treated with traction and casting, and 96% of patients with TEN would choose that treatment option again, whereas only 6% of patients treated with traction and casting would prefer to undergo the same. The main limitation of the systematic review stems from the inclusion of studies with lower levels of evidence.

Allen et al. recently performed a retrospective comparison of TEN, submuscular plating, and open reduction and internal fixation (ORIF) with plating in pediatric patients between the ages of 5 and 11 years.[16] No differences were seen in patient outcomes or perioperative variables in the plating groups and were combined for analysis. Patients undergoing titanium elastic nailing had significantly reduced operative time (1.6 hours vs 2.5 hours, p = 0.007) compared with both plating modalities; no differences were seen in estimated blood loss (EBL), fluoroscopy time, length of stay, pain scores, or postoperative narcotic requirements. The lack of differences among index procedures did not extend into those patients who underwent elective hardware removal; patients undergoing TEN removal had significantly decreased operative time and EBL than plate removal. Interestingly, the cost of TEN was lower than plating in terms of anesthesia time billed (due to the increased operative time) but not implant cost. This significant difference extended to elective removal of hardware procedures.

Flynn et al. performed a prospective cohort study of TEN versus traction and spica casting in children aged 6–16 years.[18] Of the 35 children treated with skeletal traction and spica casting, three had unacceptable angulation or leg length discrepancy at the time of fracture union, compared with 0 out of the 48 children treated with TEN. The studied recovery milestones were universally significantly difference among patients who underwent TEN: length of stay (5 days vs 24 days, p <0.0001); time to ambulation (14 days vs 70 days, p <0.0001); time to independent ambulation (67 days vs 106 days, p <0.0001); and return to school (48 days vs 103 days, p <0.0001). Total surgical charges for TEN implants were more expensive ($18 990.00 vs $13,338.49, p <0.0001), but these were offset by the increased cost due to increased length of stay in the

traction arm ($12 942.61 traction patients vs $5005.15 TEN patients, p <0.001); overall costs were not statistically significant between the two groups. Finally, 34% of patients undergoing traction sustained a complication, compared with 21% of TEN patients. Another randomized, prospective trial in 46 children aged 6–12 years comparing skeletal traction and hip spica casting and TEN fixation corroborated these results.[14]

Though beyond the scope of this clinical stem, the patient with higher-energy injuries and length-unstable patterns is generally treated with plating or external fixation; elastic nails typically result in higher loss of fixation rates in these groups.[19],[20] One study comparing TEN and external fixation in children between 5 and 11 years of age suggested that TEN fixation may be associated with lower complication rates and faster return to school in both stable and unstable fracture patterns, although the numbers of patients in this study were limited.[21]

Resolution of clinical scenario

- In the length-stable pediatric patient aged between 4 and 11 years and weighing under 45 kg, TEN offer lower rates of complications, acceptable clinical outcomes, and higher patient satisfaction.

Question 3: In children older than 11 years of age with a femoral shaft fracture, what is the ideal management of fracture fixation to optimize outcomes?

Rationale

In older children, the orthopedic surgeon should be aware of limitations of flexible nails: patients over 45 kg have been shown to have inferior outcomes with flexible nailing, and the largest flexible nails have less ability to fill the femoral canal to offer a viable load-sharing construct. Reamed, locked intramedullary nails are the standard for adult femoral shaft fractures; however, in the skeletally immature patient, with improper position of the entry reamer, the blood supply of the femoral head is at risk.[2] Additionally, the literature has raised concern for proximal femoral growth disturbance and abductor dysfunction because of disruption of the greater trochanteric apophysis.[22–24]

Clinical comment

If the patient were 12 years of age, obese, and suffered a high-energy mechanism injury, what treatment options exist for fixation?

Available literature and quality of the evidence

- Level III: 5 retrospective cohort studies[25–29] and 1 systematic review.[30]
- Level IV: 1 retrospective case series.[31]

Findings

Historically, physicians have avoided the utilization of reamed, locked, intramedullary devices in the skeletally immature patient due to concerns over disruption of the blood supply to the femoral head, leading to avascular necrosis (AVN), which can have devastating consequences. With proper placement of the entry reamer, so as to avoid a piriformis starting point, patients can experience excellent outcomes. A systematic review of locked intramedullary

nails in the skeletally immature patient identified a 2% rate of AVN when performed through the piriformis fossa, 1.4% rate of AVN for the tip of the greater trochanter entry site, and 0% rate of AVN using the lateral aspect of the greater trochanter as the entry site;[32] however, the ages of the patients included in the systematic review were not elaborated upon except to identify that all cases of AVN were in children >10 years of age. Similarly, a retrospective cohort study of 20 skeletally immature patients aged 11–16 years treated with closed, reamed, intramedullary nails using the tip of the greater trochanter as the starting point did not observe any AVN with 100% union rates.[25]

General indications for rigid nailing are in patients >11 years of age, or in select younger patients >45 kg in weight, due to studies that showed up to fivefold increased rate of complications in heavier pediatric patients treated with TEN fixation.[19,26] Quality studies are lacking in this arena; one retrospective cohort study of 78 patients with 80 fractures treated with rigid locked nails demonstrated excellent clinical outcomes with no nonunions, delayed unions, or malunions.[27] Similarly, Crosby et al. described their 20-year retrospective data of 241 patients with 246 fractures in patients aged 8–17 years.[31] The complication rate was 9.8% overall, with a 99% union rate, and a 2.2% incidence of proximal femoral growth disturbance; all patients with proximal femoral changes were asymptomatic.

In comparison with TEN, similar outcomes have been shown; however, the data are limited to retrospective studies. One small, retrospective weight-matched cohort study evaluated patients treated with TEN and rigid locked nailing, but no appreciable difference in fracture outcome metrics was found.[28] Additionally, these patients were

older (15.4 years rigid nail vs 13.5 years TEN, p = 0.005). A similar retrospective chart review corroborated these results, but the study was not weight-matched.[29]

It is the consensus that external fixation in this pediatric population can be used in unstable fracture patterns, with significant bone or soft tissue loss, and of course following a damage-control orthopedics philosophy in those patients with physiologic derangement which may preclude definitive fixation with a rigid locked nail at the index procedure.[30] Damage control external fixation is used and exchanged after physiologic resolution, typically between weeks one and two. Submuscular or open plating may also be used in cases where reamed nailing is undesirable, such as in the younger, heavier child with a more severe injury.

Resolution of clinical scenario

- Current evidence, although limited, points to lateral-entry rigid locked nailing in this patient.
- If the patient has physiologic derangements on presentation and after proper resuscitation, external fixation can be performed either definitively or as a temporizing measure until definitive rigid nailing can be performed.
- Pediatric patients >45 kg have inferior outcomes with titanium elastic nailing.

Summary of answers

- Despite excellent and equivalent fracture outcomes with casting, Pavlik harnesses are recommended in infants <6 months of age due to ease of application without general anesthesia, ease of nursing care and hygiene, and ease of adjustment if the reduction is lost.

- In patients between six months and four years of age, given the lower costs, lesser family burden, decreased return to the operating room, and equivalent fracture outcomes, immediate walking spica casting offers a reliable clinical solution.
- Cast wedging may need to be performed during the first several weeks after casting.
- In patients with shortening up to 3 cm with a negative telescope test, a standard/nonwalking spica cast can be used.
- In the length-stable pediatric patient aged between 4 and 11 years, weighing <45 kg, TEN offer lower rates of complications, acceptable clinical outcomes, and higher patient satisfaction.
- Rigid, locked lateral-entry nailing is acceptable for pediatric patients aged >11 years and weighing >45 kg.
- If the patient has physiologic derangements on presentation and after proper resuscitation, external fixation can be performed either definitively or as a temporizing measure until definitive rigid nailing can be performed.
- Pediatric patients >45 kg have inferior outcomes with titanium elastic nailing.

185 Infantile Blount Disease

Steven M. Rivero MD[1] and Sanjeev Sabharwal MD MPH[2]

[1] UMDNJ New Jersey Medical School, Newark, NJ, USA

[2] UCSF Benioff Children's Hospital, Oakland, CA, USA

Clinical scenario

- A 30-month-old boy is brought in for evaluation by his parents for progressive bowing of the child's left leg. He had a normal birth and developmental history and began walking at 11 months of age.
- He is at the 70th percentile for height, at the >95th percentile for weight, and his BMI is 24.
- On physical exam, the child is obese[1] with a varus alignment of the left knee and mild valgus alignment of the right. He walks with mild varus thrust of the left leg. His thigh–foot angle is 25° internal on the left in contrast to 5° external on the right.
- He does not have any ligamentous laxity of the knee in flexion or extension and the remainder of his physical exam is within normal limits. Standing full-length x-ray exam of both lower extremities demonstrates varus alignment on the left with a medial mechanical axis deviation and irregularity of the medial proximal tibial physis with medial beaking of the metaphysis consistent with Langenskiold stage II.
- The anatomic tibiofemoral angle is 23° of varus and his proximal tibial and distal femoral metaphyseal diaphyseal angles (FMDAs) are 14° and 8°, respectively. On the right, the tibiofemoral angle is 10°

valgus and the proximal tibial and distal FMDAs are −3° and −6°, respectively.[2–6]

Top three questions

1. Will all children who present with radiographic evidence of infantile Blount disease develop a progressive varus deformity?
2. Is bracing an effective treatment to prevent progression of deformity in patients with infantile Blount disease?
3. Is guided growth an effective treatment for correcting deformity in patients with infantile Blount disease?

Question 1: Will all children who present with radiographic evidence of infantile Blount disease develop a progressive varus deformity?

Rationale

Bowing of one or both legs in children aged 2–4 years is a common concern that prompts parents to seek orthopedic care. In 1975, Salenius and Vannka studied the natural history of the tibiofemoral angle in 979 children admitted to hospital for various reasons.[7] They noted that the tibiofemoral angle in newborn children was pronounced varus that slowly corrected until 18–24 months, when the angle changed to a valgus position between ages two and three years. In a few patients the varus alignment of the knees does not correct, but increases or persists beyond the third year of life and sometimes requires surgical intervention.[8] Below the age of two years, it can be difficult

to differentiate between patients with physiologic varus alignment, which is expected to correct spontaneously, from those who will develop infantile Blount disease, a radiographic diagnosis based on specific changes to the medial proximal tibia characterized by Langenskiold stages, which are expected to develop a progressive deformity and require treatment. Prior to the onset of these radiographic changes, certain physical and other radiographic criteria may be helpful in predicting those patients who can be safely observed versus those who are likely to develop true Blount disease who might warrant early intervention.

Clinical comment

Having noted improved patient outcomes (less chance of recurrent deformity) with surgical correction prior to age four years, some authors have emphasized early surgical realignment of children with infantile Blount disease.[8–10] This has typically been a valgus producing osteotomy to unload the medial physis to give it the best chance to recover. However, an osteotomy is an invasive surgical procedure with substantial risks such as neurovascular injury and compartment syndrome. The efficacy of bracing for Blount disease has been questioned by some authors and is discussed in greater detail in the next section.[11,12] It is still not well established as to which radiographic and physical characteristics in these young children are associated with a progressive deformity and those which will spontaneously correct. Understanding these characteristics can help determine which patients warrant early intervention versus continued observation and may help avoid unnecessary surgery in patients whose deformity could correct spontaneously.

Available literature and quality of the evidence

- Level III: 5 retrospective cohort studies and 1 prognostic study.
- Level IV: 3 case series.

Findings

The radiographic analysis of a patient with bowlegs should begin with a standing, full-length anteroposterior radiograph of both lower extremities with the patellae facing forward to help assess whether the deformity is primarily in the proximal tibia or if there is contribution from the distal femur as well.[8,13,14] Historically, the severity of a bowleg deformity was determined by comparing the anatomic tibiofemoral angle of affected patients with the normal angle for their age,[1] and examining for the classic radiographic changes of infantile Blount disease as described by Langenskiold.[15] In 1982, Levine and Drennan measured an angle between the transverse plane of the proximal tibial metaphysis and a line perpendicular to the long axis of the tibial shaft, named the *metaphyseal diaphyseal angle* (MDA), to determine its usefulness in differentiating physiologic bowing from infantile Blount disease.[2] They compared the MDA patients with infantile Blount disease to those with physiologic bowing and found that only 3 of 58 extremities with an MDA <11° developed progressive deformity compared to 29 of 30 with MDA >11° ($p < 0.001$).[2] Feldman and Schoenecker further analyzed the MDA and found that an MDA ≥11° resulted in a false-positive rate of 33% and an MDA of <11° had a false-negative rate of 9%.[3] They determined that an MDA ≤9° had a false-negative of <5% and an MDA ≥16° had a false-positive rate of <5%. They recommended observation for those with MDA ≤9° and early intervention for those with MDA ≥16°. Patients with

an MDA between 10° and 15° are in a gray area which requires close observation for progression.

Another study done in 1982 by O'Neill and MacEwen measured both the FMDA and tibial metaphyseal diaphyseal angle (TMDA),[4] and determined that patients whose TMDA was greater than their FMDA were at increased risk for disease progression. McCarthy et al. compared the FMDA to TMDA ratio, or femoral/tibial ratio (FTR), to the tibial MDA in determining which patients would develop progressive deformity.[5] The authors found that a TMDA >13° or an FTR <1° was prognostic for developing infantile Blount disease; however, the false-negative and false-positive rates were lower for the FTR. They also found that the FTR was affected less by rotation of the x-ray than the MDA. The authors concluded that the FTR was more accurate than the MDA in detecting which deformities would progress. Similarly, in 2002, Bowen et al. examined 98 patients with bowlegs and calculated the total limb varus (LV) by measuring the mechanical axes of the femur and tibia as well as the femoral varus (FV) and tibial varus (TV) by measuring a horizontal line through the joint line with the femoral and tibial mechanical axes, respectively.[6] They then calculated the percent deformity in the tibia (%DT) by dividing TV by LV. They found that a %DT >50% had a 100% sensitivity and 96% specificity as a predictor of future progression, compared to 64% sensitivity and 93% specificity for MDA ≥16°. They concluded that the %DT was more accurate than the MDA in predicting future progression but emphasized that the only true way to know was to follow a patient with serial radiographs until a trend toward progression or resolution became clear.

In 2000, Mukai et al. used MRI to try to differentiate physiologic bowing from infantile Blount disease.[16] They

found that all patients with bowlegs had a high-intensity area in the medial epiphyseal cartilage on T2 weighted imaging compared to normal tibiae, but that certain patients also exhibited an abnormality in metaphysis, and hypothesized that these patients were at higher risk to progress. At final follow-up, 5 of 11 patients with metaphyseal signal changes went on to develop the characteristic findings of infantile Blount such as medial metaphyseal beaking and fragmentation, while none of the 14 tibiae that lacked metaphyseal changes went on to progress. While magnetic resonance imaging (MRI) can be helpful, the increased cost of the study and need for sedation in a young child make it difficult to obtain such advanced imaging routinely.[8]

Scott et al. investigated the role of body mass index (BMI) in addition to radiographic findings to help determine which patients would progress.[17] They stated that the role of BMI in clinical decision-making is especially important in those patients whose MDA falls in the gray zone of 10–15°. The authors found that a TMDA ≥10° and a BMI ≥22 together had a 95% sensitivity and 100% specificity in predicting disease progression and recommended early treatment for these patients. The BMI of 22 corresponds to >99th percentile for children aged 2–4 years.

However, several other studies investigating the natural history of infantile Blount disease have questioned the predictive utility of the MDA and other radiographic parameters. Hagglund et al. followed 13 unoperated children with infantile Blount disease and found that their MDA averaged 15° at presentation but decreased to an average of 7° prior to skeletal maturity.[18] They noted that sometimes a bowing deformity with an MDA >20° could spontaneously correct. They cautioned against making treatment decisions based on a single measurement of the

MDA and recommended following such patients clinically until a trend toward progression or resolution was clearer. Shinohara et al. investigated 46 patients with an MDA ≥11° and Langenskiold stage I–III changes on initial radiographs and found that 100% of those with Langenskiold stage I and 75% of those with Langenskiold stage II–III changes resolved spontaneously.[11] They noted that all six patients that required surgical intervention showed persistent increase in the FTA and MDA at ages three and four, whereas those who went on to spontaneous resolution showed improvements by age four. The authors concluded that the only way to determine which deformities would progress was by performing serial examinations at six-month intervals until a clear trend was established. Laville et al. examined 26 patients with bowlegs and Langenskiold stage I radiographic changes and determined there was no difference in the FTA or MDA between patients that developed a progressive deformity and those who spontaneously corrected at presentation, but at subsequent visits a clear trend was detectable.[12] With increasing age, those tibiae which would spontaneously correct showed improvement in the FTA and MDA, whereas those with progressive deformity worsened, further emphasizing the need for clinical surveillance prior to making treatment decisions.

Resolution of clinical scenario

Our patient from the clinical scenario has several risk factors for disease progression. His MDA is 14°, which lies in the gray area of 10–15°; however, his FTR is <1 and %DT is >50%, indicating a high likelihood his deformity will progress. Furthermore, his BMI of 24 puts him at even higher risk for progression. Despite this, he is still less than three years old with Langenskiold stage II radiographic changes, so it is plausible that his condition could improve

with time. As such, the patient can be followed closely with serial radiographs to determine if his deformity will normalize over time or if he will progress and require treatment. If his deformity continues to progress over the next six months then surgery should not be delayed since realignment prior to age four is associated with better long-term outcomes.[8–10]

Question 2: Is bracing an effective treatment to prevent progression of deformity in patients with infantile Blount disease?

Rationale

The concept of bracing consists of producing a valgus force at the knee through various straps and hinges around the thigh and lower leg. Several different types of braces have been investigated with the most common being a knee–ankle–foot orthosis (KAFO) with a medial upright and drop lock hinges to unload the medial compartment.[8,19–22] The potential benefit of bracing over surgical correction is that it avoids all the inherent risks of an invasive surgical procedure. Some parents and surgeons may find bracing more appealing as an initial treatment, with the caveat that surgery can still be performed later if bracing is not effective. Despite this, significant challenges arise in trying to implement a strict bracing regimen in a young obese child, and the efficacy and utility of bracing for infantile Blount disease have been questioned.[8,23]

Clinical comment

Once progression of a bowleg deformity has occurred and a diagnosis of infantile Blount disease has been established,

emphasis is placed on early treatment and long-term follow-up. The classic treatment for a child with progressive deformity is a valgus producing high tibial osteotomy. Some authors advocate operating prior to age four for an optimal outcome with less chance of a recurrent deformity.[8–10] An osteotomy is an invasive procedure with associated risks such as deep infection and compartment syndrome and often requires adherence to strict postoperative weight bearing restrictions. Other authors believe that, if initiated early, brace treatment can help prevent progressive deformity of the leg and obviate the need for an invasive surgical procedure.[19–22]

Available literature and quality of the evidence

- Level III: 1 retrospective cohort study.
- Level IV: 6 case series.

Findings

Published series on bracing for infantile Blount disease primarily focus on patients with mild deformities, or Langenskiold stage I–III.[15] Schoenecker et al. initiated brace treatment on six extremities with an average MDA of 15°.[10] At two-year follow-up, they reported successful outcomes in five of six extremities (83%). The one poor outcome was in a patient with bilateral disease who had successful brace treatment on their contralateral extremity. They recommended brace treatment for any patient >2 years of age with stage I–II Langenskiold changes and a TFA <15°. Loder and Johnston initiated brace treatment for 23 patients with Langenskiold stage I–II changes and found that 11/23 patients failed brace treatment and eventually needed an osteotomy.[9] The authors recommended starting brace treatment early, at 1.5–2.5 years of age, and cautioned that despite bracing approximately half of

patients would still progress and require surgical correction.

Other authors have had similar success rates after bracing. Richards et al. reported successful outcomes in 24 of 37 extremities (64%) with infantile Blount disease treated with bracing.[19] Interestingly, the authors noted successful outcomes in 16 of 17 patients with unilateral disease (94%) compared to 3 of 10 patients with bilateral disease (8 of 20 extremities, 40%), $p < 0.001$.[19] Zionts and Shean used bracing to treat 42 extremities in 24 patients who presented before the age of three with Langenskiold stage I–III radiographic changes.[20] They reported good outcomes in 29 of 42 extremities (67%). Of these 42 extremities, two had radiographic changes consistent with Langenskiold stage III and both of these extremities had a poor outcome. They concluded that bracing may be effective in patients <3 years with Langenskiold stage I–II changes, but it is not effective for patients with stage III changes. Raney et al. implemented bracing for 60 extremities with MDA ≥16° or those with an MDA >9° and at least one risk factor for progression (ligamentous instability, weight >90th percentile, asymmetric radiographic appearance of the proximal tibial metaphysis, female gender, or black or Hispanic ethnicity[3,9,21]).[21] They obtained successful outcomes in 90% of patients. They found ligamentous instability, weight greater than 90th percentile, and late initiation of bracing (after age three) were associated with failure of bracing.[21] In 2013, Alsancak et al. used a KAFO for 22 patients and achieved improvement in the MDA of all patients and noted complete correction in 20 of 22 patients.[22] They recommended bracing for patients up to 38 months of age with Langenskiold stage I–III deformities. Despite the promising results with bracing, the published studies are subject to multiple limitations, including a retrospective study design without a control group; a lack

of long-term follow-up, including multiple variables; use of multiple different styles of braces, inconsistency among bracing regimens; a lack of specific details regarding time spent in the brace; and the difficulty differentiating infantile Blount disease from physiologic varus.[8,19–23] Furthermore, many of the recommendations for bracing were based on the Langenskiold staging system which itself has poor interobserver reliability, especially for the intermediate stages.[24] Collectively among the various published series on bracing, the most common reasons for failure were weight >90th percentile, bilateral disease, varus thrust on ambulation, age >3 at the start of treatment, and advanced deformity (Langenskiold stage ≥III).[8,19–23]

Other authors have studied the natural history of infantile Blount disease and noted a high rate of spontaneous correction among patients with less advanced deformity, leading them to question the utility of bracing. Shinohara et al. followed 40 patients with Langenskiold stage I and II radiographic changes and noted resolution in 100% of patients with stage I changes and 75% of patients with stage II.[11] Their 75% rate of spontaneous resolution in patients with stage II changes is comparable to the success rate after bracing reported by Richards et al.[19] and Zionts and Shean.[20] When analyzed using the criteria for bracing proposed by Raney et al.,[21] 27 patients would have met the criteria for bracing and 24 of these patients achieved spontaneous correction (89%), which corresponds to the 90% success rate achieved with bracing in Raney et al.'s series. The authors questioned the role of bracing, even in patients with MDA >11° and Langenskiold stage II–III radiographic changes.[11]

Resolution of clinical scenario

The child from the aforementioned clinical scenario fits into the criteria for bracing proposed by the previous authors.[19–22] However, authors have also reported a high rate of spontaneous resolution in children with such deformities.[11] While the concept of bracing is based on sound physiologic reasoning, there are currently no high-quality studies that demonstrate an improvement in correction compared to the natural history of the disease. Therefore, there is insufficient evidence to recommend use of bracing for infantile Blount disease.[8,23]

Question 3: Is guided growth an effective treatment for correcting deformity in patients with infantile Blount disease?

Rationale

Guided growth has been an effective strategy to treat angular deformities of the lower extremities of various etiologies in children. However, in patients with an abnormal physis, such as in Blount disease, the results are less predictable because the success of the technique requires growth of the medial side.[25] While there are some reports of guided growth using staples or the Phemister technique for adolescent Blount disease,[26,27] there has been an increase in the use of guided growth since the introduction of extraperiosteal tension-band plates.[28–30] Despite this, there are only a few reports on guided growth for patients with the infantile form of Blount disease.[31,32]

Clinical comment

Growth modulation through physeal stapling was first presented by Blount and Clarke in 1949 and became a popular alternative to acute correction with an osteotomy.[25] In 2007, Stevens presented the concept of guided growth with tension-band plating for patients with angular deformities, including adolescent Blount disease.[33] Some authors have reported similar outcomes between those treated with staples and tension-band plates.[34,35] Options include either permanent ablation of the lateral proximal tibial physis or a temporary growth arrest using extraperiosteal implants with the potential for growth resumption after implant removal following deformity (over)correction.[31] The appeal of the procedure is that correction of the deformity can be achieved while minimizing some of the risks associated with a high tibial osteotomy (compartment syndrome, neurovascular injury, deep infection) and allowing faster mobilization with immediate weight bearing postoperatively.[8,23,25]

Available literature and quality of the evidence

- Level IV: 3 case series.

Findings

Many of the initial series on guided growth for angular deformity correction involved a heterogeneous group of patients of varying ages and multiple diagnoses.[25,27,28,33] The patients with Blount disease included in these studies were typically either the adolescent form or no distinction between the two forms was made. Westberry et al. were one of the earliest to include results on both patients with infantile and adolescent Blount disease.[27] They reported improvement of the deformity in 55% of patients treated by hemiepiphysiodesis and an additional 33% which did not

progress after surgery, although they did not contrast outcomes between patients with the two forms of Blount.

In 2012, Scott presented results of guided growth on a series of 12 patients (18 extremities) with infantile Blount disease.[32] All patients had Langenskiold stage II–III radiographic changes, and the mean age at surgery was 4.8 years. Of these 18 extremities, 16 achieved full mechanical axis normalization (89%), one limb had residual varus deformity but improved from the preoperative mechanical axis, and one limb had persistent deformity and required an osteotomy. Follow-up ranged from 0 to 37 months after plate removal. Of eight extremities with >1 year follow-up after plate removal, the authors noted recurrent varus of >5° in three of eight extremities, highlighting the high rate of recurrence of this condition and the need for surveillance until skeletal maturity.[8],[23],[31],[36] The authors noted that while spontaneous correction of the internal tibial torsion occurred after correction of the angular deformity in most patients, 3 of the 12 patients had residual torsional deformity as determined by an internal foot progression angle.[32] Heflin et al. recently published results of a series of patients with Blount disease treated by guided growth including seven patients with the infantile form.[26] They obtained complete correction in all seven patients with infantile Blount and observed only one case of recurrent deformity at a mean of 33-month follow-up (range 14–70 months). They also noted spontaneous correction of the internal tibial torsion deformity in all patients.

The most common reported complication following guided growth is implant failure, which almost always occurs at the metaphyseal screw head–shaft junction in obese children.[8][29]–[31] Although not clinically validated, the risk of screw breakage may be lessened by using noncannulated

stainless-steel screws instead of cannulated titanium screws and using two plates instead of one or a plate with four instead of two screw holes.[37] Scott also implied that cannulated screws predispose to hematoma formation and subsequent wound dehiscence, potentially increasing the infection rate.[32] Given the unpredictable growth of the abnormal physis in Blount disease, even after deformity correction, recurrence of the varus malalignment remains a problem. Based on a recent report, children with infantile Blount disease often have advanced bone age, with an average of 26 months ahead of their chronologic age. This must be taken into consideration when performing guided growth as premature physeal closure can lead to undercorrection of the deformity.[38] Overcorrection into slight valgus (zone 2) is often performed with the anticipation of *rebound* varus growth after implant removal.[8],[23],[31] Unlike bracing, for which there are questions about efficacy (success might just be a consequence of natural history), there is better evidence that guided growth can facilitate correction in infantile Blount disease. However, in choosing who to operate on, the same considerations about the natural history of spontaneous resolution apply.

Resolution of clinical scenario

The child from the case scenario is the appropriate age with a moderate deformity and Langenskiold stage II radiographic changes which should respond to guided growth. However, he is still <3 years old with radiographic features associated with a high rate of spontaneous resolution reported in the literature.[11] As such, the patient can be followed closely with serial radiographs and observed if the deformity is shown to be decreasing over time. Surgical treatment should be offered immediately in the face of demonstrable increased deformity. If the

deformity persists (but does not increase), surgery should be offered by the age of four years. Solid stainless-steel screws are stronger than cannulated titanium screws and may minimize the risk of screw breakage. Some overcorrection into valgus is prudent prior to removal, because some recurrence or rebound is common, unless the patient has such advanced skeletal age that rebound growth is unlikely.[38] The patient should continue to have regular follow-up until skeletal maturity.

Summary of answers

- Prior to the onset of typical radiographic features of Blount disease, other radiographic criteria can be helpful in determining which patients are at higher risk for developing radiographic Blount disease. An MDA ≤9° has a false-negative of <5% and an MDA ≥16° has a false-positive rate of <5%.
- For patients with an MDA in the gray area of 10–15°, a BMI >22 is highly predictive of deformity progression.
- An FTR <1 and/or a %DT >50 is also predictive of deformity progression.
- Despite radiographic and clinical parameters, there remains a high rate of spontaneous resolution of early stages of Blount disease (Langenskiold stage I–II), so performing serial physical exams with follow-up radiographs may be the best way to determine which deformities will progress (and need treatment), and which will normalize.
- Although several small uncontrolled case series have reported promising results with the use of braces, there is no clear evidence that these results are any different from the natural history of the disease. Additionally,

there are many different types of braces and little consistency among bracing regimens, which limits the generalizability of these studies.

- Guided growth can be a safe and effective method for treating infantile Blount disease. Correction may not be permanent. The data are scarce and current reports using extraperiosteal nonlocking plates lack long-term follow-up until skeletal maturity.
- Breakage of the metaphyseal screw after guided growth and recurrence of varus deformity are common problems associated with guided growth.

186 Pediatric Anterior Cruciate Ligament Injuries

Lindsay Schlichte MS, Colleen Wixted BS, and Daniel Green MD MS FACS
Department of Orthopedic Surgery, Pediatrics, Hospital for Special Surgery, New York, NY, USA

Clinical scenario

- A 12-year-old boy presents in clinic with an acute anterior cruciate ligament (ACL) tear that occurred during a soccer game.
- The patient reports twisting his knee awkwardly and feeling something pop.
- Magnetic resonance imaging (MRI) confirms a complete intrasubstance ACL tear without meniscal tear.
- Bone age imaging confirms his skeletal age matches his chronological age and therefore he has approximately four years of growth remaining.

Top three questions

1. In a child or teenager with acute ACL tear, what are the effects on cartilage and meniscus with delayed reconstruction compared to acute reconstruction?
2. In children/adolescents with acute ACL tear, is one surgical technique superior to others with respect to ACL re-rupture rates, pain, or return to sport (RTS)?

3. In children/adolescents with an acute ACL tear, what is the risk of re-injury to the same and contralateral side, and what can be done to prevent re-injury?

Question 1: In a child or teenager with acute ACL tear, what are the effects on cartilage and meniscus with delayed reconstruction compared to acute reconstruction?

Rationale

Children and adolescents with ACL tears are indicated for anterior cruciate ligament reconstruction (ACLR) shortly after initial presentation. Historically, these patients were definitively prescribed activity restriction, bracing, and physical therapy. However, these patients showed early, severe meniscal degeneration and cartilage defects that eventually required surgical intervention.[1]

Clinical comment

Pediatric ACLR techniques have advanced significantly in recent years. There are multiple physical sparing techniques and advanced rehabilitation protocols to prevent arthrofibrosis. What is the ideal timing for pediatric ACLR? Is this patient at risk for developing arthrofibrosis if ACLR is preformed too soon?

Available literature and quality of the evidence

- Level I: 2 meta-analyses.[2],[3]
- Level III: 1 cross-sectional study[4] and 6 retrospective cohorts.[5]–[10]

- Level IV: 1 systematic review.[1]

Findings

Current literature consistently agrees that indefinite delay to surgical intervention when treating ACL injuries in pediatric patients will result in further meniscal damage.[1–3] In a group of 370 pediatric patients with ACL tears, those with surgical treatment ≥150 days after injury had a significantly higher incidence of meniscus tears compared to those treated surgically ≤150 days postinjury.[4] Furthermore, multiple meta-analyses have demonstrated that nonoperative management equates to a 12-fold greater risk of developing a meniscal tear.[2,3] There is an increased meniscal injury prevalence of 6% for every month that surgery is delayed.[5] If surgery is delayed for over three months, patients are 3.5–4.8 times more likely to present with an additional or more severe medial meniscal tear.[6]

Guenther et al. reviewed 112 patients (mean age: 15.4 years) in which 51% of those who underwent surgery >1 year postinjury presented with a new or higher-grade medial meniscal tear versus only 20% of those who had surgery <1 year postinjury.[7] Comparing a group who underwent ACLR at a mean interval of 11.5 months to a group who underwent ACLR at a mean interval of 30.3 months, findings revealed that the group with a longer time to surgery presented with a significantly higher medial meniscal tear rate.[8]

Some authors have also hypothesized the risk of arthrofibrosis as a function of time interval from ACL injury to surgery, making this another relevant concern in surgical planning. In an attempt to understand this potential risk in the pediatric population, Nwachukwu et al. retrospectively reviewed 933 ACL reconstructions with an average follow-up of 6.3 years. Arthrofibrosis was defined

as loss of 5° or more extension that required a follow-up procedure, or a loss of 15° or more extension that required a follow-up procedure. The prevalence of arthrofibrosis was 8.3%.[9] Prior knee surgery and ACL reconstruction within one month of injury were not significantly associated with postoperative arthrofibrosis. Females, patients aged ≥16, patellar tendon autograft, and concomitant meniscal repair were associated with a higher incidence of arthrofibrosis.[9]

Some practitioners advocate for the use of postoperative continuous passive motion (CPM) machine protocols to reduce the risk of arthrofibrosis. A recent retrospective review compared the postoperative rates of MUA for arthrofibrosis among pediatric ACLR patients treated with or without postoperative CPM protocol. The no-CPM cohort has a 7.4% rate of MUA for arthrofibrosis while no patients in the CPM cohort required MUA. Future work may better define the clinical utility and cost effectiveness of CPM in rehabilitation.[10]

Resolution of clinical scenario

ACLR is recommended for the current clinical scenario at the patient's and family's earliest convenience. Current research does not suggest an increased risk of arthrofibrosis with early ACLR. However, if ACLR is delayed, the patient is at high risk of further internal derangement of the knee, and should adhere to activity restrictions.

Question 2: In children/adolescents with acute ACL tear, is one surgical technique superior to others with respect to ACL re-rupture rates, pain, or return to sport (RTS)?

Rationale

A variety of surgical techniques for ACLR have been developed to restore knee stability while minimizing the risk of physeal injury in young patients. These techniques include the all-epiphyseal (AE) reconstruction, the pediatric extra-articular ACLR with iliotibial band (ITB) autograft, and the complete transphyseal (CT) reconstruction with soft tissue graft. Of note, the bone tendon bone (BTB) autograft is an adult-type reconstruction for school- and college-aged patients at or near skeletal maturity due to its risk to physeal injury. As the focus of this chapter is the pediatric ACLR; BTB autograft will not be discussed further.

Clinical comment

The elected procedure should minimize the risk of postoperative growth arrest and/or angular deformity while maximizing the opportunity to RTS and daily activities. Of the three available techniques for ACLR in skeletally immature patients, is there one that has been shown to be superior to the others? Are there specific indications for each procedure that produce the best outcomes?

Available literature and quality of the evidence

- Level II: 9 prospective cohort studies.[12–20]

- Level III: 6 retrospective cohort studies[21–26] and 1 meta-analysis.[11]
- Level IV: 3 systematic reviews.[27–29]
- Level V: 1 technique article.[30]

Findings

The surgical technique is generally based upon the patient's skeletal age, predicted growth remaining, and surgeon preference. The pediatric extra-articular ACLR with ITB autograft and AE reconstructions are generally reserved for patients with approximately 3–6 years of growth remaining, while the transphyseal reconstruction is for young adolescents with approximately 2–3 years of growth remaining.[11,12,14–17,19,20,27–29]

The pediatric extra-articular ACLR with ITB autograft

Micheli et al. reported on a series of eight patients (mean age: 11 years) who underwent this modified intra- and extra-articular extraphyseal reconstruction originally described by MacIntosh and Darby.[18] The technique was performed with ITB autograft and the patients were followed for an average of 5.5 years after surgery. At latest follow-up, none of the patients experienced any complications or required revision surgery, and they were able to return to activities with a mean Lysholm score of 97.4.[18] Further studies similarly found satisfactory results with this procedure. Out of 237 patients (mean age: 11.2 years), Kocher et al. found at mean follow-up 25.8 months, 96.8 and 98.9% of patients were grade A on the Lachman and pivot-shift test, respectively. At an average 33.5 months postoperatively, graft rupture occurred in nine (6.6%) of 137 knees. For patients who did not sustain a graft rupture, the mean Pedi-IKDC score was 93.3, the

mean Lysholm score was 93.4, and the mean score on the Tegner Activity Scale was 7.8. No cases of limb-length discrepancy or angular deformity were observed.[23]

All-epiphyseal (AE)

Anderson described a transepiphyseal ACLR for pediatric patients that mitigates the risk of iatrogenic growth disturbance by avoiding graft fixation that violates the tibial or femoral physis.[24] In a preliminary report of 12 patients (mean age: 13.3 years), Anderson reported no instances of growth disturbance.[25] Although this technique intends to minimize the risk of complications, the chance for growth disturbance remains. Out of 12 patients (mean age: 12 years) who were clinically followed for an average of 4.5 years by Koch et al., six (50%) presented with leg length discrepancy (LLD).[25] Two patients had LLD >10 mm and four others had an overgrowth of the affected leg between 5 and 10 mm; however, none of these patients required surgical intervention to correct their growth deformities.

Modifications have been made to Anderson's technique that vary by surgeon and institution, but all are *all-epiphyseal* with fixation in the distal femoral and proximal tibial epiphysis, decreasing the possibility of soft tissue tethering to the growth plate.?30? Nawabi et al. prospectively studied 23 patients (mean skeletal age: 13.2 years) with 18.5-month mean follow-up to quantify physeal violation using MRI.[13] Results showed that 10 out of 15 patients in the AE group had minimal tibial physeal violation.[13] The authors concluded that the AE reconstruction is a safe technique in which the area of physeal compromise is significantly lower than published thresholds for growth arrest.

The reported RTS rate after AE ACLR is reported at over 90%.[28] Cordasco et al. found 100% of patients (n = 49) who underwent AE ACLR were able to RTS and only 6% required revision ACL surgery.[20] In addition, Tuca et al. reported 100% RTS without re-injury at an average of 30.7 months in 16 patients who underwent AE ACLR.[26] In studies where Pedi-IKDC/IKDC was administered, patients were highly satisfied with scores in the mid-90s postoperatively. [12],[14]

Complete transphyseal (CT)

The CT technique involves femoral fixation proximal to the femoral physis and tibial fixation distal to the tibial physis. In a meta-analysis in which 60% of the reconstructions performed used the CT technique, it was noted that 10 out of the 18 knees that presented with an angular deformity postoperatively had undergone a transphyseal reconstruction.[11] Other studies have shown some instances of growth disturbance postoperatively, yet patients continue to return to their activities at a high rate and report good to excellent satisfaction scores.[15–17],[19] Calvo et al. reported a 10-year follow-up study on 27 patients who underwent CT ACLR. The results showed 100% RTS.[17] However, three patients experienced graft rupture during contact sports and one patient developed progressive instability and required graft revision.

One systematic review conducted by Pierce et al. found no significant differences between CT and physeal-sparing reconstructions when comparing LLD, angular deformities, and graft rupture.[29] In another systematic review, Collins et al. reported growth abnormalities in 39 patients from 21 published studies on ACLR complications in skeletally immature patients.[27] Eleven of these patients had postoperative limb shortening by an average of 17 mm,

seven (64%) of which underwent a transphyseal technique. Sixteen cases had an angular malformation, eight (50%) of which were transphyseal on the femur. The clinical implications of these deformities were not presented, nor details on treatments undertaken.

Resolution of clinical scenario

In the current clinical scenario, this 12-year-old boy has approximately four years of growth remaining. Therefore, CT is not recommended due to the risk of physeal injury and growth arrest. The extra-articular ACLR and the AE reconstruction are both viable options for the younger age groups with significant growth remaining. There is currently no significant evidence suggesting the superiority of one technique over the other; therefore, both options can be considered and surgical technique can be selected by surgeon preference.

Question 3: In children/adolescents with an acute ACL tear, what is the risk of re-injury to the same and contralateral side, and what can be done to prevent re-injury?

Rationale

Although surgical reconstructions in the pediatric and adolescent populations have demonstrated favorable outcomes in terms of patient satisfaction and RTS, this cohort is at high risk for re-injury on both the ipsilateral and contralateral sides. Graft failure rates vary from 0% in smaller cohorts to as high as 21%, and contralateral ACL tear rates have been reported in 8–14% of patients.[20,31,32]

Clinical comment

Children and adolescents are likely to be symptom free and RTS after ACL reconstruction. Risk to the reconstructed ACL may be due to muscular deconditioning, incomplete rehabilitation, poor compliance with activity restrictions, and/or increased participation in at risk sports. Risk to the contralateral ACL may be due to patient anatomy and muscular deconditioning in the postoperative period, and increased participation in at-risk sports.

What is the annual risk of re-rupture? What is the risk of ACL injury to the other leg? Should RTS be delayed until a specific time postoperatively?

Available literature and quality of the evidence

- Level I: 1 meta-analysis[31] and 2 prospective studies.[33],[34]
- Level III: 7 retrospective cohorts[32][35]–[40] and 1 therapeutic study.[41]

Findings

When stratified by specific technique the transphyseal, AE, and the pediatric extra-articular ACLRs have overlapping rates of graft failure: 14–15%,[17],[37] 4.3–15%,[12],[14] and 4.5–14%,[21],[24],[38] respectively. In addition to graft failure is the risk for a contralateral ACL injury. In a review of 561 ACLR cases, Ho et al. found that 8% of patients went on to tear their contralateral ACL.[36]

Patients under the age of 20 are at greater risk for secondary ACL injury in comparison to older cohorts, with high rates of revision ACLR in the first two years after returning to activities.[41] Webster et al. saw that 74% of ACL graft ruptures in a group of 316 patients (mean age:

17.2 years) occurred during the first two years postoperatively.[34] While younger patients recover more quickly and are eager to return to their activities, they may have remaining functional deficits and altered motor patterns that could place them in danger of another injury. Dekker et al. found that a prolonged period before RTS may act as a protective factor against secondary ACL injury while prolonged periods of physical therapy may not.[39] This supports the idea that there may be an important biological recovery period that is not influenced by the patient's rehabilitation protocol. When comparing ACLR postoperative MRIs of pediatric patients who subsequently suffered a re-tear versus those who did not, Pauvert et al. found no significant different differences between the two groups. The MRI appearance of the graft at six months postoperatively was not predictive of risk of re-tear.[42]

The quality of movement analysis (QMA) is another tool that focuses on a combination of qualitative and quantitative criteria to determine RTS readiness. Rather than centering rehabilitation around demarcated timepoints, the QMA reveals the strength and functional deficits that the patient must improve upon before being cleared for unrestricted activity. After achieving satisfactory results on the QMA, Graziano et al. reported 35 of 42 skeletally immature athletes were able to return to play at an average of 12 months without re-injury. The remaining seven suffered a second injury (four ipsilateral and two contralateral ACL tears, one meniscus injury).[33] Of note, three of the subsequent ACL tears were injured in sports that the patient was not cleared to play.

Cordasco et al. recently published the RTS and re-operation rates after primary ACLR in 324 adolescent athletes.[20] The patients who underwent CT ACLR had a 20% rate of revision ACLR, compared to 6% in both the AE and BTB

groups. The authors discussed the possibility that the age and grade level of the patients undergoing CT ACLR are especially relevant to the higher risk of revision ACLR. These eighth and ninth graders are returning to a skeletally mature group of high school athletes who had not lost nearly a year of competition and associated developmental physical and sport specific growth.[20] This group of adolescent athletes is at particularly high risk for ACL graft rupture. It is especially important to ensure these patients adhere to physical therapy regimens, pass QMA testing, and maintain strength and cardiovascular health before returning to high risk sports.

Resolution of clinical scenario

There is no widely accepted time point for RTS after ACLR. The previously reported average was 12 months. However, rather than setting a particular time point, surgeons should assess the patient's commitment to physical therapy and QMA results. The patient should not RTS that involve contact play, cutting, and pivoting until they are able to pass their QMA. Another important aspect is setting expectations and goals with patients and their families as to which sport and what season the patient is working toward, with particular focus on the skills required to return successfully.

Rather than setting a particular time point for RTS, surgeons should assess a patient's commitment to physical therapy and periodical QMAs. In particular, the patient should not RTS that involve contact play, cutting, and pivoting until they are able to pass their QMA.

Summary of answers

- Because there is an estimated increased meniscal injury prevalence of 6% for every month that surgery is delayed, ACLR is recommended for young, otherwise healthy, athletic patients within a month postinjury. If ACLR is delayed, the patient must adhere to activity restrictions to prevent additional damage.
- The optimal ACLR technique depends on the child's skeletal age and functional requirements. However, because of the successful outcomes reported for all techniques, the specific technique should be selected by patient factors and surgeon comfort/preference.
- There are biomechanical, biologic, and cognitive aspects to rehabilitation. Appropriate attention to all areas is recommended to prevent re-injury. Specifically, the patient's specific adherence to physical therapy, and results of the QMA, should be used when clearing patients to RTS.

187 Clubfoot

Anna D. Vergun MD[1] and Peter Moskal MD[2]
[1] Department of Orthopaedic Surgery, University of North Carolina, Chapel Hill, NC, USA
[2] Department of Orthopaedic Surgery, Children's Hospital of the King's Daughters, Norfolk, VA, USA

Clinical scenario

- The parents of a newborn boy seek treatment for his clubfeet.
- On both sides, hindfoot is in equinus and varus with a deep posterior ankle crease; there is a medial foot crease with cavus; the lateral border is convex with the forefoot adducted.
- Deformities are isolated to the feet and not passively correctable, consistent with idiopathic congenital talipes equinovarus (CTEV).
- The parents have heard about the Ponseti method but are concerned about the prolonged period of bracing required. They want information about the success rates of serial casting and the potential for recurrence compared with early surgical correction of idiopathic clubfeet.

Top three questions

1. What are the success rates and recurrence rates following primary Ponseti treatment of infants with idiopathic clubfeet compared to other casting methods or surgical release?

2. What is the optimal application, duration, and length of use of foot abduction orthoses following Ponseti treatment to optimize outcomes in patients with idiopathic clubfoot?
3. How effective is the Ponseti method in correcting (untreated) idiopathic clubfeet in older children?

Question 1: What are the success rates and recurrence rates following primary Ponseti treatment of infants with idiopathic clubfeet compared to other casting methods or surgical release?

Rationale

CTEV is among the most common orthopedic conditions of the newborn, occurring in an estimated 1 in 1000 live births. Left untreated, it leads to significant morbidity and social stigma. The clubfoot deformity persists and becomes more fixed, preventing use of regular footwear. Walking is possible but weight bearing occurs over the dorsolateral or even dorsum of the foot. The goals of treatment are to achieve a plantigrade foot that is flexible, pain-free, and allows for use of regular footwear and unrestricted physical activity. Historically, treatment started with some form of manipulative serial casting followed by surgical releases which were commonplace as recently as 20 years ago. The Ponseti method of casting comprises a weekly series of above-knee casts applied after foot manipulation, following a sequence of correction of the cavus, forefoot adductus and hindfoot varus.[1] Once these components are fully corrected, a percutaneous Achilles tenotomy is performed

to address any residual hindfoot equinus.[2] The corrected foot/feet is/are left in a cast for three more weeks followed by a foot abduction orthosis (FAO) full time for three months, reduced to night-time use for up to four years. Ponseti reported a 98% initial success rate for correction of the deformity, which was superior to other casting techniques. Cooper and Dietz showed that the majority of patients had excellent outcomes at an average of a 34-year follow-up.[3] Dobbs et al. subsequently showed that almost 50% of patients had poor outcomes 25 years following extensive soft tissue release mainly as a result of stiffness.[4]

Clinical comment

In the presenting case, the patient has no evidence of any neuromuscular or syndromic etiology to explain his isolated foot deformities. Around the world, the Ponseti method has largely replaced other methods of casting, such as those described by Kite, and intra-articular surgical releases as the treatment of choice of idiopathic clubfeet.[1] What is the evidence that justifies this dramatic change in practice? How often is correction achieved by the Ponseti method maintained? What are the recurrence rates compared with other methods?

Available literature and quality of the evidence

- Level II: 5 studies[5–9]
- Level III: 5 studies[10–14]
- Level IV: 4 studies.[15–18]

Findings

Reviewing the literature for CTEV reveals several important limitations. There is little consensus amongst clinicians about how to categorize and quantify the severity

of CTEV. Treatment algorithms and casting and/or surgical techniques differ between providers and even evolve for a single provider. There is little clarity about what constitutes *residual* (partially treated) or *recurrent* (relapsed) deformity, and the indications for and timing of further intervention, and how we define a *good* outcome. Therefore, most studies have mixed cohorts of patients, loosely defined criteria for a relapse, and variable indications for additional surgical procedures, and a lack of validated patient/parent-reported outcomes.

How does the Ponseti method of casting compare with the Kite and other methods?

The two randomized controlled trials (RCTs) comparing the Ponseti method to the Kite method showed significantly faster rates of correction of deformity.[8],[9] Sud et al. reported correction in 33 of 36 feet (91.7%) in the Ponseti group with seven (21%) relapses,[9] while the Kite method achieved correction in 21 of 31 feet (67.7%) with 10 patients (32.2%) of feet requiring conventional surgery. In a prospective cohort study reported by Halanski et al.,[10] 40 clubfeet (26 children) treated by the Ponseti method group were compared with 46 feet (29 children) treated with below-knee casting. The Ponseti group required an average of six casts compared with 11 in the below-knee group. At an average of a 3.8-year follow-up, 12/26 patients in the Ponseti group needed more than a percutaneous tenotomy compared with 27/29 patients in the below-knee casting group. However, major posterior or posteromedial releases (PMRs) were only required in 4/40 feet in the Ponseti group compared with 43/46 in the below-knee group. Herzenberg et al. showed only one of 34 feet (3%) required a PMR in the Ponseti group versus 34 feet (94%) in the traditional casting method group.[14] Derzsi et al. showed a

failure rate of 30.3% in the Kite group and of 8.5% in the Ponseti group.[13]

Steinman et al. compared the results of the French method of manipulation and taping by daily physical therapy in 80 children (119 feet) with the Ponseti method for 176 patients (267 feet) at an average of a 4.3-year follow-up.[11] The initial correction rates and relapse rates were 94.4 and 37% for the Ponseti method and 95 and 29% for the French functional method. Two-thirds of the relapsed feet in the Ponseti group and all of the relapses in the French method group required operative intervention. At the time of the latest follow-up, the outcomes for the feet treated with the Ponseti method were good for 72%, fair for 12%, and poor for 16%. The outcomes for the feet treated with the French functional method were good for 67%, fair for 17%, and poor for 16%. When offered both treatments, parents preferred the Ponseti method to the French method at a ratio of 2 : 1.

How do the outcomes of the Ponseti method (casting and percutaneous tendo Achilles tenotomy) compare with surgical releases of idiopathic clubfeet?

The meta-analysis (mostly of cases series) by Lykissas et al. reviewed 12 studies from 1950 to 2011 that included 835 idiopathic clubfeet in 516 patients treated with either Ponseti method or surgical release with outcomes measured by the Laaveg-Ponseti Function Rating System (L-P FRS) score, and at least three radiographic outcome measures.[5] Average follow-up was 15.7 ± 10.8 years (range 1–42 years). Patients managed with the Ponseti method had a higher rate of excellent or good outcomes over those with open surgery. Zwick et al. randomized 19 infants with 28 CTEV to the Ponseti method and 10 infants with 16 CTEV to a surgical method that included limited pre- and postoperative casting.[6] The L-P FRS and PODCI scores at

an average of 3.3-year follow-up revealed good to excellent results for both groups, but parental satisfaction and passive mobility were better in the Ponseti method group. In a prospective case series, Smythe et al. reported excellent initial correction with 337 feet in 218 children showing that 85% of feet reached a Pirani score of 1 or less at the end of the correction phase.[18]

With respect to motor functional outcomes, Aulie et al. in a retrospective cohort study, compared the motor function of 89 children treated with primary surgery, 93 children treated with the Ponseti method, and 45 age-matched normative peers, using the Motor Assessment Battery for Children (MABC-2).[12] There was no difference between the Ponseti and surgical groups. However, in the clubfoot groups, only 76% had normal abilities compared with 96% of children without clubfeet.

What are the rates of recurrence following the Ponseti method?

In a systematic review by Thomas et al. looking at relapses, the studies included were all case series and showed a wide range of recurrence rates from 3.7 to 67.3%.[15] This might be explained by the variable lengths of follow-up and definitions of a relapse: reappearance of appearance of CTEV, and reliance on a surgeon's determination of need for further treatment with additional casting and/or surgery. There was a strong correlation between the rates of recurrence reported and the rates of joint-sparing surgical procedures to address these, and the duration of follow-up, with relapses reported as late as 10 years of age. Zionts et al. reported the results of 101 children treated in a single institution at a mean follow-up of 81.1 ± 17.1 months. Thirty-seven percent were adherent bracing by self-report, 68% of patients had one or more relapses, and 38% underwent a tendon transfer to address the relapse.[17]

Using the Dallas criteria, 62% had outcomes rated good, 38% had outcomes rated fair, and no patient had an outcome rated poor.

Resolution of clinical scenario

The Ponseti method provides the most effective method of achieving full correction with serial casting and minimal surgery (percutaneous tendo Achilles tenotomy). It involves fewer casts and a low likelihood of requiring major surgical releases compared with any other form of casting. It is preferred by parents to the French method. Compared with surgery, the long-term results of the Ponseti method appear superior particularly with respect to flexibility, although motor functional outcomes are not significantly different. Rates of recurrence after initial correction are similarly high over time, but recurrences following the Ponseti method require far fewer major surgical interventions compared with recurrences following early surgical releases.

Question 2: What is the optimal application, duration, and length of use of foot abduction orthoses following Ponseti treatment to optimize outcomes in patients with idiopathic clubfoot?

Rationale

Although there is an excellent rate of correction following serial casting by the Ponseti method followed by the Achilles tenotomy, there remains a high rate of recurrence thereafter. To maintain the correction, the Ponseti method

includes the use of an FAO for 23 hours/day for three months after correction, continued thereafter at night and nap time until 4–5 years of age. Use of the brace does not eliminate recurrences, and there is uncertainty regarding the duration of bracing necessary.

Clinical comment

For many families, bracing is a considerable hardship to maintain. The FAO includes both feet linked with a bar, which many young children don't tolerate. Recurrences are often attributed to failure of *compliance* with the bracing. It is conceivable that a recurrence might cause the brace to be less tolerated. Once a deformity recurs, bracing alone is no longer effective and the recurrence is treated with serial casting with or without additional surgery.

Available literature and quality of the evidence

- Level II: 3 studies[19–21]
- Level III: 2 studies[22,23]
- Level IV: 4 studies.[24–27]

Findings

The definition of recurrent deformity varies between studies. Early recurrence rates after the Ponseti method range from 26 to 48%.[19–21,25,26] The studies that recorded FAO use by self-report show a significantly higher risk of early recurrence in the nonadherent groups. Avilucea et al. defined early recurrence as the need for subsequent cast treatment or surgical treatment, and compliance as strict adherence to the FAO protocol described by Ponseti.[19] Abandonment of the brace protocol was associated with a 33.3-fold increase in the likelihood of early recurrence in the urban patients closer to the treating institution (95%

confidence interval [CI]: 5.2–212.2, p <0.001) and 120 times more likely among rural patients (95% CI: 18.8–765.1, p <0.0001).

Abdelgawad et al. demonstrated statistically significant better Dimeglio and Pirani scores in compliant versus noncompliant groups.[24] Eighty-four percent of patients in the compliant group required no additional treatment after two-year follow-up versus 24% in the noncompliant group. Haft et al. found that failures resulted in a fivefold greater risk of recurrence.[20] Zionts et al. found that patients were 2–3 times more likely to have a relapse if the family did not use the FAO as prescribed.[21] Dobbs et al. reported that poor compliance of the FAO is the main risk factor for recurrence with an odds ratio (OR) of 183 (95% CI: 9.5–3519),[25] and Ramirez et al. found that poor compliance with the FAO has a ninefold greater risk of recurrence (95% CI for the OR = 2.2–38.5).[26] The association found between reduced brace wear and increased recurrence rates does not conclusively demonstrate cause and effect, and the risk of bias of labeling someone as noncompliant when they are noted to have a recurrence is very high. In contrast to all the previous studies, the study by Kuzma et al. used objective measurement of brace wear with a sensor embedded within the FAO.[23] In their cohort of 42 patients, 64 affected feet, five-year follow-up, and a recurrence rate of 40%, there was no statistically significant relationship between recurrence and compliance with the FAO. They showed a statistically significant correlation with increased difficulty of CTEV correction (greater than nine casts) during initial treatment.

With respect to the type of bracing, Janicki et al. demonstrated the importance of using a FAO (Denis Browne Boots and bar) as recommended by Ponseti instead of an ankle foot orthosis (AFO).[22] In a retrospective cohort

study of 45 infants (69 feet) who achieved full correction with the Ponseti method, recurrence occurred in 83% (25/30) of clubfeet in the group treated with AFOs during the maintenance phase compared with 31% (12/39) in the FAO group. The use of an AFO for maintenance of correction was 10.6 times higher compared with use of an FAO ($p < 001$).

Resolution of clinical scenario

Given the high rates of recurrence after initial correction, the need for bracing to maintain correction achieved by the Ponseti method is well supported in the literature. AFOs are ineffective form of bracing. The FAOs recommended by Ponseti are superior to AFOs but do not eliminate recurrence. Nonadherence with brace wear is associated with higher recurrence rates. Although a clear cause and effect is difficult to infer from these studies, the evidence is largely supportive of the use of FAO to decrease recurrence after successful initial correction with Ponseti method. However, the specific duration (hours/day) of brace wear and the age at which braces may be stopped remain poorly studied.

Question 3: How effective is the Ponseti method in correcting (untreated) idiopathic clubfeet in older children?

Rationale

The Ponseti technique was developed for the treatment of infantile CTEV; however, the upper age limit of achieving correction becomes relevant as the technique has become

increasingly available in areas where many children with clubfeet may not have had access to care as infants.

Clinical comment

After recent studies demonstrating that neglected clubfoot can be corrected with serial casting, there are new questions regarding goals of deformity correction and the need for immediate versus delayed associated surgical procedures to achieve the best result.

Available literature and quality of the evidence

- Level II: 6 prospective cohort studies.[28–33]
- Level III: 1 retrospective cohort study.[34]
- Level IV: 5 studies.[35–39]

Findings

There is a growing body of evidence that untreated CTEV in older, walking children can be successfully treated with the Ponseti method. There are six level II prospective cohort studies,[28–33] one level III retrospective cohort,[34] and six level IV studies[35–39] that demonstrate a 67–100% rate of correction to a painless plantigrade foot. Nearly all cohorts included minor extra-articular surgical procedures as part of the Ponseti treatment and report some degree of persistent deformity despite being plantigrade. The average age at initial treatment for each study ranged from 1.7 to 11.2 years, and the time in cast ranged from 7 weeks to 3.9 months. Surprisingly, the case series with the oldest average patient age also had one of the highest success rates of 94.4%.[37] Khan and Kumar reported a 24% recurrence rate with a follow-up at 4.7 years,[28] and Ayana and Klungsøyr reported a 12.5% recurrence rate with a mean follow-up of 3.0 years. Banskota et al. reported rates

of recurrence as low as 16% (aged 5–10 years) with mean 2.6-year follow-up.[31]

The case series by Adegbehingbe et al. is the largest to date with 328 feet.[38] A mean of 6.8 (3–20) casts achieved a painless plantigrade foot in 78% of feet without any additional procedures. Banskota et al. reported 95% of feet achieved a pain-free plantigrade foot; 86% were completely satisfied, with 96% having improved self-confidence and 99% having improvements in activities of daily living.[39]

Resolution of clinical scenario

The current evidence supports the use of the Ponseti method in older children with untreated clubfeet with success reported at least until early adolescence. The upper age limit for success remains unknown.

Summary of answers

- The Ponseti method has the highest and most consistent success rates of over 90% for initial correction of CTEV.
- The use of the FAO following initial correction is associated with lower rates of recurrence, but the current recommendations for the duration and length of time in FAOs are not based on objective evidence.
- The Ponseti method has excellent results, even when treatment is initiated in older children well after the onset of walking.

188 Tarsal Coalitions

Joseph Fox MD[1] and Maryse Bouchard MD MSc[2]
[1] Department of Orthopedics and Sports Medicine, Seattle Children's Hospital, University of Washington, Seattle, WA, USA
[2] Division of Orthopaedic Surgery, The Hospital for Sick Children, University of Toronto, Toronto, ON, Canada

Clinical scenario

- A 13-year-old girl has activity-related pain below the medial malleolus, and on occasion in the medial arch of foot and in the sinus tarsi.
- Clinically, she has a flat arch, valgus hindfoot alignment, forefoot abduction, and no subtalar motion.
- X-rays are suggestive of a tarsal coalition with flatfoot deformity including 16° of hindfoot valgus. There are no degenerative changes of the posterior facet.
- She is an avid soccer player and wishes to return to sport pain-free.

Top three questions

1. In children with subtalar tarsal coalition and flatfoot deformity, what are the indications for coalition resection alone, flatfoot reconstruction alone, versus combined resection and concomitant flatfoot reconstruction?
2. In children with calcaneonavicular (CN) tarsal coalition and flatfoot deformity, what are the indications for coalition resection alone, flatfoot reconstruction alone,

versus combined resection and concomitant flatfoot reconstruction?

3. In children with tarsal coalition and flatfoot deformity, when is arthrodesis of the subtalar joint indicated?

Question 1: In children with subtalar tarsal coalition and flatfoot deformity, what are the indications for coalition resection alone, flatfoot reconstruction alone, versus combined resection and concomitant flatfoot reconstruction?

Relevance

A flatfoot deformity due to tarsal coalition is characterized by a flat medial arch that will not improve on toe standing, and rigid hindfoot valgus with restricted subtalar motion.[1],[2] Concomitant flatfoot deformity is commonly seen with talocalcaneal (TC) coalitions and can cause pain and disability.[3] TC coalitions typically involve the middle facet, but can occur at any location in the subtalar joint. Symptomatic TC coalitions are commonly treated with resection and interposition of fat or bone wax. Poor results have been reported for TC coalition resection when hindfoot valgus is >16°.[4] There are no reported predictors of outcome or consensus guidelines for treatment of rigid flatfeet with tarsal coalitions.

Clinical comment

Based on the commonly used criteria established by Wilde et al., TC coalitions are deemed resectable with good outcomes if the surface area of the coalition is <50% of the surface area of the calcaneal posterior facet on coronal computed tomography (CT) images, hindfoot valgus is <16°, and there is no narrowing of the posterior facet of the subtalar joint or impingement of the lateral talar process on the calcaneus.[4]

Is this patient a candidate for coalition resection? Should her flatfoot deformity be reconstructed? If so, should it be performed simultaneously with coalition resection or staged in a second surgery?

Available literature and quality of the evidence

- Level III: 1 case control.[5]
- Level IV: 6 retrospective case series.[6–11]

Findings

Excellent functional outcomes have been reported following coalition excision in both mid- and long-term follow-up with minimal functional limitations.[6,7] In some studies, these results were independent of coalition type and size.[6,7] Postoperative subtalar range of motion was significantly decreased for TC coalitions,[6] but this restricted motion did not affect functional outcome.[7] Increased medial midfoot pressure during running has been demonstrated after TC coalition resection from the resulting altered subtalar mechanics.[5] Patient-reported functional outcomes were not obtained in this biomechanical study.

Several small series have evaluated coalition resection with simultaneous or staged flatfoot reconstruction. Reconstruction techniques and indications vary. Kernbach et al. included six adolescent feet with TC coalitions that underwent resection with naviculocuneiform fusion, Evans calcaneal lengthening osteotomy, and medializing calcaneal osteotomies.[8] They demonstrated significant improvement in radiographic alignment as measured by calcaneal inclination, Meary's, and anteroposterior talar-first metatarsal angles. All had excellent postoperative American Orthopaedic Foot and Ankle Society (AOFAS) hindfoot scores.

Mosca and Bevan found similar radiographic and clinical improvement with calcaneal lengthening osteotomy combined with plication of the posterior tibialis tendon and talonavicular joint capsule, and Achilles lengthening or gastrocnemius recession in eight adolescent patients with flatfeet and tarsal coalitions with an average follow-up of 3.7 years.[9] Five of these patients underwent osteotomy alone as the coalitions were deemed unresectable by the Wilde criteria, one patient underwent simultaneous resection and osteotomy, and two patients underwent osteotomy following prior resection. Their suggested algorithm is to resect the coalition if the posterior subtalar joint is healthy and to correct flatfoot deformity if present. In the case of a large osseous coalition, they recommend leaving the coalition in situ. Their postoperative protocol consists of a short leg cast for eight weeks, with pin removal and change to weight bearing cast at six weeks. Postoperative AOFAS scores improved in all patients and did not correlate to timing of reconstruction (staged versus simultaneous).

Gantsoudes et al. prefer to first resect the coalition, regain mobility of the joint, and realign the foot in a second surgery.[10] In their series of adolescents with coalitions treated with resection and fat interposition, 8 of 49 feet that had flatfoot deformities underwent staged resection with subsequent deformity correction with calcaneal, cuboid, and medial cuneiform osteotomies. The decision to include flatfoot reconstruction was based on preoperative hindfoot valgus. Radiographic and clinical improvement after resection was similar regardless of concomitant flatfoot deformity (average AOFAS score 88 with versus 90 without flatfoot correction).

Masquijo et al. reported similar outcomes to Mosca and Bevan in 14 feet.[9],[11] Eight were treated with flatfoot

reconstruction and coalition resection and six were by reconstruction alone. The coalitions were resected if the coalition surface area was <50% of the calcaneus posterior facet. Hindfoot valgus was >16° in all patients. Reconstruction techniques included sliding posterior calcaneal osteotomy, calcaneal lengthening osteotomy, medial cuneiform osteotomy, and Achilles tendon lengthening. Both groups showed restoration of radiographic parameters to normal range and improvement in AOFAS scores with a minimum 12-month follow-up.

To date, no studies have been published directly comparing results of resection alone to resection and reconstruction, or outcomes of coalitions treated in childhood to those treated in adulthood.

Resolution of clinical scenario

- There is level III and IV evidence that this girl's coalition can be resected successfully; studies report good results with resection and reconstruction in flatfeet with tarsal coalitions whether staged or simultaneous. There is, however, no evidence directly comparing staged versus simultaneous resection and reconstruction to establish superiority of either approach.
- Based on the available literature, she would benefit from both resection and reconstruction. To minimize the number of surgeries, she could have the procedures simultaneously.

Question 2: In children with calcaneonavicular (CN) tarsal coalition and flatfoot deformity, what are the indications for coalition resection alone, flatfoot reconstruction alone, versus combined resection and concomitant flatfoot reconstruction?

Relevance

CN is the most common type of tarsal coalition, representing 54% of all coalitions.[12] Although deformity is more common in TC coalitions, CN coalitions can also present with flatfoot deformity causing pain and disability. Unlike TC coalitions, CN coalitions do not involve a joint. They act as an extra-articular tether, limiting movement through otherwise healthy cartilage.

Clinical comment

The presentation of planovalgus deformity with TC or CN coalition is similar. Some feet may have more than one coalition present.[13] It is important to obtain CT or magnetic resonance imaging (MRI) to delineate the type and location of coalition(s) as they are not always easily visualized on x-ray. Symptoms typically develop at a younger age in CN coalitions (aged 8–12 years) compared to TC coalitions at age 12–16 years.[14]

CT confirms CN coalition and standing x-rays demonstrated flatfoot deformity. Are this patient's symptoms more from the coalition or from flatfoot deformity? Should both be treated surgically?

Available literature and quality of the evidence

- Level III: 1 retrospective case control.[13]
- Level IV: 3 retrospective case series.[6],[7],[14]

Findings

Wilde et al. comment that outcomes of CN coalition resection and graft interposition are generally better than TC coalitions.[4] Newer literature calls this into question. Khoshbin et al. followed 24 patients for an average of 14.4 years following coalition resection and graft interposition (19 CN, 13 TN).[7] They found no significant difference in clinical outcomes at any point between the coalition types. They reported on two patients, one with CN and the other with TC coalition, who underwent additional procedures for planovalgus deformity correction. Given the good to excellent clinical outcome scores and low rate of subsequent surgery for deformity correction, they advocated resection and graft interposition alone for both coalition types.

Mahan et al. likewise followed a group of both TC and CN coalitions for an average of 4.6 years after resection and graft interposition.[6] Both coalition types demonstrated significant and maintained improvement in clinical function as assessed by AOFAS scores and UCLA activity scores. They, like Khoshbin et al., did not find a significant difference between the coalition types. Average ankle valgus preoperatively was also the same between CN and TC coalitions.

To further evaluate resection and interposition of CN coalitions, Masquijo et al. retrospectively reviewed 56 patients' clinical outcomes using different interposition materials: fat, bone wax, and extensor digitorum brevis

muscle.[15] They found that all groups had significant improvement in AOFAS scores and pain VAS scores. However, the fat graft and bone wax patients had significantly better postoperative pain and AOFAS scores. Coalitions radiographically recurred in eight patients and of these, five patients, all in the EDB group, were surgically revised due to pain at the coalition. The authors conclude that resection and graft interposition results in significant clinical improvement despite graft type, but fat and bone wax are superior to EDB for interposition material.

Only study to date examines flatfeet with CN coalitions. Quinn et al. report improved radiographic outcomes in seven patients treated with simultaneous CN coalition resection and flatfoot reconstruction compared to 20 patients treated with resection alone.[16] Clinical outcome scores were not measured. Surgical techniques included gastrocnemius and soleus fascia release, calcaneal osteotomy, and/or midfoot osteotomy to achieve correction of the flatfoot deformity.

Resolution of clinical scenario

- If CT/MRI imaging confirmed an isolated CN coalition in this young patient, excision and interposition could be expected to result in improved functional outcomes.
- Excellent mid and long-term clinical outcomes have been demonstrated with resection and graft interposition with various materials, with recent superiority shown for fat graft and bone wax over EDB.
- Improved radiographic outcomes can be achieved with flatfoot deformity correction at the time of resection, but to date no study has compared outcomes of flatfoot reconstruction performed at the time of CN coalition resection versus staged after resection.

Question 3: In children with tarsal coalition and flatfoot deformity, when is arthrodesis of the subtalar joint indicated?

Rationale

Subtalar or triple arthrodesis is traditionally the treatment for large TC coalitions deemed unresectable by the Wilde et al. criteria.[4],[17],[18] Reported indications include secondary degenerative arthrosis, particularly in adults, and persistent pain with or without concomitant deformity.[4],[18],[19] No study has examined the long-term effects of arthrodesis for coalition, but known long-term sequelae of subtalar and triple arthrodesis in adults include adjacent joint arthritis, difficulty ambulating on uneven surfaces, and limitations in activity.[20],[21]

Clinical comment

This patient's coalition is resectable per the Wilde criteria, though her hindfoot deformity is at the upper acceptable limit at 16°. She has normal cartilage thickness in the posterior facet (Figure 188.1).

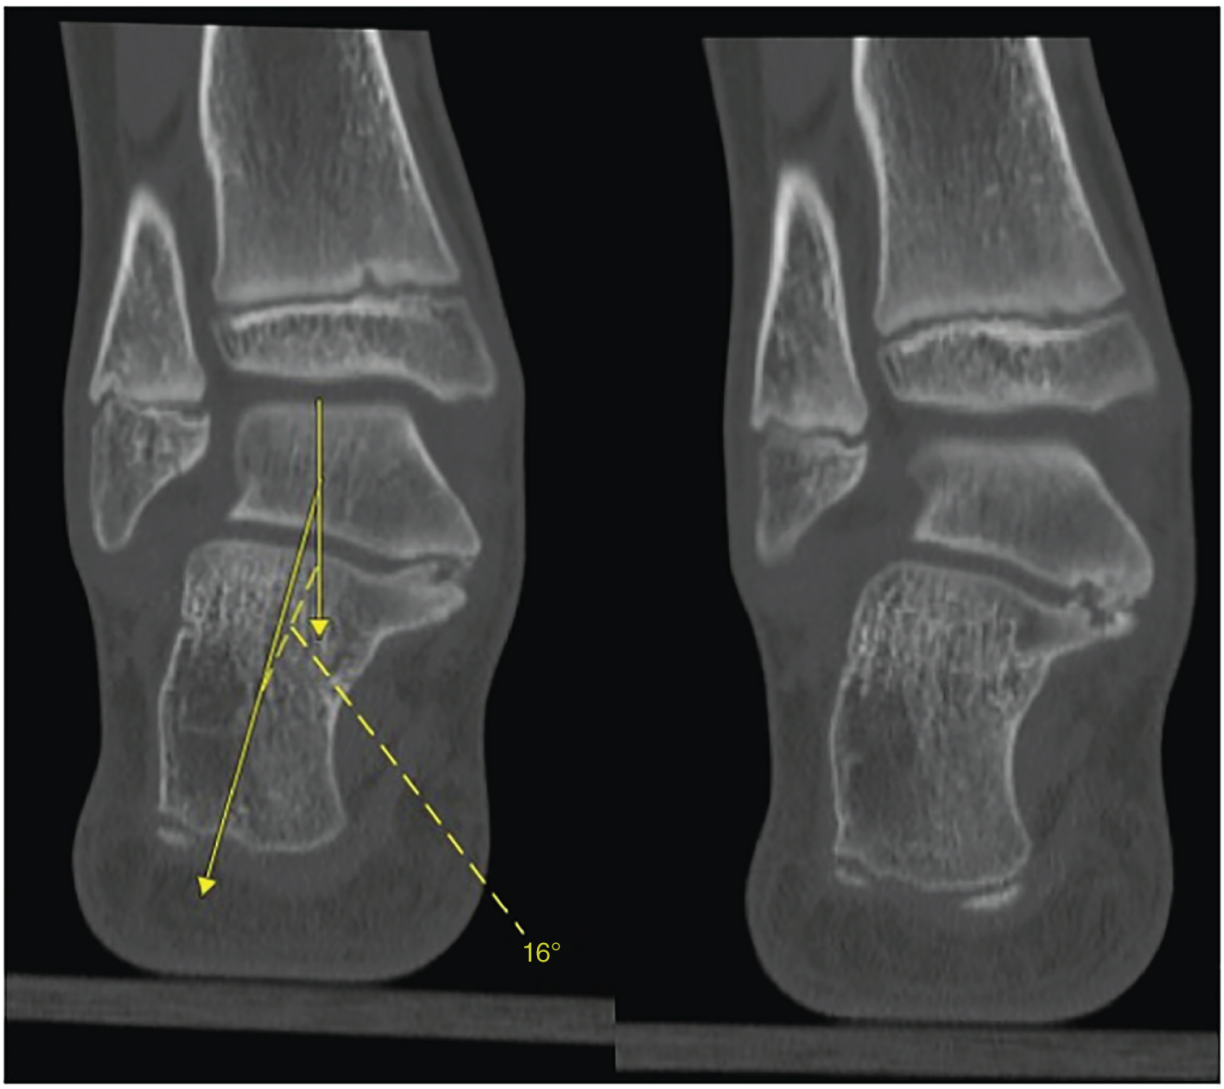

Figure 188.1 Preoperative CT scan demonstrating an osseofibrous middle facet TC coalition with a surface area measuring 30%. Hindfoot valgus measures 16°. The posterior facet is maintained, although is thin relative to the ankle joint. Source: Joseph Fox, Maryse Bouchard.

Would subtalar arthrodesis be a good solution to achieve deformity correction and prevent the possibility of deformity progression if the coalition were resected? Are the Wilde criteria predictive of need for arthrodesis?

Available literature and quality of the evidence

- Level III: 1 retrospective cohort study.[22]
- Level IV: 1 Retrospective case series,[4,17–19,23–25] and 2 biomechanical analyses.[20,21]

Findings

Wilde et al. noted poor outcome with resection of a coalition if the surface area is >50% of the calcaneal posterior facet, hindfoot valgus is >16°, there is narrowing of the posterior facet of the subtalar joint, or impingement of the lateral talar process on the calcaneus.[4] Luhmann et al. reported poor outcomes when valgus exceeded 21°.[19] Both studies advocate for arthrodesis in the setting of an *unresectable* subtalar coalition. Some studies have since called these criteria into question.

Khoshbin et al. followed 32 tarsal coalitions (19 CN and 13 TC) for an average of 13 years and found favorable clinical outcomes with resection irrespective of coalition size and hindfoot valgus.[7] Mahan et al. showed no difference in outcome scores or activity limiting foot pain between those with and without hindfoot valgus >16° and coalition surface area greater or less than 50% treated with resection alone at medium-term follow-up.[6]

Although many studies employ the Wilde criteria to determine resectability of the coalition, the only consistently described indication for arthrodesis was the presence of degenerative changes of the subtalar joint posterior facet.[8–11]

Long-term results of hindfoot and triple arthrodesis in adults without neuromuscular conditions demonstrate >50% of patients develop adjacent ankle arthrosis, difficulty with uneven ground, and pain with mild to moderate activity.[20,21] Cadaveric studies showed altered ankle biomechanics with increased peak pressure in the

ankle joint following subtalar and triple arthrodesis.[23,24] Despite this, most patients reported satisfaction with the treatment.[20,21]

The only long-term studies evaluating clinical results of triple arthrodesis in children are in patients with neuromuscular conditions.[22,25] In Saltzman et al.'s study with over 40-year follow-up, progressive ankle arthritis was observed in 100% of patients with 69% reporting overall function as *fair*.[22] These patients predominantly suffered from poliomyelitis. In the cerebral palsy population, Trehan et al. reported low rates of ankle arthritis (11.5%), high overall satisfaction (95%), and pain-free ambulation (62%) at 10 years.[25] These patients have different underlying pathology, deformity, and treatment goals than otherwise healthy children with coalitions, and therefore these results may not apply.

Khoshbin et al. reported on reoperation rates after resection of TC and CN coalitions in 304 young adults with an average age of 24.2 years.[26] Concomitant arthrodesis (typically subtalar) at the time of resection was found to be an independent risk factor for subsequent adjacent-joint arthrodesis with a hazard ratio of 9.7 and an overall rate of 5.3%.

Schwartz et al. described subtalar joint distraction arthrodesis (the technique of fusion with addition of a bone block in the joint to restore alignment) in eight pediatric patients with TC coalitions and hindfoot valgus.[27] Postoperative AOFAS scores were an average of 90.1/94 with a 25-month mean follow-up. They report good deformity correction but do not describe preoperative valgus or health of the posterior facet.

There are no studies directly comparing arthrodesis to deformity correction in flatfeet with coalitions.

Resolution of clinical scenario

- The only consistently reported indication for primary arthrodesis for tarsal coalitions is the presence of degenerative changes of the subtalar posterior facet. Size of the coalition as a criterion for fusion has been refuted in subsequent studies, suggesting the Wilde criteria are not predictive of the need for arthrodesis.
- Long-term level IV evidence demonstrates a high risk of adjacent joint degeneration following subtalar joint arthrodesis for TC coalitions. Several large, long-term studies of subtalar joint and triple arthrodesis in neuromuscular patients show high rates of ankle arthritis, with fair to good clinical function, but these studies are not directly applicable to healthy active patients.
- No long-term studies exist reporting functional outcomes or activity level of subtalar fusion in an average, active pediatric population.
- If CT/MRI imaging confirmed a TC coalition <50% the width of the posterior facet, this patient's coalition would be deemed resectable by Wilde criteria, and with the posterior subtalar joint cartilage being healthy, she would not meet criteria for arthrodesis (Figure 188.1).

Summary of answers

- In flatfeet with symptomatic tarsal coalitions, correction of the deformity is recommended in addition to resection to prevent worsening of the deformity and to address all sources of pain.
- Simultaneous flatfoot reconstruction and coalition resection is preferred to obviate the need of a second surgery.

- There is no evidence to support a particular technique of flatfoot correction, but we recommend calcaneal lengthening osteotomy with its associated procedures as it provides a powerful correction and does not rely on movement within the subtalar joint.
- We recommend resecting the coalition if it is painful at the site of the coalition and the posterior facet joint is healthy. If there is hindfoot valgus and a flatfoot, deformity correction should be performed simultaneously to prevent possible worsening of deformity and pain.
- CN coalition resection and graft interposition results in excellent long-term clinical outcomes.
- Fat and bone wax interposition shows superior outcomes in a level III study.
- Limited evidence is available regarding concomitant flatfoot reconstruction with CN resection.
- Primary arthrodesis for tarsal coalitions leads to adjacent joint arthritis and should be avoided unless posterior facet subtalar cartilage already demonstrates degenerative changes.
