Library of Congress Cataloging-in-Publication Data

Names: Bhandari, Mohit, editor.

Title: Evidence-based orthopedics / edited by Mohit Bhandari.

Other titles: Evidence-based medicine.

Description: Second edition. | Hoboken, NJ : Wiley-BMJ Books, 2020. | Series: Evidence-based medicine | Includes bibliographical references and index.

Identifiers: LCCN 2020028754 (print) | LCCN 2020028755 (ebook) | ISBN 9781119414001 (cloth) | ISBN 9781119413981 (adobe pdf) | ISBN 9781119413943 (epub)

Subjects: MESH: Orthopedic Procedures | Bone and Bones–surgery | Joints–surgery | Fractures, Bone–surgery | Evidence-Based Medicine

Classification: LCC RD755 (print) | LCC RD755 (ebook) | NLM WE 168 | DDC 617.9–dc23

LC record available at https://lccn.loc.gov/2020028754

LC ebook record available at https://lccn.loc.gov/2020028755

Cover Design: Wiley

Cover Image: © SEBASTIAN KAULITZKI/SCIENCE PHOTO LIBRARY/Getty Images

To all those whose pursuit of knowledge is not predicated on the
destination, but the mere joy of the journey itself.

Foreword

Evidence-based medicine (EBM) – or evidence-based surgery, or evidence-based orthopedics (EBO) – is about solving clinical problems. In particular, EBO provides tools for using the medical and surgical literature to determine the benefits and risks of alternative patient management strategies, and to weigh those benefits and risks in the context of an individual patient's experiences, values, and preferences.

The term *evidence-based medicine* first appeared in the medical literature in 1991; it rapidly became something of a mantra. EBM is sometimes perceived as a blinkered adherence to randomized trials, or a healthcare manager's tool for controlling and constraining recalcitrant physicians. In fact, EBM and EBO involve informed and effective use of all types of evidence, but particularly evidence from the medical literature, in patient care.

EBM's evolution has included outward expansion – we now realize that optimal healthcare delivery must include evidence-based nursing, physiotherapy, occupational therapy, and podiatry – and specialization. We need evidence-based obstetrics, gynecology, internal medicine and surgery, and, indeed, urology and neurosurgery. And, of course, we need evidence-based orthopedics.

Applying EBO to management decisions in individual patients involves use of a hierarchy of study design, with high-quality randomized trials showing definitive results directly applicable to an individual patient at the apex, to relying on physiological rationale or previous experience with a small number of similar patients near the bottom rung. Ideally, systematic reviews and meta-analyses

summarize the highest-quality available evidence. The hallmark of evidence-based practitioners is that, for particular clinical decisions, they know the quality of the evidence, and therefore the degree of uncertainty.

What is required to practice EBO? Practitioners must know how to frame a clinical quandary to facilitate use of the literature in its resolution. Evidence-based orthopedic surgeons must know how to search the literature efficiently to obtain the best available evidence bearing on their question, to evaluate the strength of the methods of the studies they find, extract the clinical message, apply it back to the patient, and store it for retrieval when faced with similar patients in the future.

Traditionally, neither medical schools nor postgraduate programs have taught these skills. Although this situation has changed dramatically in the last decade, the biggest influence on how trainees will practice is their clinical role models, few of whom are currently accomplished EBO practitioners. The situation is even more challenging for those looking to acquire the requisite skills after completing their clinical training.

This text primarily addresses the needs of both trainees and, of this last group, practicing orthopedic surgeons. Appearing 20 years after the term *EBM* was coined, the first edition of this text represented a landmark in a number of ways. It was the first comprehensive EBO text. As with the first edition, this edition represents a successful effort to comprehensively address the EBO-related learning needs of the orthopedic community, and summarize the key areas of orthopedic practice.

To achieve its goals of facilitating evidence-based orthopedic practice, the text begins with chapters that introduce the tools for evaluating the original orthopedic literature. Those interested in delving deeper into issues of

how to evaluate the literature, and apply it to patient care, can consult a definitive text: *Users' Guides to the Medical Literature*.

The bulk of the current text, however, provides evidence summaries to guide each of the key common problems of orthopedic practice. Thorough and up to date at the time of writing, they provide a definitive guide to evidence- based orthopedic practice today. That evidence will, of course, change – and in some areas change quickly. Clinicians must therefore use *Evidence-Based Orthopedics* not only as a text for the present but also as a guide for updating their knowledge in the future. That future will hopefully hold the advent of an evidence-based secondary journal similar to those that have been developed in other areas, including *Evidence-Based Mental Health*, *Evidence-Based Nursing*, and the *ACP Journal Club*, which does the job for internal medicine. These survey a large number of journals relevant to their area and choose individual studies and systematic reviews that meet both relevance and validity screening criteria. These journals present the results of these studies in structured abstracts that provide clinicians with the key information they need to judge their applicability to their own practices. Fame and fortune await the enterprising group that applies this methodology to produce *Evidence-Based Orthopedics*.

Whatever the future holds for the increasing efficiency of evidence-based practice, the current text provides an introduction to a system of clinical problem-solving that is becoming a prerequisite for modern orthopedic practice.

Preface

History has demonstrated that “evidence does not cease to exist, just because it is ignored.” The World Health Organization's declaration of a global pandemic on 11 March 2020 was preceded by what quickly became coined as an *infodemic*. Misinformation is the unfortunate consequence of 24-hour news cycles, social media, and expert opinions. Infodemics also present challenges in the propagation of scientific literature. During the first 12-week period of the 2020 novel coronavirus pandemic, we saw an unprecedented 1700 new, virus-related, peer-reviewed publications in over 400 different journals. The peer-reviewed literature was further contributing to the misinformation epidemic. In a period of uncertainty, high-quality data become invaluable. Evidence becomes the signal to guide healthcare decisions during a crisis.

The second edition of *Evidence-Based Orthopedics* is grounded in evidence, and fueled by a global collaborative of authors with wide-ranging expertise in orthopedic surgery worldwide. The uniqueness of *Evidence-Based Orthopedics* has as much to do with our global family of expert contributors as our innovative, standardized format. With over 430 contributors, this book was an enormous undertaking of commitment and purpose. I personally thank each and every individual, from associate editors to section editors to chapter contributors for aligning their chapters into the most comprehensive summary of orthopedics in our field. This second edition has updated content, a streamlined chapter design, and clear evidence-based recommendations. All chapters contain a summary of the highest level evidence studies we identified and our appraisal of this evidence. A trusted resource for best

evidence, readers can quickly review the recommendations sections in each chapter to gain the evidence-based summary of the topic.

On a personal note, this textbook comes at a time in our history where our decisions will be tested, and the evidence we used to make them scrutinized. With unparalleled focus on the value and outcomes associated with orthopedic surgical care, this book is the *signal* in a noisy information ecosystem. With access to surgery challenged, we are now re-envisioning orthopedic surgery priorities, not based on opinion – but evidence. To those before us who have spent countless hours conducting research to produce evidence to guide insights summarized in this textbook, I thank you.

I Methodology of Evidence-Based Orthopedics

1 Principles of Evidence-Based Orthopedics

Niek van der Hoek MD[1], and Paul Tornetta III MD[2]
[1] Department of Surgery, Deventer Ziekenhuis, Deventer, The Netherlands
[2] Boston University School of Medicine, Boston, MA, USA

Introduction

The traditional approach to clinical problem solving places a great emphasis on professional authority. Decision making is based primarily on the intuition, experience, and rationale of the clinician, and it is heavily influenced by their opinion.[1] Since it is unlikely that the opinion of every physician is identical, it is reasonable to suggest that not all opinions can be correct.[2] Evidence-based orthopedics does not accept this approach. Although it acknowledges the importance of clinical judgment, it emphasizes that this alone is not enough to make optimal clinical decisions, especially with the large amount of evidence that is available. Evidence-based orthopedics combines the judgment of the clinician and values of the patient with the best available clinical evidence (Figure 1.1). The goal is to use the best available evidence to guide the management of individual patients based on their preferences.

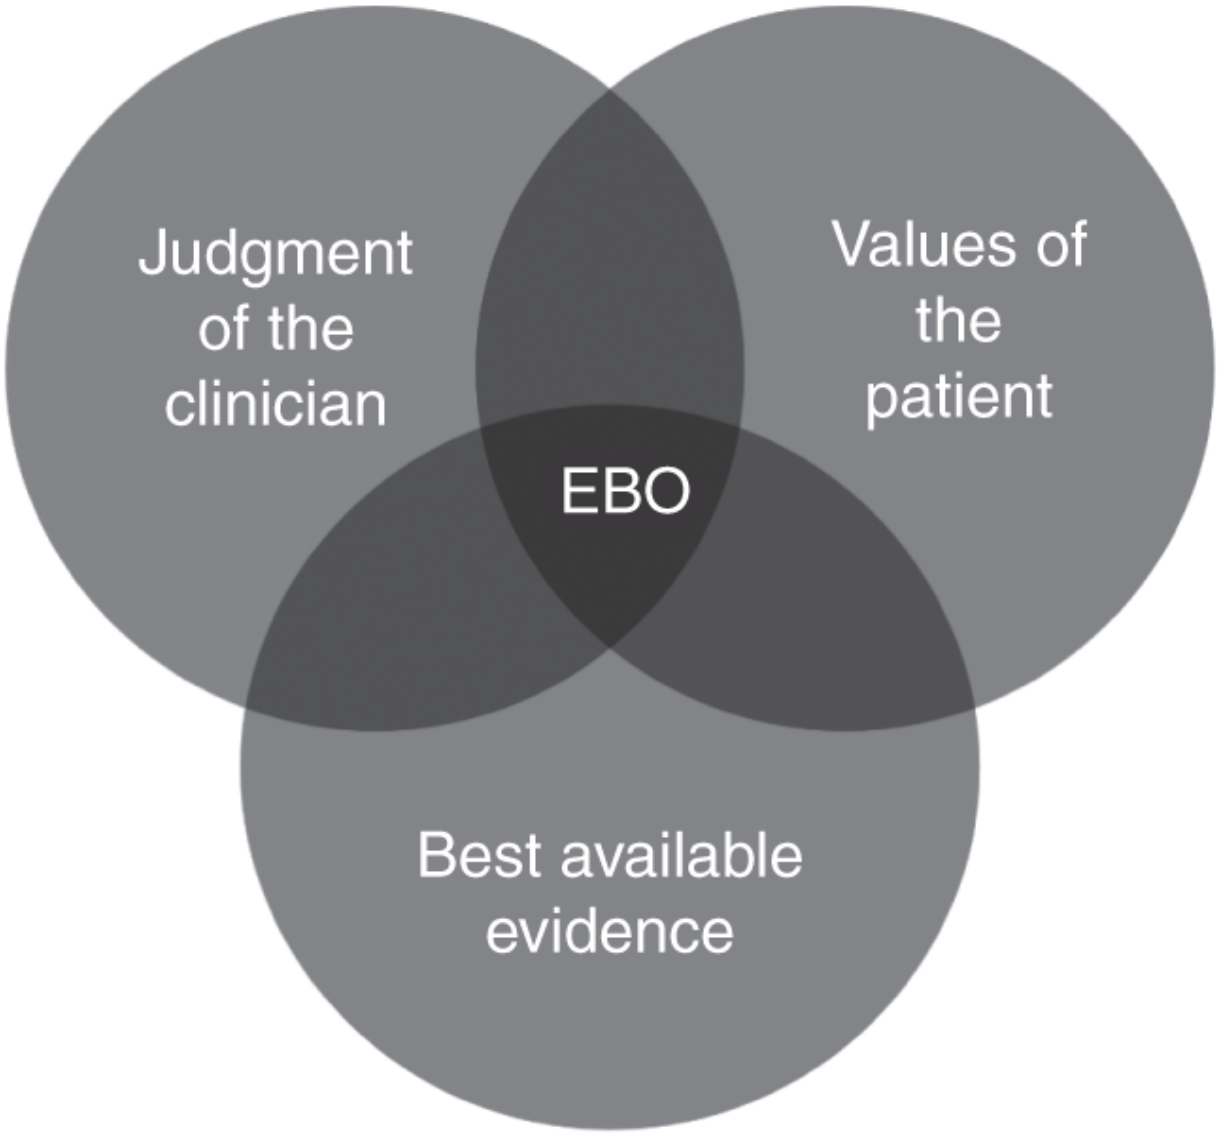

Figure 1.1 Visualization of the different aspects of evidence-based orthopedics (EBO).

Evidence-based orthopedics is a part of a larger movement called *evidence-based medicine*. This term was first used by Gordon Guyatt in the 1990s in the curriculum of the residency program at McMaster University.[3] The term was more formally defined in 1996 by Sackett et al. as "the conscientious and judicious use of current best evidence from clinical care research in the management of individual patients."[4] Evidence-based medicine is more than just a

positive alternative in patient care, it is on the *British Medical Journal*'s list of the top-15 most important medical milestones along with vaccines, the discovery of DNA structure, and the discovery of antibiotics.[5]

Importance of evidence-based orthopedics

Understanding the importance of evidence-based orthopedics is necessary to fully appreciate its principles. The goal of the clinician is to provide individual patients with the best clinical care.[2] Clinical research can help the clinician achieve this goal. The proper evaluation of clinical trials helps to define the risks and benefits of different treatment options, aiding the clinician and patient in making an optimal treatment decision.[6]

In 1992, Antman et al. compared the data from clinical research with expert opinions on the treatment of myocardial infarction.[7] This article showed that there was a difference in opinion between clinical experts and that it took experts 10 years for their opinions to catch up with the clinical evidence. While systematic reviews and meta-analyses may make information found in individual trials more accessible, there is still a lag between the publication of high-level evidence and its acceptance.[8]

Top four questions

1. What are the most important principles of evidence-based orthopedics?
2. How do you apply evidence-based orthopedics?
3. What is an example of applying evidence-based orthopedics?

4. What are the misconceptions of evidence-based orthopedics?

Question 1: What are the most important principles of evidence-based orthopedics?

Evidence is needed for optimal clinical care

Clinicians must acknowledge the importance of evidence and recognize that they need evidence in their daily practice. In evidence-based orthopedics, clinicians actively search for the best available evidence to supplement their judgment. There is a large body of evidence available to assist clinicians in many areas, from assessing the efficacy of treatment modalities to lifestyle recommendations to prevent disease.[6]

Keeping up to date with the growing volume of primary literature can be daunting, but it is incumbent upon all clinicians to do so. Systematic reviews can help the clinician to keep up to date, but these reviews are only one interpretation of the literature and clinicians should be aggressive about reading the original sentinel works. There are several resources to help the clinician find the best current evidence, such as the Cochrane Database of Systematic Reviews or the Clinical Queries feature in PubMed.[9]

Not all evidence is equally useful

There is a vast amount of evidence available and it is important to understand how the quality of the work contributes to its value in answering a clinical question. For example, a case report is much more vulnerable to bias than a randomized controlled trial (RCT). Randomized

treatment allocation balances the known and the unknown prognostic factors, making it less vulnerable to bias.[10] Table 1.1 shows the hierarchy of evidence from the least-biased study designs on the top of the hierarchy to the most-biased on the bottom.

Furthermore, there is a difference in the quality of evidence between studies, even those on the same level. For example, not every RCT is equally applicable to a particular clinical question. The inclusion and exclusion criteria must match the patient whom the clinician is treating. Outcomes of trials must be clinically important to the patient. Trials may report statistically different outcomes without a real clinical difference in patient outcomes. Finally, RCTs may have serious flaws, making them vulnerable to bias, such as a large percentage of patients who are lost to follow-up. This type of problem may threaten study validity.[11] A randomized trial with serious design flaws can no longer qualify as high-quality evidence.

Table 1.1 The hierarchy of evidence. Source: Modified from Schunemann.[1]

Least bias	Meta-analyses of RCTs
	RCTs
	Controlled trials
	Case control studies and cohort studies
	Cross-sectional studies
Most bias	Case reports, case series, and expert opinion

Evidence alone is not enough

In making a clinical decision, published evidence alone is never enough. The best treatment option is influenced by the patient's lifestyle, specific needs, and preferences as well as the judgment of the clinician. A deep understanding

of the patient, their medical history, and the pathophysiology of their disease is necessary. Most important, evidence-based orthopedics supports an active role of the patient in decision making, acknowledging the importance of the values and preferences of the patient. The most common example of this is in cases where multiple reasonable options exist. Patients should be free to choose their treatment based on their own set of goals and their personal assessment of the risk/benefit profile of the treatment options.

Question 2: How do you apply evidence-based orthopedics?

There is a five-step cycle called the *evidence cycle* that can help in applying the evidence-based orthopedics in daily practice.

Assess

A thorough understanding of the clinical situation is essential to develop a treatment plan. This includes a full understanding of the pathophysiology of the patient's complaints, symptoms, and physical findings in addition to the patient's medical history. From this, a differential diagnosis is created and whatever further testing is required to confirm a clear diagnosis is performed. Only with a correct diagnosis can the clinician form a clear question to research.

Ask

A well-formed research question is necessary to filter out irrelevant evidence without excluding valuable evidence. The PICO format can be used to compose a research question. In essence, every clinical research question

contains four components: a Patient or Population, description of the patient group; the Intervention, the treatment being considered; the Comparison, the alternative treatment(s) that is (are) to be compared; and the Outcome: the eventual goal of treatment or method of assessing treatment.

Acquire

With a well-formed research question, the clinician can start searching for evidence using any of the available search engines, such as PubMed. MeSH (Medical Subject Headings) terms are vocabulary produced by the National Library of Medicine. MeSH terms are used for indexing, cataloging, and searching of biomedical and health-related information. Using the correct MeSH terms and subheadings as well as filters helps to limit the dataset to the most relevant trials or reviews. If needed, a librarian can be of help in finding the right information. Or visit https://www.nlm.nih.gov/mesh/meshhome.html.

Appraise

Clinicians must also take it upon themselves to assess the literature for bias and quality. There are several tools available to assess primary literature, such as the Cochrane Collaboration's risk of bias assessment tool.[12]

Apply

Finally, the clinician must view all of the available evidence through the prism of a particular patient's needs. They must determine how the evidence applies to the clinical problem seen in their patient. The clinician must determine if differences exist between their patient and the evidence and judge what effect this might have on the outcome. For example, a trial comparing treatments for fractures in a

rheumatoid arthritis population may not apply to a young athlete.

Question 3: What is an example of applying evidence-based orthopedics?

A 48-year-old female arrives at the Emergency Department with pain and deformity of the clavicle after a fall on her shoulder. The patient smokes and there are no other injuries. The X-ray shows a 100% displaced midshaft clavicular fracture without an obvious shoulder droop. She reports a high degree of pain. The primary goal is to return her to her prior level of activity and have as normal shoulder function as possible. This type of fracture may be managed operatively or nonoperatively.[13–20]

The midshaft clavicular fracture is the most common fracture of the clavicle and numerous studies have been published on its treatment.[14–20] A recent meta-analysis of RCTs shows a significant reduction in nonunion rate after plate fixation of midshaft clavicular fractures compared with conservative treatment even though no clinically relevant increase of function was demonstrated.[21] Secondary operations were common in both groups. Meta-analyses of RCTs offer high-quality evidence and are the least susceptible to bias; however, they can focus only on the outcomes in each and every trial included.[1]

The authors of this meta-analysis found that there is insufficient evidence for routine plate fixation of displaced midshaft clavicular fractures, but it is a good option for patients who have risk factors for nonunion, such as smoking, highly displaced and/or comminuted fractures, and for patients who demand a faster recovery and optimal

arm function.[21] Additionally, the patient should be made to understand that if they heal their fracture then their outcome would be as good without surgery and that if it went on to nonunion and were then repaired, they could also expect a good result.[14],[17],[20_22]

This example shows that evidence can help in making a clinical decision while not replacing the judgment of the clinician and the values of the patient.

Question 4: What are the misconceptions of evidence-based orthopedics?

Evidence-based orthopedics replaces the judgment of the clinician

The judgment of the clinician is necessary in evidence-based orthopedics, the core principle being that evidence alone is not enough. The clinician and the patient are not bound to a certain course of action. While the reported evidence gives important information, the clinical decision remains in the hands of the clinician and the patient.

Only randomized controlled trials are acceptable evidence

RCTs are considered the highest level of evidence, but other types of studies have value also. Not every clinical question can be answered using a RCT. For example, it would be unethical to determine the negative effects of smoking on bone healing in a RCT. Although not all study designs can produce a definitive clinical answer, they can help to develop a relevant hypothesis.

One needs to be a statistician to practice evidence-based orthopedics

A basic understanding of statistics is attainable by all surgeons. Simply understanding the concepts of power, sample size, minimal clinically important difference, confidence intervals, and p values is all that is needed. This basic understanding can help the clinician independently determine the implications of trials.

Summary of answers

- Evidence-based orthopedics emphasizes that high-quality clinical research is necessary for optimal care.
- There is a large amount of evidence available and not all clinical research is equally useful.
- Critically appraising evidence is essential for evidence-based orthopedics.
- The clinician must determine how the evidence applies to their patient and combine this with the patient's values to find the best treatment together.

Introduction

The number of clinical studies in the field of orthopedics is overwhelmingly large and continually growing. It stands to reason that some of this research is of higher quality than others. How do we know which studies we can trust? Proponents of evidence-based medicine have developed a hierarchy of evidence which divides studies into groups according to study design to highlight the foundational role that appropriate study design plays in study quality. It should be noted that study design is not the only factor involved in study quality, but it does form the basis for making a decision about the trustworthiness or credibility of the evidence. It is important to have a thorough understanding of the theoretical underpinnings of each major study design and how these designs and methodological decisions affect study quality and credibility of the evidence. This principle of a hierarchy of evidence became prominent in the early 1990s as evidence-based medicine was formalized and physicians started to

appraise and apply evidence to their practice,[1,2] and this developed into a pyramid structure, with the best evidence placed at the top of the pyramid and called *level I evidence*, and the lowest-quality evidence at the bottom, called *level V evidence* (Figure 2.1).

Top five questions

1. What is the hierarchy of evidence for therapy studies?
2. What are randomized controlled trials (RCTs)?
3. What are observational studies?
4. What are case series and case reports?
5. What are systematic reviews and where do they fit in the hierarchy of evidence?

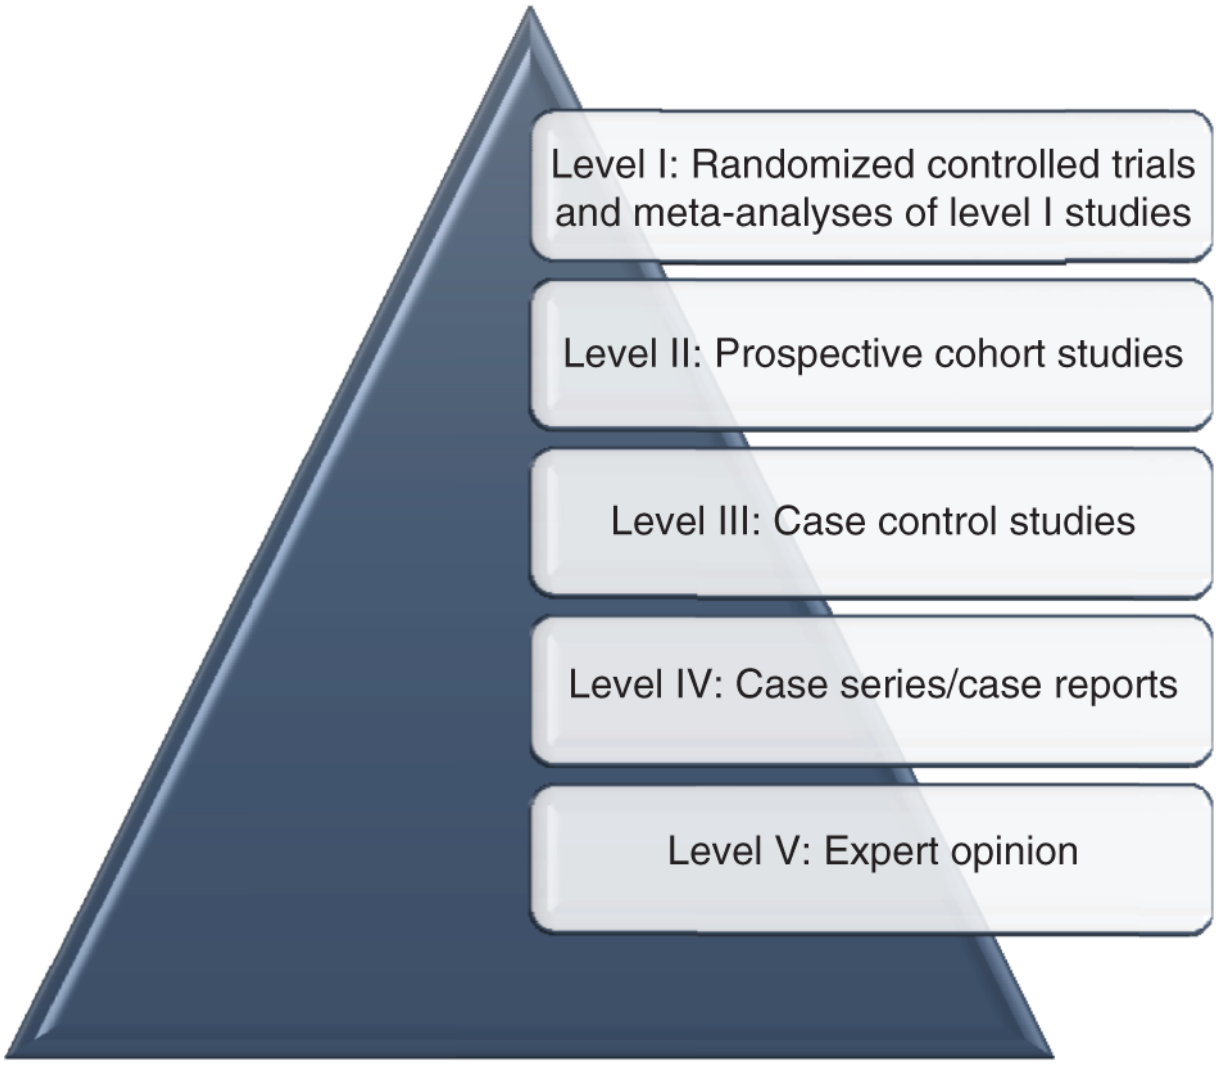

Figure 2.1 Levels of evidence pyramid for therapy studies.

Question 1: What is the hierarchy of evidence for therapy studies?

There are several major types of research questions that researchers can answer. These are typically classified into therapy, prognosis, harm, diagnosis, and economic questions.[3] In this chapter we will focus on those studies addressing therapy, as this is generally the most common type of study in the orthopedic surgical literature. In the case of therapeutic trials, RCTs and meta-analyses of RCTs

are considered the “best evidence.” This is because randomization allows investigators to control for both known and unknown prognostic factors, which cannot be done with other study designs. High-quality observational studies can control very well for known prognostic factors, but only well-done randomization with allocation concealment can control for all prognostic variables. Allocation concealment ensures that the investigators and the participants cannot manipulate the treatment group that they are randomly assigned to.

The second level of evidence is prospective cohort studies. This study design involves two (or more) groups of participants who are exposed to a factor of interest, for example direct anterior versus lateral surgical approach in total hip arthroplasty. The difference between a prospective cohort study and an RCT is that the participants are not randomized to groups: they are assigned by choosing who is in each group or by some other nonrandom means. Modern statistical methods are excellent at controlling for prognostic variables in large high-quality prospective cohort studies, but we can never be sure that all unknown prognostic variables are accounted for, as with RCTs. This is why this design is on the second level of the hierarchy of evidence. It should be noted that some groups put retrospective cohort studies on the second level of evidence, but some put them on the third level due to their retrospective nature. For example, the Oxford Centre for Evidence-Based Medicine's well-used 2009 hierarchy of evidence table puts all cohort studies on level II regardless of whether they are retrospective or prospective.[3] However, the *Journal of Bone and Joint Surgery* puts retrospective cohort studies in level III with other retrospective studies.[4]

The third level of evidence is case-control studies. This study design is unique in that it starts with an outcome and looks backward to determine if there was a particular exposure of interest. Case-control studies are useful for rare outcomes or cases where there are long latency periods between an exposure and an outcome. However, they are vulnerable to recall bias and are not randomized.

The fourth level on the hierarchy is case reports and case series. These studies are often retrospective in nature (but can be prospective) and they are characterized by having no comparison group. This means that we cannot compare the treated/exposed group to untreated/unexposed controls, and it is therefore very difficult to determine whether the participants would have improved (or not) had they not received the treatment/exposure.

Finally, the lowest level on the hierarchy is expert opinion. Experts have worked hard to develop their expertise usually over a period of many years. However, there are myriad biases that an expert can encounter that can color their opinions. Systematic research, such as the levels of evidence and study designs noted above, are theoretically more sound than expert opinion alone.

It should be noted that the study design is not the only consideration when assigning a level of evidence to a study. Studies can be downgraded for poor quality. For example, if an RCT has a major methodological flaw that leads to bias, it can be downgraded to level II evidence.

Question 2: What are randomized controlled trials (RCTs)?

RCTs, if conducted rigorously, are the gold standard for ascertaining the effectiveness and safety of a treatment.[2,3] RCTs can demonstrate the superiority of a new treatment

over an existing standard treatment or a placebo, or they can demonstrate that a new treatment is noninferior to an established treatment. In some cases, RCTs are required by government regulatory bodies as the basis for approval decisions for new medicines and medical devices.

The strengths of RCTs primarily include excellent internal validity, which is based largely on randomization. Randomization itself serves to ensure that the only difference between two (or more) treatment arms is their exposure to the treatment of interest. In other words, well-designed RCTs can provide good measures of the effect of treatments administered under ideal conditions. A criticism of RCTs is that they can be limited in terms of external validity (i.e. generalizability). In particular, patients, providers, and concurrent care in the general population are different from those in clinical trials and, as a result, the generalizability of RCTs may be limited.[2] However, RCTs can be designed such that they are more pragmatic (i.e. how care would be done in normal practice). A pragmatic approach often sacrifices some internal validity in favor of improved generalizability and giving better "real-world" data.

Since randomization is the key factor that distinguishes level I evidence from other levels of evidence, we will describe some of the major randomization methodologies. The simplest method of randomization is aptly named *simple randomization*. A common example of this approach includes flipping a coin. For example, in the case of treatment groups (control vs novel treatment), the side of the coin (e.g. heads being control and tails being treatment) determines the assignment of each participant. This randomization approach is easy to implement in a clinical setting. In large clinical studies, simple randomization is likely to generate similar numbers of participants among groups. However, simple randomization

could be problematic for smaller studies, resulting in an unequal number of participants among groups by chance.[5] The block randomization method randomizes participants into groups that result in equal sample sizes. Blocks are small and balanced with predetermined group assignments, which ensures the number of participants in each group is very close.[5] Stratified randomization is primarily used to balance the influence of important baseline factors that can affect outcomes. For example, if sex is an important factor, investigators may choose to stratify by sex. Males are randomized into treatment groups separately from females to ensure there is a balance of males and females in each group. For stratified randomization to work, baseline characteristics of all participants must be known before randomization occurs.[5]

There are other important factors to consider in RCT design as well, such as blinding participants and the research team, appropriate selection of participants, minimizing attrition, and allocation concealment.

Question 3: What are observational studies?

Observational studies inform clinicians about disease etiology, natural history, prognostic factors, and sometimes treatment effectiveness. The most common observational study designs include cohort and case-control studies.[6]

In a cohort study, participants are divided into two or more groups called *cohorts*. Cohorts are defined by whether they are exposed to a particular treatment, genetic factor, environmental factor, etc. The groups are then followed prospectively and are observed for an outcome of interest. It should be noted that cohort studies are not always prospective. They can be conducted on an existing

database, which is often called a *retrospective cohort study*. A key factor of cohort studies is temporality, or the ability to assess causality by establishing a temporal link (i.e. the exposure came before the outcome).[6] Cohort studies are particularly useful for examining rare exposures or exposures where it is impractical, impossible, or unethical to randomly assign participants to a particular exposure.[6] A common example is that it is unethical to randomize participants to smoke tobacco. A common criticism of cohort studies is that they exposure is not randomized so we cannot be sure that the exposure is the only factor that led to the outcome (i.e. confounding).[6] There are sophisticated statistical methods for accounting for confounding, but it is argued that these are not as effective as randomization at limiting bias.[7],[8]

Case-control studies are characterized by starting with an outcome of interest and looking backward (retrospectively) to see if the participant was exposed to a factor of interest. Participants who have experienced an outcome are called *cases* and they are often matched with participants who have not experienced an outcome, called *controls*. Case-control studies effectively investigate rare outcomes or outcomes with a long latency period because subjects are selected from based on their outcome status.[6] In comparison to cohort studies, case-control studies are quick, relatively inexpensive to implement, require fewer subjects, and allow for multiple exposures or risk factors to be assessed for one outcome. However, they are at greater risk of bias because there can be errors with recalling whether someone was exposed or not, particularly if the exposure occurred many years ago, and again participants are not randomized to an exposure so there may be confounding factors.

Observational studies dominate the surgical literature in orthopedic surgery. The primary reason for this is that many questions in surgical subspecialties cannot be ethically or feasibly answered with RCTs. A candidate for surgery may not wish to be randomized to operative or nonoperative treatment and a surgeon cannot feasibly be blinded to surgery. However, well-designed observational studies can provide useful data on treatment effectiveness and harms that are close to real-world usage, or they can be a stepping-stone to generate hypotheses for future studies.

Question 4: What are case series and case reports?

Case reports and case series are descriptive studies to present patients in their natural clinical setting. Case reports generally consist of three or fewer patients,[9] and are used to illustrate very rare diseases or very new treatments done in only a few patients. In addition to their teaching value for highlighting rare instances, case reports help create a foundation for further research investigation. Case series involve more than three patients. They are characterized by having only one group (i.e. lacking a control group). Usually, one surgeon or several surgeons review all patients that they have treated in a certain manner and describe what their outcomes are. Patients can either be followed prospectively or surgeons can look back at a database that they have collected over a period of time, which is called a *retrospective case series*.

The strengths of case reports and case series include the fact they can give foundational evidence or proof-of-concept that a treatment is doable and provide preliminary evidence of safety and effectiveness. Additionally, they can

be easy, quick, and inexpensive to conduct, particularly if the data are already collected.[9] They can also identify rare manifestations of a disease or drug.[9] The limitations of case reports and case series include the fact that they lack a control, which means that comparisons between treated and nontreated groups are not possible. The cases that are included may not be generalizable and are prone to selection bias.

Question 5: What are systematic reviews and where do they fit in the hierarchy of evidence?

Systematic reviews are well named because they aim to systematically review all the available literature on a topic and synthesize the information into a usable form. They are characterized by a detailed and comprehensive search strategy, critical appraisal of included studies, and either a qualitative or quantitative synthesis of the results. Systematic reviews may include a meta-analysis, which is a statistical method for quantitatively pooling results from two or more similar studies to get a summary effect size for a particular outcome. The advantage of meta-analyses is that they are able to increase the number of included patients and events for a research question of interest to provide a more precise estimate of the effect of a treatment.[10]

Systematic reviews and meta-analyses require multiple steps to conduct correctly. Firstly, the review question must be defined and hypotheses should be formulated. These studies also require defining inclusion and exclusion criteria. For examples, authors must decide on their population age range, conditions, outcomes, type(s) of interventions, and control groups. It is also important to

define what types of studies will be included (e.g. RCTs, observational studies, case series). When developing the search strategy, it is important to come up with a comprehensive list of key terms to be able to identify all relevant studies on the topic. Searches generally include several relevant electronic databases but can also include checking article reference lists, hand-searching key journals, etc. Once a comprehensive list of study titles and abstracts has been retrieved and reviewed, any studies appearing to meet inclusion criteria would then be obtained and reviewed in full.[8] Relevant data are extracted and summarized for each included study, often by two independent reviewers to prevent errors. Then the data are synthesized and, if possible, pooled using meta-analysis techniques.

It is a common misconception that systematic reviews are always the highest level of evidence. However, systematic reviews are subject to the same biases that the included studies are subject to, and more. If a systematic review included all level I evidence studies, then the systematic review is level I evidence. If the review is of observational studies, then it would be level II or III evidence, depending on the quality and design of included studies. Systematic reviews of case series are level IV evidence. The general rule is that a high-quality systematic review is more credible than an individual study from the same level of evidence. For example, a well-conducted systematic review of RCTs is preferable to a single RCT. Systematic reviews and meta-analyses are discussed in further detail in Chapter 3.

Summary

This chapter summarizes the different types of study designs and their associated levels in the hierarchy of

evidence. The hierarchy of evidence is a core principle of evidence-based medicine and addresses the question of "What is the best available evidence?"[9] It takes a top-down approach in locating the best available evidence whereby one would first search for a recent systematic review on the topic of interest, and if these studies are not available for this topic, then one would move down to the next level of evidence. The higher up the hierarchy the study design is positioned, the more rigorous the methodology and hence the more likely it is that the study design can minimize the effect of bias on the results of the study. In most evidence hierarchies, well-designed systematic reviews and meta-analyses of level I evidence are at the top of the pyramid, and expert opinion and anecdotal experience are at the bottom.

Introduction

Published medical research enhances our understanding of disease and helps us critically evaluate the efficacy of our treatments. As the volume of published research grows, it becomes unrealistic to attempt to read primary source literature on a clinical question (Figure 3.1). The purpose of a review is to summarize updates from recent research, outline the scope of a topic, or pool data from multiple studies to draw insights not obtainable with a single study. A hierarchy of reviews exists regarding methodology, objectivity, and clinical utility. The purpose of this chapter is to equip the reader with an understanding of the appropriate role of each type of review, as well as the tools to create each.

Top four questions

1. What are the types of literature reviews?
2. How is a systematic review performed?
3. How is a meta-analysis performed?

4. How does one critically appraise a systematic review and meta-analysis?

Question 1: What are the types of literature reviews?

Narrative reviews, scoping reviews, and *systematic reviews* are descriptive, or nonquantitative. *Meta-analysis* involves additional statistical comparisons of treatment effects using data pooled from multiple studies. *Network meta-analysis* indirectly compares more than two treatments by linked analyses of common treatments across multiple studies.

Narrative review

A *narrative review* is a selected summary of primary literature, often for a concise synopsis of recent advances or reference guide for readers new to a topic. A narrative review is not the most objective source of evidence for it is vulnerable to multiple types of bias. Selection bias arises from article inclusion or exclusion without specific criteria. Inattentive data abstraction produces measurement bias. Reporting bias stems from disingenuous descriptions of methods or data. Narrative reviews may include expert interpretations based on authors' experience. Confirmation bias may occur if the authors report only findings that support their personal beliefs. Time lag bias may occur if authors may omit new reports of efficacious treatment or advocate a therapy that has since been proven harmful or ineffective.[1]

Systematic review

A *systematic review* is a scientific investigation of published literature that objectively summarizes available evidence. Cook et al. defined it as, “the application of

scientific strategies that limit bias to the systematic assembly, critical appraisal, and synthesis of all relevant studies addressing a specific healthcare question."[2] The scope is narrow, often a single question on a specific topic. The review process is an algorithmic assembly and assessment of original studies as "subjects" from multiple sources following a prospectively defined protocol.[3] The protocol, which makes a systematic review a reproducible investigation, specifies the sources and search strategy for identifying potentially relevant articles, inclusion and exclusion criteria for article selection, and methods for data abstraction and analysis. When included studies are sufficiently similar to statistically pool effects, meta-analysis may be performed, as discussed below. The level of evidence of the review is dictated by included studies: level I–II evidence from randomized controlled trials (RCTs) will produce a level I–II systematic review, while level III and IV evidence may have meaningful roles in the study of rare events or justifying need for additional research on a sparsely studied topic.[4]

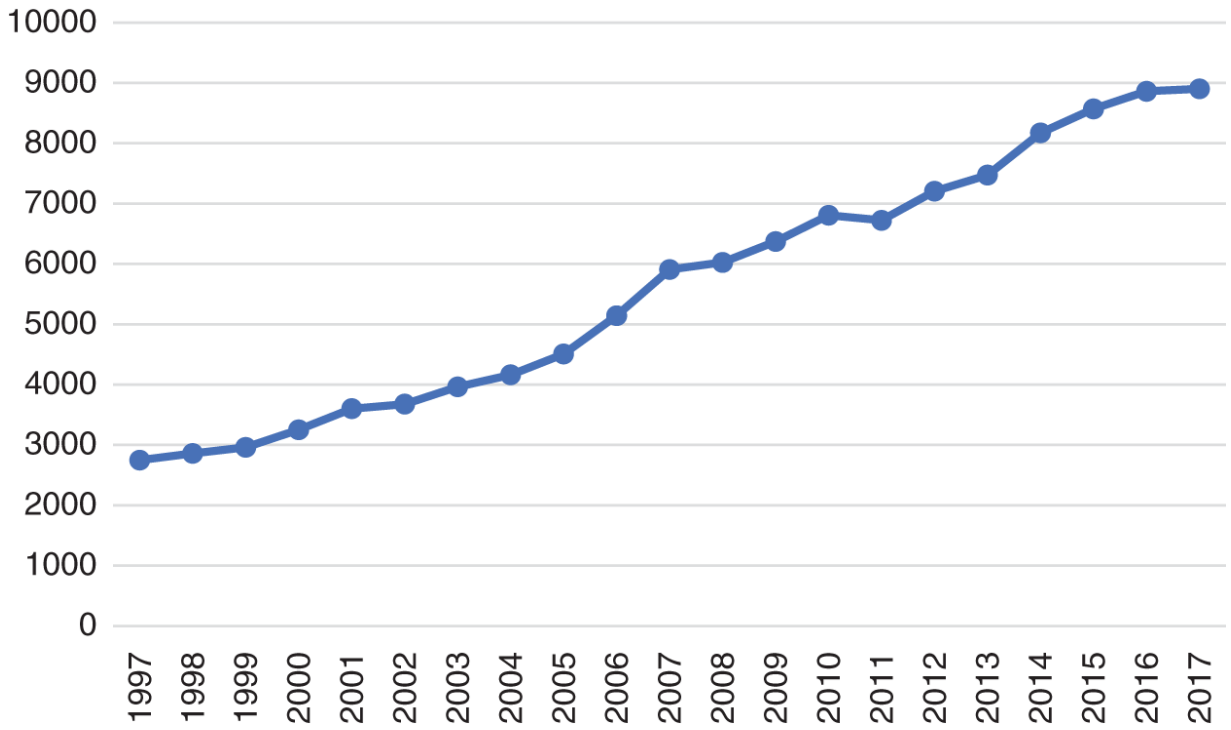

Figure 3.1 Published articles per year in the top 25 highest-impact factor orthopedic surgery and sports medicine journals 1997–2017.

Scoping review

A *scoping review* is a truncated systematic review that maps the existing literature on a subject in terms of the volume, nature, and characteristics of the primary research.[5] This review is useful when the topic has not yet been extensively reviewed, is complex, or appears heterogeneous.[6] As a rigorous and transparent method for mapping areas of research, a scoping review can be a standalone project to synthesize findings and identify gaps in the existing literature, or a preliminary step to a systematic review that defines the potential breadth and cost of undertaking a full systematic review.[5,7]

The major limitation of a scoping or systematic review is sensitivity to publication bias. Treatment effects may be overestimated: published trials are more likely to describe

positive treatment effects,[8] negative results are less likely to be published,[9] and unpublished negative results are difficult to locate.

Guidelines for systematic reviews have evolved with innovations in review design and analytic methods. The Quality of Reports of Meta-analysis (QUOROM) guidelines morphed into the Preferred Reporting Items for Systematic Reviews and Meta-analyses (PRISMA) statement.[10] The Cochrane Collaboration produces systematic reviews to inform health decision-making using an even more stringent quality standard.[11] Adherence to reporting guidelines is associated with greater citation rate and scholarly impact.[12] Prospectively and publicly registering a protocol on a registry, such as the International Prospective Register of Systematic Reviews, better known as PROSPERO, can prevent unwitting duplication by others and uncover reporting bias if a completed review does not match what was planned.[13]

Meta-analysis

Meta-analysis is the quantitative investigation of data aggregated through a systematic review of data reports.[14] Meta-analysis can be performed from published results without original or patient-level data. When individual patient data can be acquired, more nuanced analyses of predictors and effect modifiers may be conducted through *patient-level meta-analysis*. In meta-analysis, studies must be sufficiently *homogeneous* for valid comparison: studies must evaluate the same the test, exposure, or treatment and assess similar outcomes. The outcomes of multiple studies are *pooled*: the number of patients and events in each treatment or exposure group are summed across studies. Association between the exposure/treatment and the outcome is tested with the pooled data, often weighted

by the sample size of each study. Pooling studies improves the power of the statistical analysis, increasing the likelihood that any association is statistically significant. However, pooling studies does not eliminate bias or improve the quality of the studies. We describe the tools to rigorously perform and evaluate conventional meta-analysis in this chapter.

Network meta-analysis

The transitive property: if A = B and B = C, then A = C. Two distinct, direct comparisons support an indirect, inferred comparison. *Network meta-analysis* – also called *multiple treatments meta-analysis*, or *mixed-treatment comparisons* – expands on this concept to assess the relative effect sizes of more than two interventions have on one outcome.[8] Several trials each comparing two or more interventions on one common outcome each provide *direct evidence*. *Indirect* comparisons can be made between interventions not directly compared in an actual trial by organizing the studies into closed- and open-loop networks.[9,15] *Transitivity* describes similarity in patients, interventions, and outcomes across the studies in the network. If patients from all arms of the various trials do not meet the inclusion/exclusion criteria of a single intervention arm, then the principle of transitivity has been violated and the network meta-analysis is not credible.[9] *Incoherence* is disagreement between direct and indirect estimates; this may arise from bias in the indirect comparisons due to intransitivity or bias in the published direct comparisons. Numeric or visual estimates of relative treatment effect estimates may underrepresent uncertainty and do not convey bias, incoherence, or transitivity.[16] Conclusions about treatment superiority from network meta-analysis should be made with caution.

Question 2: How is a systematic review performed?

The following sections guide the reader through a workflow for performing a high-quality systematic review and conventional meta-analysis that conforms to the PRISMA statement and Cochrane Collaboration definitions.[10] For further details, we recommend the Cochrane Handbook[17] as well as texts by Petitti[18] and Egger et al.[19]

- *Define the specific review question*. Develop a research question by specifying the target population, intervention, control (or comparators), and outcomes of interest (PICO format). See Chapter 1 for guidance on formulating a research question.
- *Query PROSPERO for a similar active or published review*. A review may take months to complete. Other investigators may have recently published or may be actively conducting a systematic review that overlaps with the research question. The planned review could become redundant, and possibly unpublishable, between starting and publication.
- *Perform a preliminary search for key citations*. Identify investigations and reviews that address the research question. Review the discussions and citations for "must-include" primary papers. The titles and abstracts of these papers may contain synonyms, related concepts, alternate spellings of key words, and medical subject headings (MeSH) worth including in the *search strategy*. The National Library of Medicine curates MeSH as a restricted vocabulary of terms for indexing and cataloguing biomedical information on PubMed/MEDLINE.[20]

- *Develop the review protocol*. The protocol specifies how to perform and how others could reproduce the review. The protocol specifies the title, personnel, funding, conflicts of interest, research question, eligibility criteria, literature sources and search strategy, article selection and adjudication methods, data extraction, bias assessment, data synthesis, planned analysis, and plan for dissemination of results. A useful template is the PROSPERO standardized protocol format.[13]
- *Eligibility criteria* for a systematic review are not unlike those of human subject research: specify which studies (patients) are eligible to participate (Table 3.1). Inclusion criteria select for similar methods and participants across all studies. This will define the population to whom inferences can be made from the summarized findings.

Table 3.1 Criteria for study inclusion in a systematic review of a treatment.

Date of publication	Studies of a medication published after the date of regulatory (e.g. Food and Drug Administration) approval of the medication may reduce vulnerability of the review to reporting bias by excluding trials sponsored by the manufacturer during the regulatory approval process
Language	Including and searching as many languages as feasible for the review team minimizes selection bias Full text translation may be necessary
Study design	Type and methods of studies by ICMJE Levels of Evidence[4]
Target population	The demographics of the patients and specific conditions of interest
Intervention	The exposure or treatment of interest
Comparator	The control group, i.e. placebo or no treatment
Primary outcome	Be specific Heterogeneity in the methods of outcome assessment between studies will negatively affect the validity of pooled analyses For example, for a primary outcome of rate of deep vein thrombosis, the modalities of assessing that outcome (venography, Doppler ultrasound, or telephone survey) have different sensitivity, specificity, and accuracy
Secondary outcomes	Studies may report secondary outcomes relevant to the condition studied Assess the feasibility of a pooled analysis of these secondary outcomes

- *Literature sources*. No single electronic database includes all published, potentially relevant literature. Systematic reviews therefore combine searches of multiple sources. Table 3.2 provides a brief but not comprehensive list of English-language citation databases.

Table 3.2 Literature sources.

Electronic citation databases	• MEDLINE/PubMed (United States National Library of Medicine): electronic database of biomedical journal citations and abstracts published since 1946 • Embase is a subscription-based (Elsevier) electronic database of full text drug, disease, and medical device data published since 1947 as well as journals unique to the publisher. There is considerable but incomplete overlap with MEDLINE for orthopedic topics, such that searches may cover both databases[21] • Web of Science (Clarivate Analytics) is a subscription-based citation indexing service covering records from 1900 to present • Scopus (Elsevier) is a subscription-based electronic database of peer-reviewed scientific journals, books, and conference proceedings since 2004 • Google Scholar (Alphabet) is a free index of over 160 million of journals, books, conference papers and abstracts, theses and dissertations, technical reports, court opinions, and patents covering 80–90% of the English-language scientific literature[22]
Clinical trial registries	May identify studies that are unpublished at the time a review begins but which may become published and eligible for inclusion during the review period

	• The Cochrane Central Register of Controlled Trials (CENTRAL): PubMed, Embase, and unpublished data[23] • ClinicalTrials.gov (United States National Library of Medicine, National Institutes of Health)[24] • EU Clinical Trials Register: European Union and Economic Area member nations[25] • International Clinical Trials Registry Platform (World Health Organization)[26]
Data published outside of indexed medical journals	Not subject to the level of peer review required for journal publication. The latest data and most complete census of potentially relevant literature may come at a cost of quality without peer view • Conference abstracts. Search of conference proceedings may require manual review of final conference programs. Authors may need to be contacted for unpublished complete methods, data, and results • Preprint servers appeared in the biomedical sciences as a vehicle for sharing data prior to journal acceptance, i.e. without peer review. By consensus, orthopedic material made available via a preprint server is generally not accepted for subsequent publication on the basis of redundant publication[27]

- *Search terms* are the exact text queries entered in a search engine. Developing the search terms is an

iterative optimization of phrases coded in the engine's language. Terms should capture the maximum number of citations relevant to the research question (sensitivity) and capture the key citations identified in the preliminary search (specificity). Some authors develop separate sensitive searches for each of the PICO components of the research question.[28] We prefer to develop our search strategy in MEDLINE by identifying search terms from MeSH subject headings that apply to the research question, then add clinically related phrases, synonyms, alternate spellings, and other nosologic permutations using Boolean operators and bracket logic. Search terms published as a supplement for transparency may offer insight into formatting.[29]

- *Citation management software* (EndNote, Mendeley, Zotero, RefWorks, etc.) is helpful for organizing studies during each phase of the review. Software packages designed specifically for systematic review are also available (e.g. Covidence, DistillerSR, EPPI-Reviewer, Rayyan, RevMan, Systematic Review Data Repository, SUMARI).
- The *systematic review process* is an iteratively more detailed appraisal of the citations identified by the systematic search for eligibility per the review protocol. Multiple reviewers consider each study at each stage of the review; any disagreement regarding eligibility of an article is discussed and agreement reached by consensus. The review begins with title and abstract review, which reduces the number of full text reviews.
- *Data extraction* from each included full text article is done with a standardized data collection form. The data extracted relate to assessment by the reviewers of study design, quality, validity, and bias, as well as

sample and outcomes. Typical fields include: journal; authors; year of publication; country; study design; method of randomization; baseline population demographics including proportion of men or women, race, age, socioeconomic characterizations; sample size; allocation concealment and blinding; intervention and control arms; duration of treatment or follow-up; outcome assessment method or modality; outcome assessors; and event rates or risk estimates.

- *Assess the risk of bias* by evaluating the methodology of included studies. Factors commonly associated with bias in randomized trials include lack of concealment of randomization, lack of blinding, and failure to report reasons for excluding patients.[30] Tools designed to assess bias are available including the Newcastle–Ottawa Quality Assessment Scale for prospective and retrospective cohort and case-control studies; the Cochrane Collaboration's risk of bias tool or Jadad scale for reporting RCTs; and the Methodological Index for Non-randomized Studies (MINORS) score for nonrandomized studies.[31] Quality scoring is not required to conduct a systematic review and may impose certain biases on the review in the process; therefore, weighting studies by a quality score is discouraged in meta-analysis.[32],[33] Assessing quality based on specific characteristics is a preferred way of stratifying included studies.[32],[34],[35]

- *Reporting* should adhere to the PRISMA checklist and illustrate study inclusion using the PRISMA flow diagram.[10]

Question 3: How is a meta-analysis performed?

- *Pool the outcomes*. The pooled incidence for a binary outcome is the count of events divided by the number of patients in each groups across all studies. The risk for a binary outcome may be represented as an odds ratio, risk ratio, risk difference, or incident rate for time-dependent outcomes. The inverse of the risk difference yields the number of patients that would need to be treated (number needed to treat; NNT) to prevent one outcome. Continuous outcomes can be summarized by the raw mean difference between the treatment and comparator groups when the same scale is used. When different scales are used, a number of methods, such as the standardized mean difference (effect size), can be used. Correlation coefficients can be used to compare two continuous variables. Censoring due to loss to follow-up should be considered, especially if study durations vary. Standard methods should be applied to the management of missing data.
- *Assess heterogeneity*. Studies usually report different estimates of treatment effect. While sampling error may account for some variation, so may clinical, methodological, and statistical differences between the studies. *Heterogeneity* describes the statistical, methodological, and clinical diversity of the treatment effect reported among different sets of data, and attempts to quantify the portion of that variance attributable to sources other than random error.[36] Pooling data is appropriate only if the differences in treatment effect are mostly due to chance; otherwise, estimates of the true treatment effect from meta-analysis will be biased or may result in wide confidence intervals with limited clinical utility.

Heterogeneity should be identified and explained. The I^2 statistic is a popular test, of many available, which represents the proportion (0–100%) of total variation in the estimates of treatment effect that is due to heterogeneity between studies versus random error, independent of the number of studies and the metric for treatment.[36] The I^2 statistic is an improvement over the Cochran's χ^2 test (Q-test), which is underpowered to detect between-study variability when the number of studies is small (and the number of studies is often small).[37] For χ^2, $p < 0.10$ is an accepted cutoff to suggest heterogeneity, while I^2 values of 25, 50, and 75% have been interpreted as representing small, moderate, and high levels of heterogeneity, respectively.[38] Once heterogeneity is identified, subgroup analysis or regression of the summarized effect on individual study characteristics or methodologic features (*meta-regression*) can be used to investigate differences between study findings further.[39]

- *Assess for publication bias*. Time-lag bias can occur if a study is published more rapidly than other studies subsequently published with differing results. Small studies, nonrandomized studies, non-English-language work, and studies with negative results are less likely to be published or published in a timely manner. In the presence of publication bias, a plot of sample size or variance against effect size is usually skewed or otherwise asymmetric (Figure 3.2).[36] The inverted funnel plot, or Egger test, is commonly used to assess publication bias. A scatter plot of the standard error of each effect estimate against the effect estimate for each study is created. A random sample of unbiased studies should report effects normally distributed about

the pooled effect or summary estimate, illustrated as a vertical line along the x-axis. The “cone” of the plot typically represents a 95% confidence interval for the standard error expected for a given effect size. Asymmetry, or nonrandom deviation from the summary estimate, evidences publication bias: typically, studies reporting no significant effect or a “negative effect” have not been published and the summary effect size is falsely overestimated (Figure 3.2).[40]

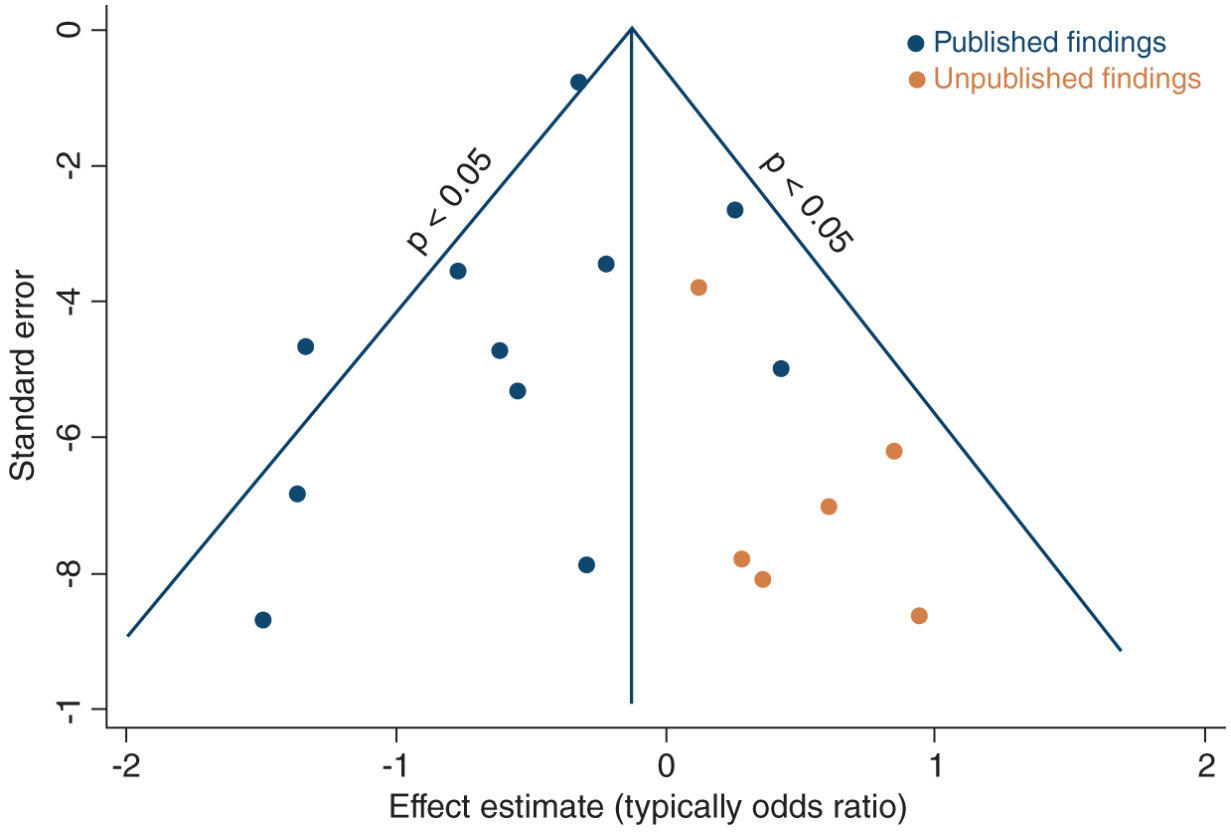

Figure 3.2 Inverted funnel plot demonstrating publication bias overestimating summary effect size. Source: Modified from Sterne and Egger.[40]

- *Select an effects model*. A *fixed effects* model assumes the only difference between studies is their power to detect the true outcome: that all were conducted under similar conditions with similar subjects without random

sampling. Fixed effects modeling may be appropriate when I^2 is low. A *random effects* model considers between-study variance in sampling the treatment effect. Consequently, more data are required for random effects models to achieve the same statistical power as fixed effects model; estimates may be unstable for sparse data.[41]

- *Perform meta-analysis* by estimating the pooled effect size using an inverse-variance-weighted mean. More advanced meta-analysis techniques such as meta-regression and network meta-analysis are beyond the scope of this chapter. Packages available for statistical software such as R, SAS, SPSS, STATA, etc., will generate a forest plot showing the confidence intervals for estimate treatment effect from each study as well as pooled estimate, represented as a diamond (Figure 3.3).[42]

Report findings as per PRISMA guidelines.[10]

Question 4: How does one critically appraise a systematic review and meta-analysis?

Systematic reviews vary in quality. Limitations may arise from how studies were selected, the quality of the included studies, the clinical utility of the outcomes assessed, and the methodologic rigor of pooling and analysis. Included studies should be assessed as above for potential within-study bias due to methodologic shortcomings. Then consider between-study variability: is the reported

heterogeneity statistic appropriate for the studies, and is the value so great that it hinders interpretation of the results? Half of 509 meta-analyses in the Cochrane database had I^2 statistics >0 indicating some level of inconsistency between studies.[43] Determine whether sensitivity analyses were performed and that the exclusion of any given study does not substantially alter the results or conclusions.

Oxman and Guyatt published a subjective 10-item index for systematically grading the quality of a systematic review (Table 3.3).[43] Using this instrument, Dijkman et al. found that 18 and 30% of meta-analyses in orthopedic surgery published in 2005 and 2008, respectively, had major to extensive flaws in their methodology.[8]

Table 3.3 Oxman and Guyatt criteria for assessing scientific quality of research overviews. Source: Modified from Higgins, et al.[43]

1. Were the search methods reported?	Yes, partially/can't tell, no
2. Was the search comprehensive?	Yes, partially/can't tell, no
3. Were the inclusion criteria reported?	Yes, partially/can't tell, no
4. Was selection bias avoided?	Yes, partially/can't tell, no
5. Were the validity criteria reported?	Yes, partially/can't tell, no
6. Was validity assessed appropriately?	Yes, partially/can't tell, no
7. Were the methods used to combine studies reported?	Yes, partially/can't tell, no
8. Were the findings combined appropriately?	Yes, partially/can't tell, no
9. Were the conclusions supported by the reported data?	Yes, partially/can't tell, no
10. What was the overall scientific quality of the overview?	1. Extensively flawed

	3. Major flaws 5. Minor flaws 7. Minimally flawed

The purpose of a systematic review is to inform clinical practice with evidence. When appraising a review, consider the clinical question addressed. Is it relevant to my practice? How well could the design of the review objectively answer that question? Were the target populations of the included studies inclusive of patients with problems similar to mine? Was heterogeneity reported and, if so, were sources adequately investigated? Were there clinically relevant differences reported? Were other sources of bias considered?

Summary of answers

- Narrative reviews provide background information across a broad scope relating to a topic.
- Systematic reviews are a preferred, scientifically rigorous method for mapping the types of literature pertaining to a field of inquiry (scoping reviews) or specific clinical question.
- Meta-analyses and network meta-analyses quantitatively synthesize evidence to answer a specific clinical question and require a high-quality systematic review as a prerequisite.
- When performing a review: register systematic reviews before starting and follow guidelines; assess bias, appreciate the statistical basis of analysis, and perform quantitative synthesis only when appropriate.

4 Healthcare Recommendations: Grades of Recommendation, Assessment, Development, and Evaluation (GRADE) Approach

Mark Phillips BSc PhD, Cand
Health Research Methods, Evidence and Impact, McMaster University, Hamilton, ON, Canada

Case scenario

You have been asked to join a guideline panel working group that is tasked with developing a clinical practice recommendation for the use of hemiarthroplasty (HA) versus total hip arthroplasty (THA) for the management of displaced femoral neck fracture in patients over the age of 60. The team has decided that the important outcomes to evaluate within their recommendation are revision rates, one-year mortality, and dislocation rates. Interested in understanding the best method in developing this recommendation, you have decided to investigate the Grades of Recommendation, Assessment, Development, and Evaluation (GRADE) approach to guideline recommendation development.

Top three questions

1. What is GRADE?
2. What are the components of a GRADE quality of evidence assessment, and how do you evaluate them for a body of evidence?
3. How do you use your GRADE quality of evidence assessment to develop a clinical recommendation?

Question 1: What is GRADE?

GRADE is a tool that has been developed to provide a transparent and thorough guide for rating the quality of evidence and strength of recommendations made within healthcare research.[1] A GRADE assessment is conducted on a body of literature that was collated through a systematic review. The first step of recommendation development, after the guideline panel and clinical question to be answered have been defined, is to conduct a comprehensive systematic review that captures all evidence pertaining to the research question of interest.[1] For this scenario, we are assuming that this systematic review of available literature on displaced femoral neck management using HA or THA has already been conducted, and all relevant research evidence has been collected for the outcomes of interest.

It is important to note that GRADE is used to assess the quality of evidence for each individual outcome that will be considered within the clinical recommendation.[1] This means that the GRADE approach would be repeated three times for the current scenario: assessing the quality of evidence for revision rates, one-year mortality, and dislocation rates separately. This is done because the body of evidence for each outcome may not be the same. For example, there may be different ratings of the quality of evidence due to a large number of studies reporting revision rates, while fewer of them provide information on dislocation. The GRADE framework then provides guidance on how the working group should proceed to develop a clinical recommendation on HA or THA use for displaced femoral neck fractures.

After collecting all relevant evidence and assessing the quality of that evidence for each individual outcome, the GRADE approach provides a transparent framework to create clinical recommendations based on the strength and quality of the evidence. This includes decisions by the working group regarding the balance between desirable and undesirable consequences of using the treatment options.[2] It also requires the working group to provide a strength to their recommendation, based on the available evidence.

Recommendations may be considered either “strong” or “weak,” depending on the certainty that the working group has regarding the quality and magnitude of the evidence that has been evaluated.[2]

Question 2: What are the components of a GRADE quality of evidence assessment, and how do you evaluate them for a body of evidence?

Quality of evidence assessment

The GRADE approach to assessing quality of evidence takes the following concepts into consideration: the study design of the available evidence, risk of bias, imprecision, inconsistency, indirectness, and publication bias.[3] Additionally, assessment of all plausible confounders, magnitude of effect, and the presence of a dose-response gradient are additional factors that are assessed within GRADE when evaluating observational data in order to potentially increase the quality of evidence rating.[3] These considerations are each taken into account to provide a categorical quality rating of either very low, low, moderate, or high for each of the outcomes of interest.[4] Evidence from randomized trials is initially regarded as high quality, but the evaluation of each of the considerations can influence the final rating given to the body of evidence (Table 4.1).

Table 4.1 GRADE approach to rating quality of evidence. Source: Modified from Balshem, et al.[3]

Study design	**Quality of initial body of evidence**	**Decrease the quality rating if**	**Increase the quality rating if**	**Final quality rating**
Randomized controlled trials Observational studies	High (initial score of 4) Low (initial score of 2)	Risk of bias −1 Serious −2 Very serious Inconsistency −1 Serious −2 Very serious Indirectness −1 Serious −2 Very serious Imprecision −1 Serious −2 Very serious Publication bias −1 Likely −2 Very likely	For observational studies: Large effect +1 Large +2 Very large Dose response gradient +1 Present Plausible residual effect +1 Would reduce the demonstrated effect +2 Confident that all plausible confounders are accounted for	**High** (score of 4 or higher) **Moderate** (score of 3) **Low** (score of 2) **Very low** (score of 1 or lower)

A rating of high-quality evidence by the guideline panel signifies that “[the panel] is very confident that the true effect lies close to that of the estimate of the effect”; while a rating of very low evidence is described as “[the panel] has very little confidence in the effect estimate: The true effect is likely to be substantially different from the estimate of effect.”[3] In order to determine an appropriate rating for the quality of evidence, each of the

aforementioned considerations need to be evaluated in detail for each of the included outcomes.

Assessing risk of bias

Assessors evaluating risk of bias can reduce the quality of evidence by one category if it is deemed to be a serious risk, or by two categories if it is deemed to be very serious. For example, a body of randomized trial evidence would initially be categorized as high-quality evidence. If there was considered to be a serious risk of bias within the evidence, the rating would then be categorized as “moderate quality.” A rating that states a very serious risk of bias within the evidence would change the rating from high quality to low quality.[5] In order to comprehensively evaluate the risks of bias for GRADE, there are a number of key study limitations that should be assessed in order to decide the risk of bias rating for a body of study of randomized trials:[5]

1. Inappropriate/absent allocation concealment.
2. Inadequate blinding.
3. Incomplete follow-up or failure to conduct intention-to-treat analysis.
4. Selective outcome reporting.
5. Trials that were stopped early for benefit.
6. The use of inappropriate/unvalidated outcome measures.
7. Inappropriate carryover effects (in cross-over studies).
8. Recruitment bias (in cluster randomized trials.)

There are specific limitations for bodies of evidence containing observational studies as well, which are described in detail within the GRADE publication series.[5]

Assessing inconsistency

The quality of evidence rating can be rated down by either one or two categories depending on the assessment of inconsistency

by the guideline panel.[4] *Inconsistency* refers to the similarity (or lack thereof) of effects seen within each individual study within the body of evidence.[6] This is evaluated by assessing the similarity in point estimates from included trials, the extent of overlap between individual trial confidence intervals, and statistics of heterogeneity for the included studies.[6] It is important for studies to explore plausible hypotheses regarding any heterogeneity seen, and the guideline panel should consider rating down the quality of evidence if there is a large amount of unexplained inconsistency. This should be particularly considered if some included studies demonstrate a large benefit, while other included studies demonstrate no effect or harm.[6] The use of forest plots is valuable in aiding with the visualization of inconsistency, as forest plots provide the point estimates, confidence intervals, and heterogeneity statistics. All of these components are important for the guideline panel to review in order to decide whether the quality of evidence should be rated down due to inconsistency.

Assessing indirectness

Indirectness refers to the extent to which the research questions of the included studies applies to the research question that is being answered by the guideline panel.[7] In order to assess indirectness, an assessment must be done of the similarities or differences between the study patient populations, interventions, and outcomes assessed.[7] If there is not a sufficient body of evidence evaluating the outcomes for the appropriate interventions within the patient population of interest, indirect evidence may be used to make inferences about the guideline panel research question. Indirectness could be a result of a lack of evidence for a specific patient age group, so evidence from a different age group is used to infer the effects of the interventions on the population of interest. If this is done, the quality of evidence should be rated down for indirectness.[7]

Another possible reason for downgrading the quality of evidence for indirectness is the use of comparison between two

treatments that have not directly been compared to one another within primary investigations.[7] From the example scenario of this chapter, this could be conceptualized if we were to imagine that there is currently no evidence directly comparing HA and THA. Instead, there is only evidence of these treatments being compared to internal fixation. If this were true, the guideline panel could assess the effects of both treatments against internal fixation, and statistically infer the relative difference in effect of between HA and THA. If this were to be done, the quality of the evidence would be rated down for indirectness.[7]

Assessing imprecision

Imprecision is a term used to characterize the confidence that individuals in the guideline panel have regarding the estimates of effect for each of the outcomes. This is primarily done by evaluating the confidence intervals (CIs) surrounding the pooled effect estimate for each outcome.[8] The criterion that should be considered by the guideline panel when assessing imprecision is the clinical decision that would be made if the true effect laid at either extreme end of the CI. If the panel believes that a different clinical decision would be made if the true effect resembled a value at the high end of the 95% CI versus a value at the low end of the 95% CI,[8] then the panel would consider rating down the quality of evidence for imprecision. This scenario would typically occur in situations with wide CIs that may range from substantial clinical benefit to minimal/no effect.[8] For example, if the relative risk of revision surgery between HA and THA yielded a CI that extended from potential superiority of one treatment at the high end of the CI to no difference in revision rates at the low end of the CI, the body of evidence for revision rates may be rated down for imprecision.

Assessing publication bias

The last criterion that can be used to rate the quality of evidence lower is *publication bias*. The risk of publication bias is typically considered if the body of evidence for the outcome consists of a small number of studies, especially when those

studies are primarily funded by industry.[9] This often leads to an overestimate of the true effects of a treatment. Publication bias may be common, particularly in newer treatments that do not have a substantial body of studies with large sample sizes. Funnel plots are a typical tool used to visualize publication bias; however, there are no concrete criteria for the decision to rate down for publication bias.[9] Without concrete criteria for determining publication bias, the guideline panel should be careful when dealing with small bodies of evidence for newer treatment options.

Criteria for increasing quality of evidence ratings

Although many guideline panels seek evidence from randomized trials in order to develop clinical practice recommendations, there may not always be randomized investigations available for the research question of interest. For example, it can be imagined that there are no available randomized trials assessing one-year mortality after HA versus THA for displaced femoral neck fractures in patients over 60. The guideline panel must thus utilize evidence from a number of cohort studies in order to gain insights into the quality of evidence for this outcome. After assessing each of the criteria to rate down the quality of evidence for one-year mortality, there are now three criteria that the guideline panel needs to assess in order to possibly increase the quality of evidence rating.

The first criterion for increasing the quality of evidence rating for observational studies is the presence of a large magnitude of effect. The GRADE group suggests that a twofold increase in risk would constitute a substantial magnitude of effect.[10] This would warrant increasing the quality of evidence by one category. The quality of evidence rating may be increased by two categories if there is a fivefold difference in risk between the interventions with regard to our example outcome of one-year mortality.[10]

The second possible reason for the guideline panel to increase the quality of evidence for observational studies is the presence of a dose-response gradient. This criterion does not apply to the

example scenario due to the comparison being between two surgical interventions; however, it may be more relevant to guideline questions that evaluate therapies that could be provided at a variety of dosages. If there is a strong relationship between an increased dose and a corresponding increase in treatment effect, there may be greater confidence that the treatment effects seen are a direct result of the treatment.[10] This warrants an increase of one quality of evidence category for the assessed outcome.

The final criterion that can be used to increase the quality of evidence rating for observational evidence is the presence of a comprehensive evaluation of all plausible confounders that could have an impact on the treatment effects observed.[10] Well-done observational studies will include adjusted analyses that incorporate all important factors that may be confounders. When the guideline panel is confident that the included observational data have taken these confounders into account in their analyses, the quality of evidence rating may be increased by one category.[10]

Question 3: How do you use your GRADE quality of evidence assessment to develop a clinical recommendation?

It takes significant consideration and deliberation regarding the available evidence in order to move from rating the quality of evidence to developing a guideline recommendation. When determining the direction and strength of a guideline recommendation, there are four key factors that must be considered:[11]

- Balance of desirable and undesirable outcomes of interest.
- Confidence in the effect estimates observed for each outcome.
- Considerations of values and preferences for all relevant stakeholders.

- Resource use related to the treatment options evaluated.

When deciding on the balance of desirable and undesirable effects by the guideline panel, there are a number of suggested considerations. A strong recommendation would typically be warranted if there are large differences in the magnitude of benefits and harms.[11] For example, if the evidence suggested a large clinical improvement with very little associated harms, a strong recommendation may be warranted. When considering the confidence that the guideline panel has in the effect estimates, they should consider the quality of evidence that they had determined using the criteria from the previous section of this chapter. When the quality of evidence is high, guideline panel members should be inclined to have greater confidence in the effects.[11] Values and preferences of relevant stakeholders are also an important consideration.[12] The strength of a guideline recommendation may be reduced if there are strong preferences from relevant stakeholders that would be pertinent to the clinical decision-making process.[11] Finally, the strength of the guideline recommendation should take resource use into consideration. If there is a large difference in cost between the two treatments evaluated, the guideline panel should consider this when developing their recommendation.[11]

Summary of answers

- GRADE is a tool that provides a comprehensive and transparent method of developing clinical practice recommendations.
- GRADE requires the guideline group to evaluate the quality of evidence based on the following factors:

    Risk of bias.

    Inconsistency.

    Indirectness.

    Imprecision.

Publication bias.

Magnitude of effect (observational studies).

Dose-response gradient (observational studies).

Assessment of all plausible confounders (observational studies).

- Quality of evidence assessments are used to generate an overall rating of high, moderate, low, or very low quality for the evidence of each outcome.
- After determining the quality of evidence, guideline panel members must take the evidence and formulate clear clinical recommendations. These recommendations need to account for:

  The balance between desirable and undesirable outcomes of interest.

  Confidence in the effect estimates observed for each outcome, through assessment of the quality of evidence.

  Considerations of values and preferences for all relevant stakeholders.

  Resource use related to the treatment options evaluated.
- The GRADE approach results in a transparent clinical recommendation with a corresponding strength associated with the certainty of the guideline panel.

Additional resources

There is a complete series of GRADE publications that comprehensively discusses each of the concepts summarized within this chapter. This GRADE series is published online by the *Journal of Clinical Epidemiology*. Software is available that provides a comprehensive method to using and organizing the GRADE approach (GRADEpro GDT).

5 Outcomes and Their Interpretations

Leah Gitajn MD
Dartmouth-Hitchcock Medical Center, Dartmouth Geisel School of Medicine, Lebanon, NH, USA

Introduction

The World Health Organization defines an outcome measure as a “change in the health of an individual, group of people, or population that is attributable to an intervention or a series of interventions.”[1] Outcome measurement is becoming increasingly important in an effort to document the value of interventions to both patients and society. Harvard Business School professor and healthcare policy expert Michael Porter has proposed a framework that defines *value* as health outcomes achieved relative to the costs incurred.[2] Outcome measures are critical to both clinical research and public health, because this is the primary driver influencing one's ability to answer important questions in a reliable manner. Outcome measures serve as the target that both researchers and healthcare organizations or governments monitor or attempt to modulate in an effort to improve the quality and/or cost of care. The past 30 years have seen a rise in interest in the measurement of the outcomes of medical care, to the extent that an “outcomes movement” has been described and been labelled “the third revolution in healthcare.”[3] Types of outcome measures can be seen, broadly, as biophysical measures, like morbidity and mortality, or patient-based measures that incorporate a patient's subjective experience of illness.

Top three questions

1. What is an outcome measure?
2. What properties of outcome measures do I have to know?
3. How should I choose an outcome measure?

Question 1: What is an outcome measure?

An outcome measure is a measure of the health of an individual, group of people, or population. There are several broad categories of outcome measure:

1. Biophysical outcome measures: these are objective health measures. Some common examples include morbidity, mortality, complication rate, and quality of reduction.
2. Patient-based measures: these outcome measures incorporate a patient's subjective experience of illness. These may be generic or disease/joint-specific.
    a. Generic outcome measures are not specific to any one disease or anatomic location. They can be used to compare across or within specific pathologic conditions. These have the potential advantage of being more able to measure downstream consequences of a treatment or condition that permits comparison to other unrelated conditions. They also may measure the side effects of complications of a treatment or condition that occur in a different anatomic location. Two common examples of a generic patient-reported outcome measure are the Short Form 36 (SF-36) and the

Patient-Reported Outcomes Measurement Information System (PROMIS) Physical Function. Preference-weighted outcome measures are a subset of generic outcome measures. These outcome measures weight items or dimensions differently to account for how people value a health state, rather than assigning equal weight to each dimension or item included in the outcome measure. Measuring preference-weighted generic outcome measures is becoming increasingly important in an effort to optimally distribute resources in a resource-constrained environment. The most commonly used preference-weighted generic outcome measures are the EuroQol five-dimensional questionnaire (EQ5D) and the six-dimensional health state short form (SF6D).

b. Disease- or joint-specific outcome measures may be more sensitive measures of the specific disease or joint being assessed. For example, joint-specific outcome measures have been shown to be more sensitive to arthroplasty procedures compared to generic outcome measures.[4–7] Common joint-specific outcome measures in orthopedic surgery include the Western Ontario and McMaster Universities Arthritis (WOMAC) Index, Harris Hip Score (HHS) and the Hip Disability and Osteoarthritis Outcome Score (HOOS) Knee Injury and Osteoarthritis Outcome Score (KOOS).

Question 2: What properties of outcome measures do I have to know?

There are several properties and attributes that have to be considered when choosing appropriate outcome measures.

1. Reliability: the degree to which a score or other measure remains unchanged upon test and retest, across different interviewers or assessors, or across items on the same test.
    a. Forms of reliability include:
        i. Internal consistency: measures whether several items or questions that propose to measure the same general construct produce similar scores.
        ii. Test–retest reliability: measures whether the same person receives the same score on the same test at different time points.
        iii. Intra-rater reliability: the degree of agreement among repeated administrations of an outcome measure assessed by a single rater.
        iv. Inter-rater reliability: the degree of agreement between different administrations of the same outcome measure.
    b. Measured by statistics:
        i. Kappa: a statistic which measures inter-rater agreement for categorical items.
        ii. Intra-class correlation coefficient: descriptive statistic which describes how strongly units in the same group resemble each other.
2. Validity: the degree to which a measure or tool actually measures what it is intended to measure.
3. Variability: distribution of values associated with an outcome measure in the population of interest.
    a. Broader range of values shows more variability.

i. *Ceiling and floor effects* are a measurement limitation that occurs when the highest and lowest possible scores on an outcome instrument does not reflect the true range of the domain being tested. This can lead to a mismatch between the distribution of responses and the true distribution of the concept of interest in the population. For example, if a patient reported outcome (PRO) instrument only assesses physical activities that are easy to perform, and the majority of the population scores perfect, then the instrument will not reflect the true distribution of physical abilities.

4. Responsiveness: ability to detect change in the underlying construct, even if changes are small.
    a. Minimally important difference (MID).[8,9]
        i. Smallest change in an outcome that a patient would identify as important or meaningful.
        ii. This is an important property because, given a large enough sample size, statistical significance between groups may occur with very small differences that are clinically meaningless.[9]
        iii. When determining how many patients to enroll in a study, the calculation usually reflects the intention to reliably find a clinically important effect of a treatment as well as a statistically significant difference.

Question 3: How should I choose an outcome measure?

When choosing an outcome measure, there are issues that are critical to consider:

- Does the outcome measure answer the question that you are asking?
- Reliability, validity, variability, and responsiveness.
- Ease/cost of data collection.
- Latency from intervention to occurrence of outcome event.

The choice of outcome measures may be the most critical component in study development. These decisions drive important protocol and funding decisions including the data source, the frequency and length of follow-up, as well as sample size (which is influenced by the expected frequency of outcome and magnitude of treatment effects).

Intermediate outcome measures are measures that serve as a proxy for the true outcome of interest. The underlying assumption is that the intermediate outcome measure correlates perfectly with the true outcome of interest. They are most frequently chosen to improve ease and feasibility of data collection given study-specific constraints. This is often related to constraints associated with cost and/or follow-up (such as length of follow-up, time needed to collect the outcome measure, or follow-up frequency). They are more often utilized in association with pilot studies or in situations when the outcome of interest is extremely difficult to measure or extremely rare. For example, ultrasound-detected deep vein thrombosis can serve as an intermediate outcome measure for death from pulmonary embolus.[10] The increased incidence of deep vein thrombosis detected via screening lower extremity ultrasounds helps improve study feasibility with regards to sample size. However, it is critical to keep in mind the

outcome measure that you are truly interested in. For example, hospital readmission rate is frequently used as a proxy for a patient's health state. However, in reality, readmission can occur for many reasons other than the health state of the patient. A high readmission rate may indicate that the patient's health has deteriorated, or it could indicate another issue, such as lack of caregivers in the home or a misjudgment about the discharge destination at time of discharge. A high rate of readmission could reflect poor care during the first admission or superior care leading to rescue and a sicker population on average at discharge. When designing a study utilizing intermediate outcome measures, investigators must always consider the degree to which the intermediate end point is reflective of the main outcome, as well as the degree to which effects of the intervention may be mediated through the intermediate endpoint. Investigators must always consider other factors that may influence the relationship between the process of care and the outcome.

The usefulness of a study as a contribution to clinical knowledge hinges on the adequacy of the chosen outcome measure. The best design and most rigorously executed procedures cannot make up for a poorly chosen measure. Important knowledge about the impact of the intervention may be lost because the selected measure was unable to capture it or, even worse, distorted the true results.

Biophysical/clinical outcome measures

These are objective health-related outcomes. They tend to be dichotomous outcomes that are relatively easy to interpret with good face validity. Some examples include

mortality, complications (operative or nonoperative), hospital readmission rate, new institutionalization, direct costs of care, return to work, range of motion, and radiographic alignment. There are several advantages of biophysical or clinical outcome measures:

- Obvious face validity, leading to easy buy-in from clinicians and public health officials.
- Generally easy to understand both analytic plan and clinical relevance.
- Hawthorne effect: measurement alone may improve outcomes. For example, surgical morbidity and mortality rates in Veterans Affairs hospitals have fallen dramatically since the implementation of the National Surgical Quality Improvement Program (NSQIP) in 1991.[11] This may be an advantage for patients as it has been shown that studying these outcomes improves them. However, it is important to consider the implications of this effect in analyzing and interpreting studies.
- Disadvantages of utilizing biophysical or clinical outcome measures include:
- Sample size: adverse events may be relatively uncommon, resulting in a need for huge numbers of patients to show meaningful, procedure-specific differences.
- These outcome measures do not detect the effect or weight of these variables on patients' lives.

Patient-reported outcome measures (PROMs)

Patient-reported outcome measures (PROMs) refer to patient perceptions and ratings on symptoms, functioning, health status, health-related quality of life, and/or satisfaction. They can focus on generic health-related outcomes (e.g. SF-36), disease/diagnosis-specific outcomes (e.g. WOMAC), or regionally/anatomically specific outcomes (e.g. Disabilities of the Arm, Shoulder, and Hand (DASH). Data are provided by patients or their proxies.

While biophysical/clinical outcomes tend to have the highest impact, they measure extremes. Most patients, particularly in elective orthopedic practices, elect to undergo orthopedic surgery to relieve pain and improve physical function (and not to avoid complications or revisions). Some have argued that, in order to demonstrate value, orthopedic surgeons must assess the results of their surgical interventions by measuring the degree of pain relief and improved physical function the patient experiences after surgery. Thus PROMs are becoming increasingly important as focus shifts to patient-centered care.

Generic outcomes measure general health status inclusive of physical symptoms, function and emotional dimensions of health. These are designed to be used across different subgroups of individuals and contain common domains that are relevant to almost all populations. They can be used to compare one population to another or to compare scores in a specific population to normative scores. Furthermore, they can focus on a comprehensive set of domains or on a narrow range of domains. Some examples include physical function (e.g. PROMIS physical function), pain (e.g. Brief Pain Inventory), return to activities (e.g. Paffenbarger Physical Activity Scale), or general health/quality of life (e.g. SF-36). Some advantages of generic outcome measures include the ability to compare a patient population of interest to normative populations and that

they are easily generalizable. Some disadvantages include that they may not always provide a sufficient level of detail or responsiveness for measuring change in a single patient over time. Furthermore, they tend to be less responsive when capturing particular changes at the targeted region due to the multiple components, such as mental, social, and physical constructs, all of which are related to overall health.

Health-related quality of life (HRQoL) is a multidimensional concept that includes domains related to physical, mental, emotional, and social functioning, specifically focusing on the impact that health status has on quality of life. These constructs comprise outcomes from the patient perspective and reflect the relative importance of the domain on their life. These outcome measures weight items or dimensions differently to account for how people value a health state, rather than assigning equal weight to each dimension or item included in the outcome measure. HRQoL measures can be translated into quality-adjusted life years (QALYs) which can be used for economic or cost-effectiveness analyses. Utility (preference) scores are reported on a generic scale where dead equals 0 and perfect health equals 1. This is becoming increasingly important in an effort to optimally distribute resources in a resource-constrained environment. The most common generic measures of HRQoL are the EQ5D, the SF-6D, and the Health Utilities Index (HUI).

Anatomic-specific or condition-specific measures are outcome measures that are specific to anatomic areas, for example DASH, or to specific diseases, for example Western Ontario Rotator Cuff (WORC) Index. These may be more sensitive to symptoms that are experienced by a particular group of patients and are, thus, thought to detect smaller or subtler differences and changes in scores when they occur in response to interventions. Anatomic- or

condition-specific measures may be able to detect small changes that generic measures may not be sensitive to. This may be important in trials comparing interventions but may not as useful for population-based analyses.

There have been several new developments in measurement of PROMs. Item response theory (IRT) is a process used to develop tests that differentiate respondents along the continuum of a specific trait, such as degrees of pain or levels of physical function.[12] IRT focuses on the measurement parameters of each item or question, allowing test designers to verify that each item or question actually measures what they expect it to measure. This allows IRT-based surveys to be more valid estimations of the trait of interest than those provided by classical test theory. IRT-based scores can be directly compared with scores from different surveys, as long as both surveys were calibrated to measure the same underlying trait (e.g. physical function). The benefits of IRT are derived from defining the measurement parameters of each individual item or question (as opposed to the entire questionnaire). Each item or question is, essentially, a test for a portion of the trait scale, with each response to an item positioning the respondent along the continuum.

Computerized adaptive testing (CAT) is another innovative development in PROMs, based upon IRT. CAT achieves the goal of minimizing burden by only delivering the items needed to measure the respondent's condition. After starting at a predefined point on the trait scale, CAT software chooses each subsequent item based on answers to previous items. The software refines its estimate of the person's trait level with targeted questions, narrowing in on the patient's true condition until a predetermined precision has been achieved.

Objective physical function outcome measures

Objective physical function outcome measures can be used to objectively measure physical performance. These may be less influenced by culture, language, or education level than by self-reported or proxy-reported measures. However, more resources are required to collect these data, such as time and adequately trained personnel. It is important to consider the patient population in choosing the most appropriate measures. The physical function outcome measure most appropriate for a geriatric patient will be very different than that appropriate for a young active patient. Objective physical function outcome measures can be stratified by domain (agility, strength/power, speed, postural stability) or by the demand of test (less demanding/more demanding).

Summary of answers

- Choice of outcome measure is a critical component to optimize data collection in research and quality improvement.
- Understanding the definitions and nuances of each type of outcome measure is essential to optimize choice of the most appropriate outcome measure(s).
- An understanding of the strengths and limitations of each type of outcome measure is essential in appropriately interpreting and applying the results of the data collected.
- Please see Chapter 173 for an in-depth look at pediatric orthopedic outcome instruments

Introduction

Healthcare expenditures account for roughly 10–20% of the gross domestic product in most high-income countries.[1] Despite rising healthcare costs in many of these countries, most countries have observed limited improvement in basic health outcomes, such as life expectancy.[2] Currently, models of healthcare are often volume based and compensate providers using a fee-for-service system. While the volume-based reimbursement model rewards activity, it has limited influence in ensuring improved patient outcomes. To reduce the disconnect between health treatments and patient outcomes, Robert Kaplan and Michael Porter, professors at the Harvard Business School, have proposed a new model deemed *value-based healthcare*.[3]

Top four questions

1. What is value-based healthcare?
2. How can value be improved?
3. How can value-based healthcare be applied to orthopedics?

4. What are the practical challenges with value-based orthopedics?

Question 1: What is value-based healthcare?

In value-based healthcare, *value* is generally defined as the benefits (health outcomes, patient satisfaction, prevention of illness) over the costs, both direct and indirect.[4] As in other fields, value should be from the consumer's perspective, or in healthcare – the patient's perspective. The delivery of healthcare services involves numerous organizational units, ranging from hospitals to a physician's clinic and laboratories to imaging facilities. However, the proper unit for measuring value should encompass all of the services or activities that, in combination, will determine if a patient meets their desired outcomes for a given medical condition.

Value for the patient is created through the combined efforts of healthcare providers over the full cycle of care for a given medical condition. The benefits of any one intervention may be contingent on the effectiveness of other interventions throughout the care cycle. For primary and preventative care, value should be measured for a defined patient population with similar healthcare needs, such as healthy children, healthy adults, or frail elderly people.

Defining specific outcome dimensions and measures

For patients with multiple medical conditions, value should be measured for each condition, with the presence of the other conditions used for risk adjustment. This approach allows for relevant comparisons among the patient's

results, including comparisons of providers' ability to care for patients with complex conditions.

Determining the group of relevant outcomes to measure for any medical condition should follow several principles. Outcomes should include the health circumstances most relevant to patients and include both short-term and long-term health. Long-term health should be a time period long enough to encompass the ultimate results of care. Risk factors or initial conditions should be incorporated into the outcome measurement to allow for accurate risk adjustment. For any medical condition or patient population, multiple outcomes measures will collectively define success. The complexity of medical care means that competing outcomes (e.g. short-term safety versus long-term function) must often be weighed against one another.

Hierarchy of outcomes

The outcomes for any medical condition can be arrayed in a three-tiered hierarchy. The top tier is generally the most critical, and the lower-tier outcomes involve a progression of results contingent on higher-tier outcomes. Each tier of the framework contains two levels, involving one or more distinct outcome dimensions. For each dimension, success is measured with one or more specific metrics.

Tier 1 is the health status that is achieved or, for patients with some degenerative conditions, retained. The first level, survival, is of overriding importance to most patients and can be measured over various periods appropriate to a given medical condition. However, maximizing the duration of survival may not be the most important outcome to all patients. The second level in Tier 1 is the degree of health or recovery achieved or retained. Examples may include freedom from disease and relevant functional status. For

some patients, the second level in Tier 1 may, in fact, be more important than survival.

Tier 2 outcomes are related to the recovery process. The first level is the time required to achieve recovery and return to the patient's normal or best attainable function. Recovery can be further divided into the time needed to complete various phases of the care cycle. Cycle time is a critical outcome for the patient – not a secondary process measure. Delays in diagnosis or formulation of treatment plans can cause unnecessary anxiety. Furthermore, reducing the cycle time can improve functionality and reduce complications. The second level in Tier 2 is the disutility of the care or treatment process in terms of discomfort, short-term complications, adverse events.

Tier 3 is the sustainability of health. The first level of Tier 3 outcomes is the recurrences of the original disease or longer-term complications. The second level captures new health problems created as a consequence of treatment. When recurrence or new illnesses occur, all outcomes must be remeasured.

Measurement efforts should begin with at least one outcome dimension at each tier, and ideally one at each level. Improving one outcome dimension can benefit others. Mapping these trade-offs, and seeking ways to reduce them, is an essential part of value-based healthcare.

Relating outcomes to processes

To identify the set of outcome dimensions, the cycle of care for the medical condition can be charted using a care delivery value chain (CDVC). A CDVC maps the full set of activities or processes involved in patient care and highlights the associated entities or units within the full care cycle. This chart allows a systematic identification of all relevant outcome dimensions as well as when and where

measurement should occur. The CDVC also enables particular outcome dimensions to be linked to the specific processes of care from which they arise. Using the CDVC and outcomes in tandem can guide outcome improvement.

Selecting particular measures

The specific measure selected for an outcome dimension should be based on several criteria. First, measures should optimally reflect the perspective of the patient. For some outcomes, a general health utility metric such as the EuroQol five-dimensional questionnaire (EQ5D) may be appropriate. For other medical conditions, a more specific index such as the Western Ontario *and* McMaster Universities *Arthritis (*WOMAC*)* Index may be more suitable. One should also strive to use validated measures that will enable reliable comparison across providers as this reduces bias and interpersonal errors. Many outcomes may require multiple measurements at various times in the cycle of care depending on the medical condition.

Practical considerations, such as the availability of data and the cost of data acquisition, will also factor into the measures selected. Measures that require patients to self-report are vulnerable to respondent bias. Immediate complications are much easier to track than longer-term outcomes that require patient follow-up. Advances in electronic medical records are continually reducing the costs associated with measuring outcomes.

Adjusting for risk

Achievable outcomes for a given patient will depend, to some degree, on a patient's initial condition or risk factors. Measuring and adjusting for risk factors is crucial to accurately interpret, compare, and improve outcomes. Patient compliance may also be interpreted as a risk factor.

Accurate risk adjustment is challenging but may be achieved through a variety of strategies including stratification or regression. Inadequacy or an inability to adjust for risk will limit the validity of any value-based outcome measure and reduce the acceptance of these data by the medical community. Robust risk adjustment mitigates the risk that providers will discriminate against unhealthy patients to improve their outcomes. Inadequate risk adjustment limits the understanding of actual costs and often leads to underpayment of providers for complex care.

Determining costs

Few clinicians are aware of what each component of care costs, and fewer understand how costs relate to the outcomes achieved. In a field with rising costs, the absence of accurate cost information in healthcare is an astounding systematic barrier to improving value. In the United States, cost allocations are often based on charges, not the actual costs, creating further error in cost estimates.

Costs, like outcomes, should be measured around the full cycle of care for a patient's medical condition. Many healthcare costs for a patient involve shared resources, such as physicians, administrative staff, investigations, facilities, and equipment. However, to measure true costs, shared resources costs must be attributed to an individual patient based on actual resource use for the care. The substantial cost variation among medical conditions presents a tremendous opportunity for cost reduction.

The optimal method to measure costs is time-driven activity-based costing (TDABC).[5] TDABC attempts to simplify accounting by using only two parameters. First, determine the cost of each of the resources used in the

cycle of care. Second, determine the quantity of time the patient spends with each health resource.

Question 2: How can value be improved?

Value depends on results, not inputs, and therefore value in healthcare must be measured based on the outcomes achieved, not the volume of services delivered. Shifting the focus from volume to value is a systematic challenge. As value is based on outcomes relative to costs, efficiency is paramount. Cost reductions without regard for the outcomes achieved are dangerous and self-defeating, and lead to false saving and potentially less effective care. Outcomes in healthcare, the numerator in the value equation, are inherently condition-specific and multidimensional. No single outcome encapsulates the results of care. *Cost*, the value equation's denominator, refers to the total costs of the full cycle of care for the patient's medical condition, not the cost of individual services. To reduce overall costs, the best approach may be to spend more on some services to reduce the need for other expenses.

Innovation in care delivery comes not only from focusing on individual outcome dimension but also from harnessing efficiencies from complementary aspects of care. A value-based system should aim to eliminate unnecessary process variation and processes that fail to add value. Improving value is an iterative process. As survival rates improve for a certain medical condition, providers may shift focus to increase the speed and reduce the discomfort associated with a treatment.

Measuring the full hierarchy of outcomes not only ensures multidimensional quality improvement but also expands the

areas in which providers can differentiate themselves. As providers achieve parity on specific dimensions, providers can look to other dimensions in the hierarchy that may be more heavily weighted by certain segments of a given patient population. Furthermore, certain health services and treatments may be performed by lower-cost healthcare professionals without adversely affecting patient outcomes. Such process changes would avail physicians and nurse to focus on their highest-value roles in the cycle of care.

Innovation outcomes must be measured continually and prospectively with constant reporting to providers. Feedback to providers that includes both outcomes and costs is fundamental to improving efficiency.

Hierarchy of outcomes and cost reduction

Historically, there has been tremendous focus on improving Tier 1 outcomes, particularly survival for a given medical condition. Marginal improvements in survival are often associated with substantial costs and may lead to lesser second level Tier 1 outcomes, such as functional status. A broader focus on the hierarchy of outcomes should lead to a re-evaluation of the cycle of care. Lower-tier outcomes are almost invariably associated with lower costs. Faster cycle times, fewer complications, and fewer failed therapies have considerable cost efficiencies. Improvements to Tier 2 and Tier 3 outcomes can also reduce the cost of improving Tier 1 outcomes due to many complementary forms of care. Advances in early diagnostics of medical conditions have enabled early, typically less costly, treatments that may improve the overall value for a given medical condition.

New reimbursement structures

Improving value is often confused with cost reduction. Efforts toward cost containment and strategies to ration

healthcare services can often lead to the increased demand for downstream, much costlier, interventions. Innovation to the healthcare reimbursement system is critical to driving the change to value-based health systems that will allow patients to achieve excellent outcomes through a more efficient and sustainable health system. Bundle reimbursement payment models are a practical approach to compensate for value-based care, where a fixed reimbursement amount is shared among all providers for a defined cycle of care that meets specific quality standards. Such an approach requires hospitals and health providers to work collaboratively to manage costs and processes across the cycle of care. Models, such as bundled payments, are intended to shift financial incentives away from service volume and toward more coordinated, patient-centered care with more predictable results.

The TDABC approach identifies how much of each resource's capacity is actually used to perform health services and to treat patients versus how much capacity is unused. Resource utilization data also uncover where increasing the supply of certain resources will ease a bottlenecked process, enabling more timely care and serve more patients with minimal cost increases.

Question 3: How can value-based healthcare be applied to orthopedics?

Orthopedics, as a specialty, is well suited to applying the principles of value-based care. There is a high prevalence of musculoskeletal disease and injury, implants and procedural costs are high, and there is a significant impact on patient quality of life associated with good treatment outcomes. For many orthopedic conditions, the cycle of care will include acute care, related complications, rehabilitation, and reoccurrences. Shifting focus to the full

cycle of care is essential to improving value. If a surgical procedure is performed flawlessly, but a patient's subsequent rehabilitation fails, the outcome will likely be poor.

Orthopedics, as a specialty, has many disease-specific, patient-reported outcome measures available, such as the WOMAC, the Knee Injury and Osteoarthritis Outcome Score (KOOS), and Disabilities of the Arm, Shoulder, and Hand (DASH). These instruments can be used to measure disease states both pre- and postintervention to assess patient improvement. However, as many of these measures report numeric scores, determining a minimum clinically important difference for the outcome can present another challenge to calculating value. There are different techniques available to define a minimum clinically important difference for a disease-specific, patient-reported outcome, such as distribution-based and anchor-based techniques. Incorporating minimum clinically important differences into the value measurement ensures patient-important improvements are appropriately valued.

Question 4: What are the practical challenges with value-based orthopedics?

The current organizational structure, information, and accounting systems in most healthcare systems make it challenging to measure and deliver value-based care. Providers tend only to measure what they directly control in a particular intervention and what is easily measurable, rather than what matters for patient outcomes. For example, a measure may only cover a single department (too narrow to be relevant to patients) or outcomes, such as infection rates, calculated for a whole hospital (too broad to

be meaningful for the patient). Often providers only measure what is billed, even though most reimbursement practices are misaligned with value. Implementation of value-based orthopedics will require standardized outcome measures for orthopedic conditions and new cost accounting systems.

Delivering health services requires multidisciplinary teams. It is difficult to determine which specific aspects or interactions in a cycle of care are improving patient value, primary due to the delays from treatment to a realized benefit for the patient. A patient will often interact with several different units of care or health systems during their cycle of care. Reimbursing multiple units based on the outcomes achieved by a shared patient presents a challenge and may require substantial reorganization in patient-care processes. Finally, health providers dictate which treatments will be provided to a patient. Successful implementation of value-based care requires clinicians to be engaged in the process and believe the measures are valid and important for patient care.

The application of value-based orthopedics should not be restricted to high-income countries. The principles of a value-based model can have a substantial impact on underserved and resource-poor health systems. Using easy-to-administer tools to measure a hierarchy of outcomes for common orthopedic conditions and injuries, in combination with a simple TDABC system, can enable the identification and evaluation of value within care cycles. Viewing orthopedic conditions and injuries through the value-based perspective, rather than an intervention perspective, has several implications. This model assists in the prudent use of limited health resources. A value-based model rewards shared delivery infrastructures, including facilities, information systems, and personnel. Finally, the value-based model can be used to identify opportunities for

improved reach and access for patients, as identified in the CDVC.

Summary of answers

- Healthcare systems can be incredibly complex. A single surgeon may provide treatment for a variety of different medical conditions. However, the process of measuring and prioritizing value in healthcare will spawn systematic innovation in both the delivery of care and reimbursement for health services.
- Value-based healthcare rewards providers for efficiency in achieving good outcomes while creating accountability for substandard care.

II Orthopedic Medicine

7 Critical Issues in Osteoporosis Management

Matthew Wong-Pack BHSc MD (Cand)[1], Kyra Cummings[2], Arthur Lau MD FRCPC[3], and Jonathan D. Adachi MD FRCPC[3]

[1] Faculty of Medicine, University of Toronto, Toronto, ON, Canada

[2] Western University, London, ON, Canada

[3] Department of Medicine, McMaster University, Hamilton, ON, Canada

Clinical scenario

- Seventy-year-old ambulatory postmenopausal Caucasian female who lives independently slips and falls in the bathtub.
- She is unable to bear weight with her right leg and has significant pain in the right groin.
- Radiographs in the Emergency Department reveal a femoral neck fracture and she is sent in for surgical repair of the fracture.
- Following discharge, she is sent for bone mineral density (BMD) testing by dual energy x-ray absorptiometry (DXA) and has blood tests to rule out secondary causes of osteoporosis (negative).
- The DXA scan reveals that the patient has a T score of −2.0 at the lumbar spine (L1–L4), a T score of −3.9 at the left femoral neck and a T score of −4.1 at the left total hip.

- The patient discloses that she has had a prior wrist fracture at age 55 and that her mother had a hip fracture.
- A complete dietary history reveals that the patient consumes 1 glass of milk (350 mg dietary calcium), 1000 mg of elemental calcium in the form of supplements, and 1000 IU of vitamin D per day.
- The patient has since been started on calcium, vitamin D, and denosumab. Although upset about her recent fracture she is optimistic and eager to learn and has many questions.

Importance of the problem

Over 200 million people worldwide suffer from osteoporosis.[1] Fragility fractures, the consequence of osteoporosis, are responsible for increased morbidity, mortality, chronic pain, and increased healthcare utilization.[2] These fractures account for 0.83% of the global burden of noncommunicable disease.[3] In postmenopausal women, fragility fractures are more common than stroke, myocardial infarction, and breast cancer combined.[4]

In the year 2000, there were an estimated 9 million fragility fractures worldwide, of which, 1.6 million were hip fractures, 1.7 million were forearm fractures and 1.4 million were vertebral fractures.[3] It is projected that there will be an increase to 2.6 million hip fractures by 2020, and 4.5 million vertebral fractures by 2050.[5] The lifetime risk of any fragility fracture is 40–50% in women and 13–22% in men.[6]

Hip fractures are the most severe type of fragility fracture as they require hospital admission and are associated with significant morbidity and mortality.[6] At one year post hip

fracture, mortality (in part due to other co-morbidities) ranges from 12–20%,[6] with the majority of deaths occurring within the first few months after fracture. An excess risk of death may persist for at least 5 years afterwards.[7] Globally, there are approximately 740 000 deaths per year due to hip fracture and resulting complications.[8]

The long-term costs associated with hip fractures are devastating. Available data on the economic burden of osteoporosis shows that currently, the cost of osteoporosis is 37 billion EUR per year in the European Union, 19 billion USD per year in the United States and $2.3–$3.9 billion per year in Canada.[9–11] Due to the significant burden fragility fractures put on patients, their families, and the economy it is important to find the optimal pharmacotherapy to improve bone mass and prevent further traumatic injuries.

Top three questions

1. In postmenopausal women aged >50 who have sustained fragility fractures, how does the diagnosis of osteoporosis determine the risk for future fracture?
2. In postmenopausal women with low BMD or prior fragility fractures, which pharmacological therapies, compared to no medications, best reduce the risk for future fractures?
3. In patients with low BMD or who have sustained a fragility fracture, what is the appropriate duration of pharmacotherapy to avoid adverse side effects?

Question 1: In postmenopausal women aged >50 who have sustained fragility fractures, how does the diagnosis of osteoporosis determine the risk for future fracture?

Rationale

The presence of a fragility fracture is a major risk factor for osteoporosis and is an important indicator for osteoporosis diagnosis and treatment.[12]

Orthopedic surgeons are in an ideal position either individually or collaboratively with colleagues to initiate and provide osteoporosis care for patients with fragility fractures, as they are the first physicians to make contact with the patient following fracture. It is estimated that the annual number of hip fractures worldwide will increase to 4.5–6.3 million by 2050.[3,13,14] Therefore, identifying those who are at risk for future fractures is an important step in the management and prevention of osteoporosis.

Clinical comment

The diagnosis of osteoporosis is determined by measuring a patient's BMD – the average concentration of bone mineral (g) per unit of bone area (cm^2). Bone mineral density is measured using DXA, the gold standard method of measurement.[2] A T-score is the number of standard deviations (SD) above or below the mean value of BMD for young adults (20–30 years old). The World Health Organization (WHO) defines *osteoporosis* as a T-score of −2.5 or less at the hip or lumbar spine.[15]

Findings

A systematic review of 35 studies that evaluated practice patterns related to osteoporosis management after fragility fracture found that recognition and treatment of osteoporosis in these patients remained inadequate,[16] confirming the persistence of an earlier identified global osteoporosis care gap.[17] In this review, a clinical diagnosis of osteoporosis was reported in less than 30% of patients in the majority of studies. Further, DXA scans were performed in less than 15% of patients in studies that reported on BMD testing.

Until recently, decisions about osteoporosis therapy were made based on the presence or absence of fractures and on T-score values ≤ −2.5 SD from DXA measurements of BMD. While low BMD is a strong and independent risk factor for fracture,[18,19] it is not the only risk factor for fracture. Indeed, most fractures occur in women with osteopenia (T-score between −1.0 and −2.5 SD) and not osteoporosis.[15] A reason for this observation is that BMD measures bone quantity and does not take into account bone quality. Bone quality represents characteristics of bone tissue other than BMD that contribute to the strength of a bone, such as geometry, microarchitecture, remodeling, mineralization, and damage accumulation.[20] For this reason, recent treatment guidelines have focused on evaluating a patient's absolute fracture risk, which considers BMD as well as other clinical risk factors for fracture.

The Fracture Risk Assessment Tool (FRAX®), can be used to compute the 10-year probability of fractures in men and women based on clinical risk factors for fracture, with or without the measurement of femoral neck BMD.[21] The performance characteristics of the clinical risk factors have been validated in independent, population-based, prospectively studied cohorts with over a million person years of observation.[22] The FRAX® tool calculates the 10-

year probability of a major fragility fracture (clinical spine, hip, forearm, or proximal humerus) and hip fracture calibrated to the fracture and death hazard of several countries.[23]

Moreover, there is the Osteoporosis Canada 10-year Fracture Risk Assessment Tool which was developed by Osteoporosis Canada using the Canadian 2010 Osteoporosis Guidelines[2] and the Canadian Association of Radiologists and Osteoporosis Canada (CAROC) system (http://www.osteoporosis.ca/health-care-professionals/clinical-tools-and-resources/fracture-risk-tool/). The Canadian Association of Radiologists and Osteoporosis Canada tool was calibrated using the same fracture data as the FRAX Canada calculator.[24–26] The CAROC tool can be used on men and women over the age of 50, and stratifies them into three groups for risk of major fragility fracture within the next 10 years, low (<10%), moderate (10–20%), and high (>20%). The CAROC tool integrates age, sex, T-score at the femoral neck, prior fragility fractures, and recent prolonged systemic glucocorticoid use.[2]

Resolution of clinical scenario

In patients aged 50 years or older who have sustained a hip or other fragility fracture, evidence suggests that:

- Many patients are not receiving appropriate evaluation and treatment for osteoporosis post fracture.
- The FRAX and CAROC tools can and should be used to calculate the 10-year probability of a major fragility fracture (clinical spine, hip, forearm, or proximal humerus) and hip fracture.

Question 2: In postmenopausal women with low BMD or prior fragility fractures, which pharmacological therapies, compared to no medications, best reduce the risk for future fractures?

Rationale

A number of different pharmacologic agents are available for the treatment of osteoporosis.[27] Opinion among orthopedic surgeons is divergent on which pharmacologic agents are best to reduce the relative risk of hip fractures in postmenopausal women who present with low BMD or a fragility fracture.

In a systematic review of 35 studies evaluating osteoporosis management after fragility fracture, more than half of the studies reported that no more than 30% of fracture patients were taking calcium and vitamin D and less than 15% of patients were receiving bisphosphonate therapy.[17] As the majority of pivotal clinical trials were in postmenopausal women, data in men are limited and will not be reviewed.

Clinical comment

Recommended daily calcium and vitamin D intakes for populations vary between countries. The US National Osteoporosis Foundation (NOF) recommends an intake of 1200–1500 mg of calcium and 800–1000 IU of vitamin D per day for men and women aged 50 years and older.[28]

Available literature and quality of the evidence

Current opinion suggests that orthopedic surgeons prescribe one of the recommended anti-osteoporotic drugs for the treatment of fragility fractures in addition to calcium, vitamin D, and exercise. The majority of pharmacological agents available for the treatment of osteoporosis are antiresorptive agents which include: bisphosphonates (oral or intravenous [IV]), hormone replacement therapy, raloxifene, denosumab, and to a lesser extent strontium ranelate. Other available anabolic agents are parathyroid hormone (PTH 1-84), teriparatide (rh-PTH 1-34), and abaloparatide (PTHrP). A summary of the efficacy of pharmacologic agents on the relative risk reduction of hip fractures is presented in Table 7.1. As the majority of pivotal clinical trials were in postmenopausal women, data in men are limited. Several studies have examined the use of alendronate and risedronate for the treatment of osteoporosis in men.[29–31] These medications have been shown to improve BMD and reduce the risk of vertebral fracture. However, given the limited number of studies, clinicians should refer men with osteoporotic fractures to a bone specialist for further recommendations and management.

Table 7.1 Efficacy of pharmacologic agents on the relative risk reduction of hip fractures in postmenopausal women.

Drug	Description of Clinical Trial	% Relative Risk Reduction for Hip Fracture
Oral bisphosphonates		
Alendronate[32–34]	FIT-1; n = 2027; postmenopausal women with low femoral neck BMD and ≥ vertebral fracture; alendronate 5 mg/d (then increased to 10 mg/d at 24 months) or placebo; 3 yr	51%
	FIT-2; n = 4432; postmenopausal women with low femoral neck BMD but no vertebral fracture; alendronate 5 mg/d (then increased to 10 mg/d at 24 mo) or placebo; 4 yr	NS
	FLEX; n = 1099; postmenopausal women from FIT-1 and FIT-2 trials; alendronate 5 mg/d or alendronate 10 mg/d or placebo; 5 yr	NR

Drug	Description of Clinical Trial	% Relative Risk Reduction for Hip Fracture
Risedronate[35–38]	VERT-NA; n = 2458; postmenopausal women with ≥2 vertebral fractures or 1 vertebral fracture and low lumbar spine BMD; risedronate 2.5 mg/d (discontinued partway through trial) or risedronate 5 mg/d or placebo; 3 yr	NR
	VERT-MN; n = 1226; postmenopausal women with ≥2 vertebral fractures; risedronate 2.5 mg/d (discontinued partway through trial) or risedronate 5 mg/d or placebo; 3 yr	NR
	VERT-MN Extension; n = 265; risedronate 5 mg/d or placebo; 2 yr	NR
	HIP; n = 9331; postmenopausal women with osteoporosis at femoral neck and/or with ≥1 non-skeletal risk factor for hip fracture; risedronate 2 mg/d or risedronate 5 mg/d or placebo; 3 yr	30%

Drug	Description of Clinical Trial	% Relative Risk Reduction for Hip Fracture
	BONE; n = 2946; postmenopausal women with 1 to 4 vertebral fractures and osteoporosis in ≥1 vertebra; ibandronate 2.5 mg/d or ibandronate 20 mg every other day for 12 doses every 3 mo or placebo; 3 yr	NR
Intravenous bisphosphonates		
Ibandronate[39,40]	DIVA; n = 1395; postmenopausal women with osteoporosis; 2 mg ibandronate injections every 2 mo plus oral placebo or 3 mg ibandronate injections every 3 mo plus oral placebo or 1 of 2 groups receiving oral ibandronate 2.5 mg/d plus placebo injections every 2 or every 3 mo; 1 yr	NR

Drug	Description of Clinical Trial	% Relative Risk Reduction for Hip Fracture
Zoledronic acid[41,42]	HORIZON – Pivotal Fracture Trial; n = 7765; postmenopausal women with osteoporosis at femoral neck with or without vertebral fracture or osteopenia with radiologic evidence of ≥2 mild vertebral fractures or 1 moderate vertebral fracture; single 5 mg infusion of zoledronic acid every 12 mo or placebo; 3 yr	41%
	HORIZON – Recurrent Fracture Trial; n = 2127 men and women ≥50 yr who had undergone recent surgical repair of a low trauma hip fracture; single 5 mg infusion of zoledronic acid every year; 2 yr	30%
Other		
Raloxifene[43]	MORE; n = 7705; postmenopausal women with osteoporosis; raloxifene 60 mg/d or raloxifene 120 mg/d or placebo; 3 yr	NS

Drug	Description of Clinical Trial	% Relative Risk Reduction for Hip Fracture
Denosumab[44]	FREEDOM; n = 7868; postmenopausal women with osteoporosis; denosumab 60 mg subcutaneously every 6 mo or placebo, 3 yr	40%
Calcitonin[45]	PROOF; n = 1255; postmenopausal women with osteoporosis; calcitonin 100 IU/d or calcitonin 200 IU/d or calcitonin 400 IU/d or placebo; 5 yr	NS
Anabolic agents		
Teriparatide (rh-PTH 1-34)[46]	n = 1637; postmenopausal women with prior vertebral fractures; PTH (1-34) 20 µg/d or PTH (1-34) 40 µg/d of or placebo; 1.8 yr	NR
Parathyroid hormone [PTH (1-84)][47]	TOP; n = 2679; postmenopausal women with low BMD at hip or spine; recombinant human PTH (1-84) 100 µg/d or placebo; 1.5 yr	
Antiresorptive/Anabolic agents		

Drug	Description of Clinical Trial	% Relative Risk Reduction for Hip Fracture
Strontium ranelate[48]	TROPOS; n = 5091; postmenopausal women with osteoporosis; strontium ranelate 2 g/d or placebo; 3 y	NS

Findings

Calcium and vitamin D

There is no clear evidence that calcium in combination with vitamin D reduces the risk of fragility fractures,[49] but we do know that vitamin D on its own has no fracture risk benefit.[50–53] That being said, there is strong evidence that calcium and vitamin D together are beneficial in patients with osteoporosis, especially postmenopausal women.[51,52] The most severe adverse effect from taking calcium is the potential increased risk of cardiovascular events. At this time, there is no clear evidence to suggest that taking

calcium with or without vitamin D increases one's risk of cardiovascular events.[54,55]

Exercise

The mean BMD at the lumbar spine (1.77% [1.26–2.28%]) significantly increased after 18 months in the exercise group ($p < 0.001$). There was also significant differences in BMD at both locations between the exercise and control groups ($p < 0.001$).[56] Tai chi has been investigated as well and has shown less BMD loss at the hip compared to controls ($p < 0.05$) but did not show an overall increase in BMD.[57] The most inclusive meta-analysis of randomized control trials on the effect of resistance training 2–4 days/week for 15–90 minutes in postmenopausal women demonstrated a weighted mean difference in BMD of 0.012 g/cm^2 (95% CI 0.002–0.022) at the lumbar spine and 0.014 g/cm^2 (95% CI 0.003–0.025) at the femoral neck ($p < 0.001$).[58]

Bisphosphonates

A recent review article summarized the efficacy results from pivotal clinical trials of four commonly prescribed bisphosphonates – alendronate, risedronate, ibandronate, and zoledronic acid – for the treatment of postmenopausal osteoporosis.[59] In the review, a total of 11 randomized placebo-controlled trials were identified (three for alendronate, [32–34] four for risedronate,[35–38] two for ibandronate,[39,40] and two for zoledronic acid[41,42]). Compared with placebo controls, alendronate, risedronate, and zoledronic acid but not ibandronate (no available hip data) were found to reduce the relative risk of hip fractures in postmenopausal women by 20–51%, vertebral fractures by 41–70%, and nonvertebral fractures by 12–40% in

postmenopausal women with low BMD and/or prior vertebral fracture.

The most common side effects from oral bisphosphonates are nausea, epigastric pain, esophagitis, and gastric ulcers.[60] The most common adverse effects when taking zoledronic acid include pyrexia, myalgia, flu-like symptoms, bone pain, and chills, which can be classified as acute phase response.[61] This usually occurs after the first infusion, resolves in 3–4 days, and is less common with subsequent infusions.[62] Acute anterior uveitis is associated with zoledronic acid therapy, usually occurs within three days of infusion, resolves with topical cyclopentolate, and has no lasting sequelae.[63] The more severe adverse events include osteonecrosis of the jaw (ONJ) and atypical femoral fractures (AFF). The American Society for Bone and Mineral Research (ASBMR) has recently published a revised case definition for AFF as a fracture located along the femoral diaphysis from just distal to the lesser trochanter to just proximal to the supracondylar flare. Further criteria are provided in the ASBMR Task Force 2013 Revised Case Definition of AFFs.[64] A systematic review and meta-analysis of 11 studies, including five case controls and six cohorts, showed bisphosphonate use was associated with increased risk of subtrochanteric femoral shaft fractures (adjusted risk ratio [RR] = 1.70; 95% CI 1.22–2.37).[65] The report concluded that, while the relative risk of patients with AFFs taking bisphosphonates is high, the absolute risk of AFFs in patients on bisphosphonates is low, ranging from 3.2 to 50 cases per 100 000 person years. However, long-term use may be associated with higher risk (~100 per 100 000 person years).[64] They also published recommendations for orthopedic and medical management of AFFs (Table 7.2).[64,66]

Table 7.2 ASBMR Task Force on Atypical Femoral Fracture recommendations for orthopedic and medical management of atypical femoral fractures. Source: Modified from Shane, et al.[64]

Issue	Recommendations
Surgical management	
History of thigh or groin pain in a patient on bisphosphonate therapy	Rule out femoral fracture. AP and lateral plain radiographs of the hip, including the full diaphysis of the femur should be performed. If the radiograph is negative and the level of clinical suspicion is high, a technetium bone scan or MRI of the femur should be performed to detect a periosteal stress reaction

Issue	Recommendations
Complete subtrochanteric/diaphyseal femoral fracture	Orthopedic management includes stabilizing the fracture and addressing the medical management (below). Endochondral fracture repair is the preferred method of treatment since bisphosphonates inhibit osteoclast remodeling. Intramedullary reconstruction full-length nails accomplish this goal and protect the femur. Locking plates preclude endochondral repair, have a high failure rate, and are not recommended as the method of fixation. The medullary canal should be overreamed to compensate for the narrow intramedullary diameter, facilitate insertion of the reconstruction nail, and prevent fracture of the remaining shaft. The proximal fragment may require additional reaming to permit passage of the nail and avoid malalignment. The contralateral femur must be evaluated radiographically whether or not symptoms are present

Issue	Recommendations
Incomplete subtrochanteric/femoral shaft fractures	Prophylactic reconstruction nail fixation is recommended if pain is present. If there is minimal pain, a trial of conservative therapy in which weight bearing is limited through the use of crutches or a walker may be considered. However, if there is no symptomatic and radiographic improvement after 2– 3 months of conservative therapy, prophylactic nail fixation should be strongly considered because of the possibility of complete fracture. For patients with no pain, weight bearing may be continued but should be limited and vigorous activity avoided. Reduced activity should be continued until there is no bone edema on MRI
Medical management	

Issue	Recommendations
Prevention	Decisions to initiate pharmacologic treatment including bisphosphonates to manage patients with osteoporosis should be made based on an assessment of benefits and risks. Patients who are deemed to be a low risk of osteoporosis-related fractures should not be started on bisphosphonates. Physicians need to be wary of thigh or groin pain in patients on bisphosphonates. Complaints of thigh or groin pain in a patient on bisphosphonates require urgent radiographic evaluation of both femurs even if pain is unilateral

Issue	Recommendations
Treatment	For patients with a stress reaction, stress fracture, or incomplete or complete subtrochanteric femoral shaft fracture, potent antiresorptive agents should be discontinued. Dietary calcium and vitamin D status should be assessed and adequate supplementation should be prescribed. Teriparatide should be considered in patients who suffer these fractures, particularly if there is little evidence of healing by 4–6 weeks after surgical intervention

The patients who are most at risk of ONJ are those with other risk factors, including glucocorticoid therapy, chemotherapy, antiangiogenic agents, and radiotherapy. The incidence of ONJ in cancer patients is estimated to be 1–15% and is associated with the dose and duration of bisphosphonate therapy.[67]

Denosumab

The fracture clinical trial of denosumab (FREEDOM) reported a relative risk reduction of hip fracture with denosumab of 40% and vertebral of 68% (Table 7.1).[44] A post hoc analysis of the FREEDOM trial data stratified by level of kidney function showed that denosumab was effective in reducing fracture risk among patients with impaired kidney function and was not associated with any increase in adverse events.[68] The DIRECT clinical trial

conducted on male and female Japanese patients with osteoporosis showed that denosumab reduced the risk of new or worsening vertebral fracture by 65.7%.[69] In a systematic review, serious side effects were seen in 24.9% compared to 23.8% of controls.[70] The FREEDOM study showed no significant difference in side effects between groups.[44] There were a total of two AFF in the FREEDOM trial where 7868 postmenopausal women with osteoporosis were enrolled.[44] In the first three years of the FREEDOM there were no reported cases of ONJ; in the extended study that went up to 10 years there were 13 cases.[44,71] Postmarketing exposure to denosumab is estimated to be 1 960 405 patient years in 2 427 475 patients as of May 2014 and a total of 47 cases of ONJ have been confirmed. In these patients they have all had other risk factors.[72]

Teriparatide (rh-PTH 1-34) and parathyroid hormone (PTH [1-84])

Two pivotal trials have examined the effects of recombinant human parathyroid hormone ([rh-PTH[1-34]) and parathyroid hormone analogues (PTH [1-84]) on fracture risk reduction in postmenopausal women.[46,73–79] rh-PTH(1-34) was shown to reduce the relative risk of nonvertebral fractures.[46] However, the number of women with hip fractures was too small to estimate the incidence of hip fracture, and thus the specific relative risk reduction at the hip site. Similarly, the PTH(1-84) trial[47] did not report on the specific relative risk reduction of hip fractures, but the difference in the number of reported nonvertebral fractures was not statistically significant between treated and untreated groups. The most common adverse effects associate with teriparatide are nausea, headache, dizziness, and leg cramps.[46] There are data that suggest a link between osteosarcoma and teriparatide in rats.[80] In the US

postmarketing surveillance study there was no association between teriparatide exposure and osteosarcoma.[81]

Resolution of clinical scenario

- Calcium and vitamin D are essential components of all osteoporosis treatment plans and mandatory components in drug trials testing the fracture risk reduction of other medications.[82]
- Exercise has always been part of osteoporosis treatment as it is thought to strengthen bones through stress.
- High-intensity exercise programs that focus on balance, stretching, isometric strength training, and weight-bearing exercises have proven to increase BMD and decrease the fall rate in postmenopausal women.
- Alendronate, risedronate, and zoledronic acid are all effective pharmacologic agents for reducing the relative risk of hip fracture.
- There is no clear association between bisphosphonate use and the rate of serious or nonserious atrial fibrillation, regardless of dose or duration of bisphosphonate therapy.
- The risk of developing bisphosphonate-associated ONJ with routine oral therapy for osteoporosis is very low.
- Atypical femur fractures are associated with long-term bisphosphonate therapy. The risk of this is small, while the benefits of treatment are great in reducing fractures.
- Denosumab is an effective pharmacologic agent for reducing the relative risk of both hip and vertebral fractures and for patients who either cannot tolerate

oral or IV bisphosphonates or have impaired renal function.

- The risk of developing denosumab-associated AFF and ONJ with routine subcutaneous therapy for osteoporosis is very low.
- Parathyroid hormone/parathyroid hormone-related protein analogs should be considered in patients with severe osteoporosis at high risk of fracture and in patients who have failed other anti-osteoporosis medications.

Question 3: In patients with low BMD or who have sustained a fragility fracture, what is the appropriate duration of pharmacotherapy to avoid adverse side effects?

Rationale

The optimal duration of pharmacological treatment for osteoporosis is up for debate. The area of concern is centered on the long-term side effects and the benefit-to-risk relationship. The beneficial effects of bisphosphonates persists for months to years after discontinuation because of their high affinity for hydroxyapatite, meaning they can be stopped and still have an effect on BMD.[33] The retention of bisphosphonates in the bone also raises the concern for increased potential side effects such as AFF and ONJ. In contrast, drugs that are not retained in the skeleton – such as denosumab, teriparatide, and raloxifene – may require a longer or indefinite duration of treatment. If therapy is stopped, then alternative therapies should be considered or commenced.

Clinical comment

First-line therapies include bisphosphonates and denosumab. Duration of therapy remains controversial with some recommending therapy limited to five years of bisphosphonate use given the potential for side effects.[83] Others recommend indefinite treatment for those at high risk for fracture as the benefits of therapy in preventing fractures are felt to outweigh the potential risk for rare side effects.[84,85] If denosumab is discontinued, alternative therapy must be commenced to prevent bone loss and fractures.[86]

Current opinion

While one might consider a drug holiday for those on bisphosphonates in those at low to moderate risk of fracture, for those on denosumab or PTH, discontinuation of treatment results in bone loss and an increase in fracture risk if some other treatment is not instituted. Studies have focused on the discontinuation of bisphosphonates and denosumab.

Bisphosphonates

The FLEX study on alendronate concluded that stopping alendronate resulted in significant decline in lumbar, total hip, and femoral neck BMD compared with treatment extension for five years.[33] The HORIZON extension study which looked at patients who received zoledronic acid annually found that 55% of the participants had a low three-year risk of fracture (average 3.2% risk of morphometric vertebral fracture and 5.8% risk of nonvertebral fracture) if treatment was discontinued.[87] The ASBMR Task Force has provided its recommendations for bisphosphonate therapy based on evidence from these studies. They recommend after three years of treatment

with IV zoledronic acid or five years with oral bisphosphonates, a treatment break often referred to as *drug holiday* should be considered, unless there are characteristics indicative of high fracture risk (e.g. older age, low hip T-score, or high fracture risk score, previous major fragility fractures, or fractures on therapy).[83] Additionally, the UK National Osteoporosis Guideline Group (NOGG) (Figure 7.1)[88] and the European Menopause and Andropause Society (EMAS) have issued similar recommendations.[85]

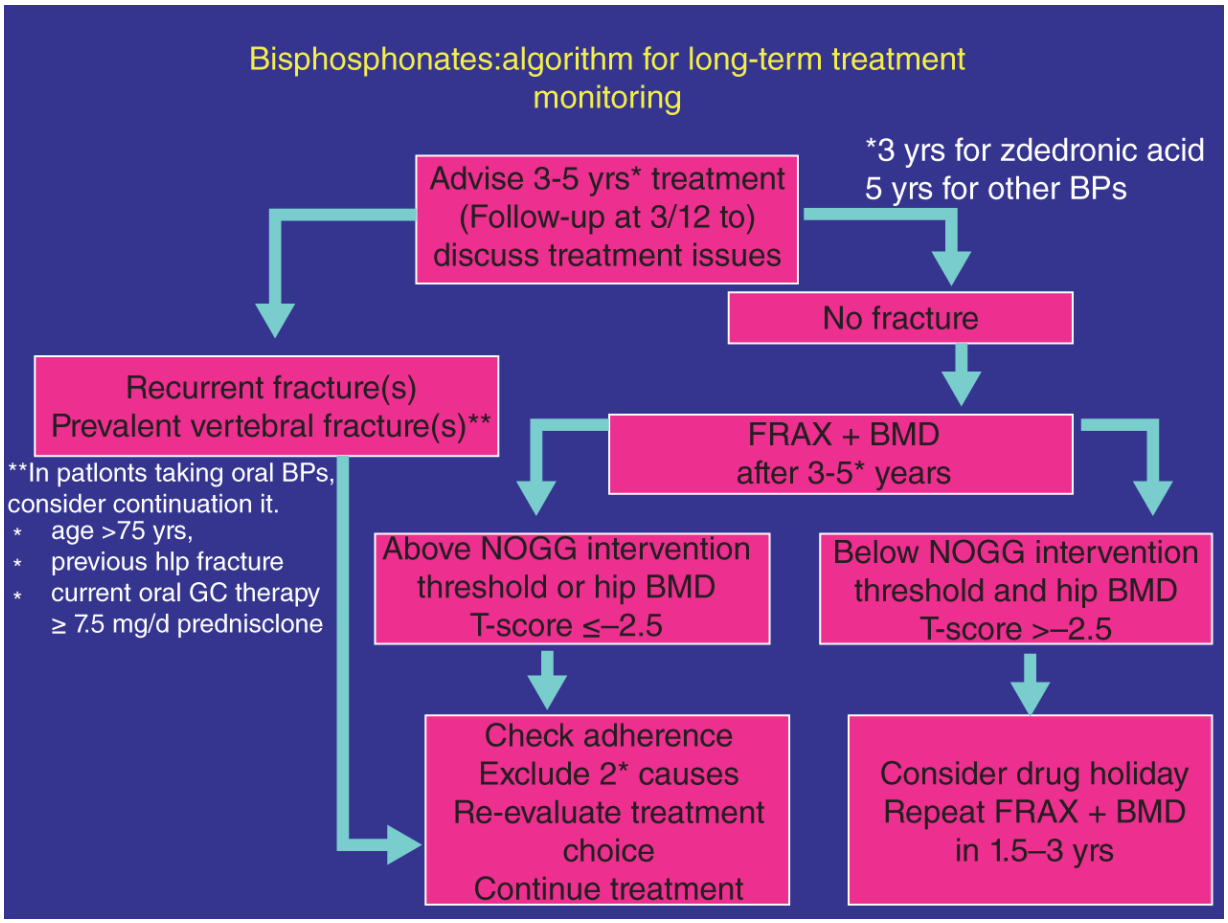

Figure 7.1 NOGG recommendations for long-term bisphosphonate use. Source: Reproduced from Compston J, et al.[88]

There are few data estimating the risk of AFF after discontinuing bisphosphonates. Schilcher et al. reported the odds of AFF increased with the duration of treatment. They further found age-adjusted relative risk of atypical fracture associated with bisphosphonate use. The RR after four years or more of use reached 126 (CI: 55–288), with a corresponding absolute risk of 11 (CI: 7–14) fractures per 10 000 person years of use. After stopping therapy, the risk of AFF decreased by 70% per year since last use.[89]

Denosumab

The FREEDOM extension trial on denosumab, which extended the original three years of denosumab therapy for up to 10 years, showed continued increase in BMD, a sustained reduction in bone turnover markers (BTMs) and low fracture incidence.[90] Multiple studies have shown a rapid decrease in BMD that was gained during treatment upon discontinuation.[91–93] In a post hoc analysis of the FREEDOM trial and its extension, fractures were examined after treatment discontinuation. Of all the patients who sustained new vertebral fractures off treatment, 60.7% of those that discontinued denosumab and 38.7% who discontinued placebo sustained multiple vertebral fractures.[94] However, in the DATA follow-up study they found the large increases in BMD by denosumab were maintained by those who received prompt treatment with bisphosphonates, but not those who were left untreated.[95] As a result of these studies, the European Calcified Tissue Society (ECTS) has proposed the following recommendations:

- In patients who are low risk for fracture after five years there are two options:

    discontinue denosumab and promptly initiate a bisphosphonate to prevent rebound bone turnover;

or

continue denosumab for a total of 10 years and wait for further publications to guide treatment strategies.

- In patients who are high risk for fracture after five years, continue denosumab for up to 10 years and consolidate with a single infusion of zoledronic acid, or one or more years of an oral bisphosphonate.[86]

Withdrawing treatment of other osteoporosis medications (excluding bisphosphonates) results in rapid loss of their effects on BMD and BTMs. The gains in BMD that are achieved with selective estrogen receptor modulators (SERMs), estrogens, teriparatide, and denosumab are lost over the first 1–2 years.[86] With regards to ONJ, the American Dental Association reported that there is insufficient evidence to recommend a drug holiday from antiresorptive medications before performing dental treatment for prevention of ONJ.[96]

Resolution of clinical scenario

In patients aged 50 years or older who use long-term antiresorptive therapy for osteoporosis, evidence suggests that:

- It is important to re-evaluate patients after initiating pharmacotherapy as there are severe potential side effects, such as AFF, ONJ, venous thromboembolism (VTE), and stroke.
- After three years of treatment with IV zoledronic acid or five years with oral bisphosphonates a treatment break often referred to as *drug holiday* should be considered, unless there are characteristics indicative of high fracture risk.

- Patients taking denosumab should be re-evaluated after five years of treatment. Patients at high risk for fracture should continue denosumab, whereas patients at low risk should either continue denosumab or switch to a bisphosphonate.

Summary of answers

Many patients are not receiving appropriate evaluation and treatment for osteoporosis post fracture.

The FRAX and CAROC tools can and should be used to calculate the 10-year probability of a major fragility fracture (clinical spine, hip, forearm, or proximal humerus) and hip fracture.

Alternative methods are also available to determine absolute fracture risk.

Alendronate, risedronate, zoledronic acid, and denosumab are all effective pharmacologic agents for reducing the relative risk of hip fracture.

The risk of developing bisphosphonate-associated ONJ with routine oral therapy for osteoporosis is very low.

Atypical fractures are associated with anti-resorptive therapy. The exact mechanism by which they occur has yet to be determined.

- It is important to re-evaluate patients after initiating pharmacotherapy as there are severe potential side-effects such as AFF, ONJ, VTE, and stroke.
- After three years of treatment with IV zoledronic acid or five years with oral bisphosphonates, a treatment break often referred to as *drug holiday* should be considered, unless there are characteristics indicative of high fracture risk.

- Patients taking denosumab should be re-evaluated after five years of treatment. Patients at high risk for fracture should continue denosumab, whereas patients at low risk should either continue denosumab or switch to a bisphosphonate.

8 Venous Thromboembolic Events

Ernest Kwek MBBS FRCS(Ed)[1], and Richard E. Buckley MD FRCSC[2]

[1] Department of Orthopaedic Surgery, Woodlands Health Campus, Woodlands Health Pte Ltd, Singapore

[2] Division of Orthopaedic Surgery, Department of Surgery, University of Calgary, Calgary, AB, Canada

Clinical scenario

- An 81-year-old lady was admitted after a ground-level fall.
- She has a history of diabetes mellitus and hypertension and was premorbidly ambulant.
- She suffered a femoral neck fracture and had a cemented hemiarthroplasty within 24 hours.
- On the third postoperative day, she developed a fever and shortness of breath.
- Examination revealed swelling of the right lower leg.
- Deep venous thrombosis (DVT) extending above the knee was demonstrated on ultrasonography, and CT angiography showed a large saddle pulmonary embolism (PE) within the pulmonary trunk.
- The patient required ventilator and inotropic support, and eventually succumbed to secondary pneumonia after a prolonged stay in intensive care.

Top three questions

1. In patients undergoing major orthopedic surgery, does one modality, compared to others, most effectively reduce thromboembolic event rates?
2. In patients undergoing major orthopedic surgery, does preoperative initiation of thromboprophylaxis, compared to peri- or postoperative initiation, reduce thromboembolic event rates?
3. In patients with isolated lower-limb injuries who require immobilization, does thromboprophylaxis, compared to no prophylaxis, reduce thromboembolic event rates?

Question 1: In patients undergoing major orthopedic surgery, does one modality, compared to others, most effectively reduce thromboembolic event rates?

Rationale

Major orthopedic procedures including hip and knee arthroplasty and hip fracture surgery confer the highest risk for venous thromboembolic events and remain a challenge globally.[1]

Mechanical compression methods – including graduated compression stockings, intermittent pneumatic compression, and foot-pumps – are widely available, variable in expense, and have very few contraindications. These measures can be employed as monotherapy in patients with contraindications to anticoagulant therapy, or in conjunction with anticoagulants in higher-risk patients. The 2012 American College of Chest Physicians (ACCP) guidelines recommend the use of several anticoagulants for

orthopedic surgery.[2] These include low-dose unfractionated heparin (LDUH), low-molecular-weight heparin (LMWH), more recent novel oral anticoagulants, aspirin, and vitamin K antagonists (VKAs), exemplified by warfarin.

New oral anticoagulants (NOACs) are broadly divided into direct thrombin inhibitors (dabigatran) or direct factor Xa inhibitors (fondaparinux, rivaroxaban, and apixaban).

Clinical comment

Evidence has been contradictory regarding the effectiveness of mechanical thromboprophylaxis.

LDUH has largely been surpassed by the LMWHs. NOACs may have even greater thrombo-prophylactic efficacy and ease of administration, but this is balanced by a higher rate of bleeding events. The ideal anticoagulant should have high efficacy, safety, low levels of bleeding, rapid onset of action, fixed dosing, and no requirement for therapeutic monitoring.

Available literature and quality of the evidence

- Systematic reviews/meta-analyses: 2 (level I).
- Systematic reviews/meta-analyses with methodological limitations: 1 (level II).
- Case series: 2 (level IV).

Findings

Pooled data from low-quality randomized controlled trials (RCTs) comparing mechanical compression to no thromboprophylaxis show a relative risk reduction of >50% for both DVT and PE in arthroplasty and hip fracture surgery (pulmonary embolism [PE] risk ratio [RR] = 0.4,

95% confidence interval [CI]: 0.17–0.92; DVT RR = 0.46; 95% CI: 0.35–0.61).[2]

A meta-synthesis identified six good-quality systematic reviews that compared anticoagulants with LMWH.[3] The risk for symptomatic DVT was reduced with factor Xa inhibitors compared to LMWH (four fewer events per 1000 patients), albeit with an increase in major bleeding events (two per 1000 patients). Dabigatran had similar outcomes to LMWH. Conclusions about differences between NOACs could not be ascertained. In a meta-analysis of six RCTs on arthroplasty patients, the combination of pharmacologic and mechanical prophylaxis conferred a lower risk for DVT (relative risk 0.48, 95% CI 0.32–0.72) compared to pharmacologic prophylaxis alone.[4]

Asian patients undergoing hip and knee arthroplasty have been shown to have a noticeable low prevalence of DVT and PE. A recent large case series highlighted the prevalence of DVT at 6.6%, and proximal DVT of 0.4%, with no PE in patients undergoing total knee arthroplasty with only mechanical prophylaxis.[5] Another case series in Asian patients undergoing total hip arthroplasty with only mechanical prophylaxis revealed a DVT prevalence rate of 4.8%, 1.6% with proximal DVT, 0.7% with asymptomatic PE, and no symptomatic PE.[6] The authors recommend mechanical compression devices only in Asian patients.

Resolution of clinical scenario

There is no ideal modality for thromboprophylaxis. Upon recognition of this patient's high risk for venous thromboembolism, she should have received mechanical prophylaxis via foot-pumps, or intermittent pneumatic calf compression on admission. An LMWH should be started 12–24 hours after acute fracture surgery.

Question 2: In patients undergoing major orthopedic surgery, does preoperative initiation of thromboprophylaxis, compared to peri- or postoperative initiation, reduce thromboembolic event rates?

Rationale

The belief that venous thrombi are formed perioperatively has directed the practice of providing antithrombotic prophylaxis preoperatively to maximize antithrombotic effectiveness. On the other hand, postoperative initiation of anticoagulation allows hemostasis of the wound and reduces the risk of bleeding complications.[7] Thromboprophylaxis is commonly administered for the duration of the hospital stay, which can range from 4 to 14 days. However, patients are still at risk of developing symptomatic thromboembolism after discharge from hospital. New guidelines now recommend the use of extended, out-of-hospital prophylaxis, but this has to be balanced against the cost effectiveness and risk–benefit ratio of such regimens.

Clinical comment

Current opinion suggests that there is no significant difference in venous thromboembolism (VTE) incidence if thrombo-prophylaxis is initiated pre- or postoperatively. The optimal duration of prophylaxis after major acute or elective orthopedic surgery is still controversial.

Available literature and quality of the evidence

- Systematic reviews/meta-analyses: 2 (level I).

Findings

A meta-analysis compared three regimens for elective hip surgery: preoperative (at least 12 hours, or the evening before surgery), postoperative (12–24 hours after surgery), and perioperative (2 hours before to ≤ 4 hours after) initiation of LMWH.[8] DVT rates were 19.2, 12.4, and 14.4%, respectively, suggesting that postoperative regimes were just as effective as pre- or perioperative prophylaxis. However, the rate of major bleeding was highest in the perioperative group at 6.3%, compared to 1.4% in the preoperative, and 2.5% in the postoperative groups.

In a meta-analysis of eight RCTs,[9] extended-duration prophylaxis for ≥21 days reduced the rate of pulmonary embolism (odds ratio [OR] = 0.14; 95% CI: 0.04–0.47; absolute risk reduction [ARR] 0.8%) and symptomatic DVT (OR = 0.35; 95% CI: 0.15–0.81; ARR 1.5%) when compared with standard duration therapy (7–10 days). However, this was associated with a higher rate of minor bleeding events (OR = 2.44; 95% CI: 1.41–4.20; ARR 6.3%). There are insufficient data relevant to knee arthroplasty or hip fracture surgery.

Resolution of clinical scenario

In the absence of any contraindications or bleeding risk, the patient should receive chemical prophylaxis in the form of LMWH, 12–24 hours following acute fracture surgery. Anticoagulation should be extended for at least 21 days into her postoperative rehabilitation period to reduce the risk of out-of-hospital embolism. If available, NOACs may be used

for extended thromboprophylaxis, as they are easily administered and do not require monitoring.

Question 3: In patients with isolated lower-limb injuries who require immobilization, does thromboprophylaxis, compared to no prophylaxis, reduce thromboembolic event rates?

Rationale

Injuries at or below the knee are associated with a low-to-intermediate VTE risk, and rarely does asymptomatic DVT propagate or progress to become clinically important VTE.[10–14] In contrast, rates of DVT for injuries involving the femoral shaft have been reported up to 40%,[10,15] with proposed mechanisms, including direct endothelial injury in these higher energy fractures, hypercoagulable states following significant blood loss, as well as immobilization in the perioperative period.

Clinical comment

Routine anticoagulation for isolated lower-limb injuries requiring immobilization, is still controversial, and is not based on strong evidence or guidelines.

Available literature and quality of the evidence

- Systematic reviews/meta-analyses: 1 (level I).
- RCT: 1 (level I).

Findings

In patients who had received surgical treatment for fractures of the tibia, ankle, or foot, chemoprophylaxis with an LMWH compared with placebo did not significantly reduce the risk of clinically important VTE (RR = 0.865; 95% CI [pooled RR = 0.112–3.963], p = 0.790; homogeneity P = 0.718, I^2 = 0%).[16] For patients with lower leg casts, the POST-CAST Trial showed that chemoprophylaxis with LMWH during the full period of immobilization did not significantly reduce the risk of clinically important VTE compared to no treatment (RR: 0.8; 95% CI: 0.3–1.7).[17]

Resolution of clinical scenario

There is no evidence base for the use of prophylaxis in injuries at or below the knee. If the injury involves the femur shaft or is associated with a polytraumatic scenario or failure to mobilize, then prophylaxis with an LMWH is recommended for up to 35 days from the day of surgery[2].

Summary of answers

- Low-molecular-weight heparins remain the best anticoagulation agent currently available for thromboprophylaxis in elective orthopedic or orthopedic trauma patients. They are effective, safe, and relatively inexpensive.
- New oral anticoagulants are feasible alternatives in elective arthroplasty patients, but they should be used judiciously in patients with increased bleeding risk.
- Mechanical prophylaxis in combination with pharmacological prophylaxis should be considered in patients undergoing major orthopedic surgery. In patients with high bleeding risk or Asian patients undergoing arthroplasty, it can be provided as monotherapy.

- Thromboprophylaxis started 12 hours before surgery has not been shown to be more effective than prophylaxis initiated 12–24 hours after surgery.
- Close-proximity perioperative regimens are not recommended due to the higher risk for bleeding complications.
- Extended duration of prophylaxis is an effective and safe means to reduce the rate of symptomatic out-of-hospital venous thromboembolic events in elective hip arthroplasty patients and hip and femur trauma patients.
- For isolated lower-limb injuries below the knee requiring immobilization, routine pharmacologic thromboprophylaxis is not required.

9 Blood Transfusion

Seper Ekhtiari MD MSc[1], David W. Sanders MD FRCSC[2], and Jeffrey L. Carson MD[3]

[1] Division of Orthopaedic Surgery, Department of Surgery, McMaster University, Hamilton, ON, Canada

[2] Division of Orthopaedic Surgery, Western University, London, ON, Canada

[3] Rutgers Biomedical and Health Sciences, Newark, NJ, USA

Clinical scenario

- An 84-year-old woman is admitted to hospital with an intertrochanteric hip fracture and undergoes surgery for a cephalomedullary nail.
- Medical history is significant for coronary artery disease, hypertension, and chronic renal failure.
- On the second postoperative day, the patient is having difficulty ambulating due to fatigue. Vital signs are stable; electrocardiogram (ECG) is unchanged. Bloodwork reveals a hemoglobin concentration of 82 g/L.

Top three questions

1. Amongst patients undergoing orthopedic surgery, how common are perioperative blood transfusions compared to patients undergoing other types of surgery?
2. In patients undergoing orthopedic surgery, are perioperative blood management strategies effective at reducing transfusion rates compared to usual care?

3. In postoperative orthopedic surgery patients, what transfusion threshold results in optimal outcomes compared to usual care?

Question 1: Amongst patients undergoing orthopedic surgery, how common are perioperative blood transfusions compared to patients undergoing other types of surgery?

Rationale

Anemia is common in perioperative patients. It is important to understand how orthopedic patients compare, and if these trends are changing over time.

Clinical comment

Approximately one-third of patients are found to be anemic at their preoperative assessment.[1] In addition, perioperative anemia is an independent risk factor for increased length of stay in hospital, increased time in intensive care, perioperative complications, and mortality.[2] Patient blood management (PBM) is an evidence-based approach to reducing the need for transfusions, and, when necessary, making transfusions safer and more effective.[3] In order to implement PBM principles effectively, it is important to know how frequent the need for transfusion is among orthopedic surgery patients.

Available literature and quality of evidence

Mazzeffi et al. performed a retrospective review of the National Surgical Quality Improvement Program (NSQIP) over a five-year period comparing various surgical

specialties, including orthopedic surgery (2018, level III).[4] Slover et al. performed a database study (2017, level III) looking at 59 038 patients undergoing total joint arthroplasty and analyzed transfusion rates among this population.[5] Sherrod et al. analyzed the NSQIP Pediatric database for 1184 patients undergoing surgery for hip dysplasia to examine transfusion rates (2018, level III).[6] Soleimanha et al. performed a prospective study (2016, level II) to analyze transfusion rates among 872 patients at a trauma centre.[7]

Findings

In their retrospective review of NSQIP data, Mazzeffi et al. identified an interesting trend in transfusion rates across five different surgical specialties (orthopedics, vascular, gynecology, neurosurgery, and thoracic surgery). In the first year of the study (2011), orthopedic surgery had the highest rate of transfusions among the various specialties (22.4%). By the final year of the study (2015), this rate was down to 6.3%, and was lower than vascular and gynecological surgery (2018, level III).[4] In their large database study of nearly 60 000 patients, Slover et al. found that 18% of patients undergoing total joint arthroplasty required transfusion (2017, level III).[5] In their NSQIP pediatric database study, Sherrod et al. found 22.4% of patients undergoing surgery for hip dysplasia required transfusions (2018, level III).[6] Finally, in their study of orthopedic trauma patients, Soleimanha et al. found that 36.5% of patients required a transfusion in the perioperative period (2016, level II).[7]

Resolution of clinical scenario

- Based on large database studies, transfusion rates in orthopedic surgery range from between 20 and 35%,

compared to 5–15% in other surgical specialties.

- Based on a longitudinal study, transfusion rates in orthopedic surgery have been on the decline more recently and are now comparable to other surgical specialties.

Question 2: In patients undergoing orthopedic surgery, are perioperative blood management strategies effective at reducing transfusion rates compared to usual care?

Rationale

Transfusion of blood products is both expensive and has numerous associated risks. Thus, it is important to identify evidence-based perioperative strategies that can reduce transfusion rates.

Clinical comment

Over one hundred million units of blood are collected worldwide annually.[8] Transfusion is one of the only therapeutic interventions available to increase oxygen delivery to tissues; however, transfusion is expensive and not without risk. The total cost of a single unit of allogenic blood – including acquisition, storage, and personnel – is close to CAD$700.[9] Blood transfusion safety is continuously improving, but adverse events including transfusion-related acute lung injury (TRALI), cardiac overload, hemolysis, and infection do continue to occur.[10] A number of well-studied PBM strategies have been described, including (i) iron therapy, (ii) erythropoietin (EPO) administration, (iii) cell salvage, and (iv) antifibrinolytic therapy.

Available literature and quality of the evidence

Four separate randomized controlled trials (RCTs) (all level I) have analyzed the effectiveness of intravenous (IV) iron therapy in orthopedic surgery patients. The four studies, conducted between 2006 and 2016, randomized between 31 and 306 patients to IV iron, control, and in some cases IV iron plus EPO groups.[11–14] A meta-analysis of 32 RCTs (2019, level I, n = 4750) has evaluated the efficacy and safety of perioperative EPO administration in multiple surgical specialties, including seven orthopedic surgery trials.[15] Similarly, a meta-analysis of 25 RCTs by Li et al. (2018, level I, n = 4159) analyzed the use of EPO in total hip and knee arthroplasty.[16] A meta-analysis of RCTs (2016, level I) assessed the use of cell salvage in multiple surgical specialties, including 15 orthopedic RCTs (n = 1207).[17] Perhaps one of the most-studied PBM strategies in orthopedic surgery is the use of tranexamic acid (TXA). Comprehensive network meta-analyses have analyzed the use of TXA in total hip (2018, level I, n = 2227) and knee (2018, level I) arthroplasty.[18,19] In addition, a meta-analysis by Sun et al. (2019, level I), analyzed the use of IV, topical, or combined TXA regimens in hip and knee arthroplasty.[20]

Findings

Iron therapy

Four RCTs analyzing the efficacy of IV iron therapy in orthopedic surgery included a total of 616 patients (all level I). None of the studies found a statistically significant benefit for IV iron therapy in terms of transfusion rate, units per patient, length of stay, infection rate, or mortality.[11–14]

EPO administration

A meta-analysis of 25 RCTs (n = 4159) looking at the use of EPO in total hip and knee arthroplasty found that the use of EPO, whether compared to controls or preoperative autologous blood donation, provided significantly reduced rates of blood transfusion, with an odds ratio of 0.42 ($p < 0.0001$).[16]

Cell salvage

Meybohm et al. performed a meta-analysis which included 15 orthopedic surgery RCTs (level I, n = 1207). They found that the use of cell salvage significantly reduced the need for allogenic blood transfusion (risk ratio [RR] = 0.43; $p < 0.001$) and resulted in an average saving of 0.80 units per patient. Cell salvage did not result in a difference in infection or mortality rates.[17]

Tranexamic acid

In their network meta-analysis of 25 RCTs looking at total hip arthroplasty (level I), Yoon et al. found that IV, topical, or combined TXA were all effective at reducing transfusion rates, with no significant increase in thromboembolic events. In addition, they found that combined IV and topical TXA was superior to single route regimens.[18] Fillingham et al. conducted a similar network meta-analysis in total knee arthroplasty, including 67 RCTs and over 9000 patients (level I). They found that, while IV, topical, or combined TXA were all superior to placebo, none of the administration regimens was clearly superior to the others.[19] Finally, a meta-analysis of 26 RCTs looking specifically at the question of which administration regimen was superior was performed by Sun et al. (level I). They found that combined regimens (i.e. IV and oral administration) had significantly less blood loss (−198 mL; $p < 0.05$), significantly lower transfusion rates (RR = 2.51; p

<0.05), and no difference in thromboembolic events (p = 0.32).[20]

Resolution of clinical scenario

- Level I evidence suggests that IV iron therapy does not result in significantly reduced transfusion rates after orthopedic surgery.
- Level I evidence suggests that cell salvage and EPO administration does significantly reduce the need for transfusion in orthopedic surgery patients.
- Strong level I evidence demonstrates that TXA administration does consistently reduce the need for transfusions after total joint arthroplasty, and that combined IV and topical is as safe, and possibly more effective, than single route administration.

Question 3: In postoperative orthopedic surgery patients, what transfusion threshold results in optimal outcomes compared to usual care?

Rationale

Based on the emergence of high quality evidence, traditionally liberal transfusion thresholds have been re-evaluated and restrictive thresholds are advocated for most patients, particularly in the intensive care setting. Given the importance of early mobilization and compliance with rigorous physiotherapy routines, it is important to understand whether these same thresholds can be applied to orthopedic surgery patients.

Clinical comment

The Transfusion Requirements in Critical Care (TRICC) trial (level I) is a landmark study which randomized over 800 intensive care unit (ICU) patients to a either a restrictive (70 g/L) or liberal (100 g/L) transfusion threshold. The number of units transfused was lower in the restrictive group (2.6 vs 5.6 units; $p < 0.01$), and overall 30-day mortality did not differ between the two groups. There was, however, lower mortality in the restrictive group for patients under 55 years of age ($p < 0.02$) and less ill patients ($p < 0.02$). The only group that may have benefited from a liberal transfusion threshold were patients with acute myocardial infarction and unstable angina.[21] Since the publication of the results from the TRICC trial, the transfusion threshold of 70 g/L has become popular across a wide range of inpatient settings. Given that the TRICC trial was limited to ICU patients, it is important to understand how these findings compare in orthopedic surgery patients specifically.

Available literature and quality of evidence

Two overlapping meta-analyses of RCTs (level I) have considered the question of transfusion thresholds in orthopedic surgery patients. The two meta-analyses by Mitchell et al. (2017, level I) and Gu et al. (2018, level I) include the same nine RCTs, while Gu includes an additional RCT.[22,23] The 10 RCTs involved 3968 participants, and were conducted between 1998 and 2015. Sample sizes ranged from 66 to 2016 patients, and all trials were focused on hip and knee surgery, specifically arthroplasty and hip fracture surgery. The focus of all of these trials was on older patients, with the mean participant age ranging from 68.7 to 86.9 years old. The most common thresholds were 80 g/L for the restrictive

group and 100 g/L for the liberal group. None of the trials was found to be at high risk of bias.

Findings

In their meta-analysis of RCTs, Gu et al. (level I) analyzed cardiovascular events as their primary outcome. They found that, based on eight of the included RCTs (n = 3618), restrictive transfusion thresholds were associated with a significantly higher risk of cardiovascular events (RR = 1.51; p = 0.003), which remained the case regardless of preexisting cardiovascular disease. Subgroup analyses revealed that the increased risk of cardiovascular events was observed in patients undergoing hip fracture surgery, but not in those undergoing elective arthroplasty. In terms of secondary outcomes, based on moderate quality evidence, no difference between the two thresholds in terms of infection, 30-day mortality, or cerebrovascular accidents was found.[22]

Interestingly, in their overlapping meta-analysis, Mitchell et al. (level I) found that restrictive transfusion thresholds resulted in significantly lower infection rates compared to liberal thresholds (RR = 0.60; p = 0.004). Subgroup analysis revealed that this difference was true for the arthroplasty population, but not for the fracture patients. There was no significant difference between the two thresholds in terms of total adverse events.[23]

Resolution of clinical scenario

- Based on moderate-strength level I evidence, a restrictive transfusion threshold does reduce infection rates, particularly in those undergoing hip and knee arthroplasty surgery.

- Based on moderate-strength level I evidence, a restrictive transfusion threshold is associated with a significantly higher risk of cardiovascular events, particularly in those undergoing hip fracture surgery.

Summary of answers

- Orthopedic surgery patients are at a relatively higher risk (20–35%) of receiving a transfusion compared to other surgical specialties, though this rate may have been trending down in recent years.
- Cell salvage and erythropoietin administration are effective interventions in reducing the need for transfusions in orthopedic surgery patients.
- Tranexamic acid (TXA) is supported by extensive level I evidence as an effective and safe intervention in orthopedic surgery patients, and combined intravenous and topical TXA may the most effective regimen.
- It remains unclear whether liberal or restrictive transfusion thresholds are best for orthopedic surgery patients, with different thresholds likely indicated based on patient comorbidities and type of surgery.

10 Wound Infections

Mark D. Hasenauer MD[1], Michael D. Hunter MD[2], Kyle J. Jeray MD[2], and Atul F. Kamath MD[3]
[1] Department of Orthopaedic Surgery, University of Pennsylvania, Philadelphia, PA, USA
[2] Greenville Hospital System, Greenville, SC, USA
[3] Cleveland Clinic, Cleveland, OH, USA

Clinical scenario

- A 30-year-old male sustained a lateral split-depression tibial plateau fracture after a fall from a ladder.
- He underwent open reduction and internal fixation, and at his two-week follow-up appointment there was wound drainage with surrounding erythema.

Top three questions

1. In patients undergoing orthopedic surgery, does routine antibiotic prophylaxis, compared to antibiotic administration, prevent surgical site infections?
2. In patients with a suspected surgical site infection, what is the optimal workup leading to accurate diagnosis and treatment?
3. In patients with a surgical site infection and infected hardware, does hardware retention, compared to removal of hardware, result in improved outcomes?

Question 1: In patients undergoing orthopedic surgery, does routine antibiotic prophylaxis, compared to antibiotic administration, prevent surgical site infections?

Rationale

Optimal prophylactic antibiotic management in orthopedic surgery has not been fully answered and is an area of ongoing research.

Clinical comment

Despite established guidelines for surgical site infection (SSI) prevention, studies show that antibiotic prophylaxis is not always correctly administered.[1,2] Antibiotics should be administered within 30 minutes prior to incision, and inappropriate utilization of antibiotics contributes to antibiotic resistance and increased health care costs.[3–6]

Available literature and quality of the evidence

- Level I: 16 studies
- Level II: 8 studies
- Level III: 14 studies
- Level IV: 6 studies
- Level V: 9 studies.

Findings

Prophylactic antibiotic effectiveness was first demonstrated in 1961 in a *Staphylococcus aureus* infection model in guinea pigs; antibiotics given within one hour of bacterial

inoculation showed no inflammatory response.[7] Guinea pigs that received antibiotics >3 hours after inoculation received no more benefit than those not receiving antibiotics. Lidwell et al. demonstrated a threefold decrease in total knee and hip arthroplasty infections with usage of antibiotic prophylaxis.[8] A prospective, randomized double-blind study of general orthopedic procedures showed that a group receiving cefamandole compared to placebo had a significantly reduced rate of infection.[9] The Dutch Trauma Trial assigned 2195 patients with closed fractures to a single 2 g preoperative dose of ceftriaxone versus placebo, with a placebo group infection rate of 8.3% versus ceftriaxone rate of 3.6%.[10]

The optimal duration of antibiotics is not known with poor evidence.[11,12] Current American Academy of Orthopaedic Surgeons (AAOS) guidelines recommend antibiotic duration <24 hours, even with drains or catheters present.[12] In trauma and elective surgery populations, single-dose antibiotic prophylaxis appears to be noninferior to multiple doses.[13–15] In a meta-analysis by Morrison et al., 921 patients pooled between two studies analyzing single versus multiple postoperative antibiotic doses demonstrated no significant differences. Multiple doses of postoperative antibiotics had a slightly lower deep SSI rate (risk ratio [RR] = 0.13; 95% confidence interval [CI]: 0.02–0.99).[16] Antibiotics should be re-dosed for operations >3 hours, >2 half-lives of the antibiotic, or with blood loss >1500 mL.[17] Antibiotic dosing should be weight based to ensure adequate tissue concentrations.[1,18]

Resolution of clinical scenario

- Antibiotics should be administered within 30 minutes prior to incision.

- Perioperative antibiotic course should not exceed 24 hours.
- Antibiotics should be re-dosed when the duration of the procedure exceeds two-times the antibiotic half-life, with significant intraoperative blood loss, and dosed by weight.

Question 2: In patients with a suspected surgical site infection, what is the optimal workup leading to accurate diagnosis and treatment?

Rationale

Accurate and timely diagnosis of SSIs is important for guiding treatment.

Clinical comment

The evaluation of a suspected wound infection is clinically based. C-reactive protein (CRP) and erythrocyte sedimentation rate (ESR) are useful for diagnosis and following treatment response.

Available literature and quality of the evidence

- Level II: 7 studies
- Level III: 4 studies
- Level IV: 1 studies
- Level V: 7 studies.

Findings

The Centers for Disease Control and Prevention categorizes SSIs as *Superficial Incisional SSI* (<30 days involving skin/subcutaneous tissues), *Deep Incisional SSI* (involves deep soft tissues <30 days without implant, <1 year with implant), or *Organ/Space SSI* (involves any part of the anatomy other than incision which was opened/manipulated, <30 days without implant, <1 year with implant).[19] Infection course is subject to many variables, including organism virulence, wound condition, host factors, and presence of nonbiologic substances such as metallic implants.[6,20,21] Failure of eradication leads to colonization and further bacterial adaptation including biofilm and glycocalyx formation.[22]

Drainage, erythema, fever, and pain may signify SSI. Laboratory workup should include blood cultures, white blood cell (WBC) count, ESR, and CRP. Erythrocyte sedimentation rate peaks five days postsurgery followed by a slow and irregular decrease, often remaining elevated at 42 days after uncomplicated spine surgery.[23,24] CRP is a more effective marker for diagnosis of infection due to established postoperative kinetics, as demonstrated in spine literature, with a half-life of 2.6 days and first-order elimination kinetics.[24] Most diagnostic data are drawn from the arthroplasty literature, so caution must be taken when interpreting for trauma populations. In fracture patients, studies show persistent elevation of CRP beyond postoperative day (POD) 4 is associated with an SSI; one study demonstrated 92% sensitivity and 93% specificity for deep infection, with elevation of CRP >96 mg/L beyond POD 4 associated with infection.[25,26] When used together, ESR and CRP demonstrated a 98% sensitivity in a study of 265 children with osteoarticular infections.[27] Elevated ESR, CRP, and WBC demonstrated 100% positive predictive value of infection in 30 patients with infected nonunions.[28] For concerns of periprosthetic joint infection

(PJI) following arthroplasty for fracture, additional tests are utilized. Leukocyte esterase (LE) is an enzyme produced by activated neutrophils. Synovial fluid testing of LE showed pooled sensitivity of 81% and specificity of 97% for PJI.[29] The role of this test in infection associated with nonarthroplasty fracture treatment has not yet been investigated. Interleukin-6 (IL-6) is supported by the arthroplasty literature, but is prone to nonspecific elevation in trauma patients and less specific than CRP.[30,31] Next-generation sequencing is a molecular technology that can characterize all microbial DNA present within a sample. Further clinical testing is needed.[32] The 2018 Definition of Periprosthetic Hip and Knee Infection incorporates variables including CRP, ESR, synovial fluid WBC count or LE, synovial alpha-defensin, and synovial polymorphonuclear WBC percentage broken down into major and minor criteria. It demonstrated a 97.7% sensitivity and 99.5% specificity.[33]

An optimal diagnostic approach necessitates proper diagnosis of the infectious organism. Deep intraoperative cultures are the gold standard for diagnosis and necessary to guide treatment. Polymerase chain reaction (PCR) testing has an evolving role in diagnosing slower-growing organisms, albeit with a sensitivity of 9–85%.[34]

Radiographic imaging is normal initially; 30–50% of bone density loss is necessary to be visible on plain xrays.[35,36] Magnetic resonance imaging (MRI) is the test of choice for soft tissue evaluation; however, infection is hard to diagnose with metallic implants present.[36] Standard bone scintigraphy has high sensitivity, but lacks specificity, while technetium tc-99m-labeled leukocyte scans demonstrate excellent accuracy and sensitivity, but they are limited by cost and extensive preparation.[37] F-18 fluorodeoxyglucose (FDG) positron emission tomography (PET) demonstrates increased sensitivity and specificity as compared to prior

modes of bone scintigraphy, showing results of 100, 93, and 97% for sensitivity, specificity, and accuracy of metallic implant-associated infections and osteomyelitis, respectively.[38]

Resolution of clinical scenario

- Wound drainage, erythema, fever, and pain may suggest an SSI and should prompt workup.
- CRP and ESR in conjunction with appropriate imaging should be used to diagnose and follow a wound infection.
- MRI is the test of choice for evaluation of soft tissue infection. PET scan is an adjunct method for evaluation in the setting of metallic implants.

Question 3: In patients with a surgical site infection and infected hardware, does hardware retention, compared to removal of hardware, result in improved outcomes?

Rationale

Hardware-related infections are a challenging problem. As implants and techniques continue to improve, there is an increasing number of operatively treated fractures with subsequent associated infections.

Clinical comment

Infected hardware can affect fracture healing and cause significant morbidity with prolonged recovery.

Available literature and quality of the evidence

- Level II: 2 studies
- Level III: 3 studies
- Level IV: 3 studies
- Level V: 3 studies.

Findings

The need for continued fracture stabilization versus implant removal is a debated topic in managing infections in operatively treated fractures. Fracture stabilization and union helps both prevent and clear infections.[39] Rightmire et al. demonstrated that 32% of patients with acute infection who received irrigation and debridement, antibiotics, and hardware retention needed hardware removal before fracture healing.[40] Only 49% of original study group achieved healing and were infection-free at six months. Berkes et al. demonstrated a 71% fracture union following operative debridement, hardware retention, and culture-specific antibiotic treatment.[41] Open fractures and presence of an intramedullary nail, smoking, and *Pseudomonas* were associated with failure. It is reasonable to conclude that, in most patients, hardware should remain in place in the acute period followed by debridement and culture-specific antibiotics. Antibiotic cement-coated plates, antibiotic impregnated polymethylmethacrylate, and antibiotic cement-fashioned intramedullary nails are treatment options being used in hardware removal cases for infection eradication.[42]

Resolution of clinical scenario

- Prompt debridement and hardware retention is recommended for most acute deep infections.

- After fracture union, the hardware should be removed to reduce risk of recurrent infection.

Summary of answers

- Prophylactic antibiotics should be administered prior within 30 minutes to incision and be continued for no more than 24 hours. Antibiotics should be dosed according to patient weight, re-dosed for excessive blood loss and prolonged operative time.
- ESR, CRP, and appropriate imaging modalities should be used together as part of workup for wound infection.
- Infected hardware may prevent full eradication of infection, but must be weighed with need for fracture union. In most cases, it is recommended to retain hardware in the acute period and remove after fracture healing.

11 Smoking Cessation

Paul E. Matuszewski MD[1], David Zuelzer MD[1], and Robert V. O'Toole MD[2]
[1] Department of Orthopaedic and Sports Medicine, University of Kentucky, Lexington, KY, USA
[2] University of Maryland, Shock Trauma, Baltimore, MD, USA

Clinical scenario

- A 27-year-old female with a history of depression and tobacco abuse presents to the Emergency Department after falling off a ladder at home.
- Physical and radiographic examinations demonstrated an open tibial plafond fracture.
- She was urgently debrided and temporized with external fixation.
- She follows up in clinic one week later to schedule her definitive fixation.
- She asks what she can do to improve her chances of walking again and whether she should stop smoking.

Introduction

Despite national public health campaigns, smoking in the United States remains a common and preventable cause of morbidity and mortality. In 2015, 15.1% of all adults (36.5 million people) were current everyday cigarette smokers.[1] Smoking is linked to 480 000 deaths per year in the United States (1 in 5 deaths) and 8 million deaths worldwide and has been clearly linked to multiple types of cancer,

cardiovascular and respiratory disease, reproductive complications, and multiple other effects. Patients that smoke die on average 10 years earlier than patients that do not smoke.[2] Fortunately, this may be reversible. Five to 15 years of smoking abstinence makes the risk of coronary heart disease, stroke, and all-cause mortality drop to the level of nonsmokers.[3]

Despite widespread knowledge regarding the general ill effects of smoking on personal health, less is known about smoking with regards to the musculoskeletal system.[4] This is concerning, as orthopedic trauma is associated with a much higher rate of smoking than the general public, with some studies quoting as high as 50–60% smokers.[5] Smoking carries significant risks for the musculoskeletal system. Tobacco smoke contains approximately 4000 potentially toxic substances. Nicotine is the most frequently cited culprit, although evidence supporting this is contradictory. Basic science research has shown that nicotine has sympathomimetic action, stimulating epinephrine and norepinephrine release, causing vasoconstriction and stimulating platelet adhesion causing micro clot formation and limiting tissue perfusion.[6,7] Nicotine also reduces red blood cell, macrophage, and fibroblast proliferation and has been linked to decreased vascular endothelial growth factor, various bone morphogenic proteins, and collagen expression. It has been suggested, based on experimental animal studies, that these combined molecular influences cause nicotine to impair bone healing by inhibiting neovascularization and osteoblast differentiation.[8–11] However, other studies have shown that nicotine at lower doses may, in fact, increase osteoblast activity *in vitro*.[12,13] Thus, the negative musculoskeletal effect of nicotine may be dose dependent.

Top three questions

1. In patients undergoing orthopedic procedures, do smokers, compared to nonsmokers, have worse outcomes?
2. In patients undergoing orthopedic procedures, does smoking cessation, compared to persistent smoking, decrease the likelihood of a poor outcome?
3. In orthopedic patients, are certain modalities, compared to others, more effective at initiating smoking cessation in orthopedic patients?

Question 1: In patients undergoing orthopedic procedures, do smokers, compared to nonsmokers, have worse outcomes?

Rationale

To improve patient outcomes in orthopedics, it is critical to understand which reversible factors may predispose to poor outcome. Similarly, in orthopedics, it has been conclusively shown that smoking is associated with worse outcomes.

Clinical comment

Patients that smoke tend to be younger and have lower comorbidity profiles than nonsmokers.[14] However, despite being on average younger and healthier, orthopedic patients that smoke have been found to have longer surgical and anesthesia times, spend more time in the hospital, and have higher average hospital charges compared to nonsmokers. The reason for this discrepancy

is difficult to decipher. Patients that smoke may be more likely to have other associated underlying diagnoses that make their care more complex and smoking is more likely in patients with underlying psychiatric illnesses including depression, schizophrenia, and bipolar disorder, which have been linked to poor outcomes.[15] Regardless, smoking is now recognized as a moderator for poor outcome. Smoking increases the risk of postoperative complications of any kind as well as deep wound infections.[16] Procedures reliant on bony healing or osseointegration may be particularly susceptible. Smokers have increased time to union and nearly twice the risk for nonunion after fracture, spinal fusion, osteotomy, arthrodesis, or nonunion treatment.[17]

Findings

In the arthroplasty literature, smoking has been linked to increased risk of prosthesis-related complications. A meta-analysis of 8181 smokers undergoing total hip arthroplasty (THA) found a significantly increased risk of aseptic loosening (risk ratio [RR] = 3.015; 95% confidence interval [CI]: 1.42–6.58), deep infection (RR = 3.71; 95% CI: 1.86–7.41), and all-cause revision (RR = 2.58; 95% CI: 0.77–2.10).[18] A large retrospective cohort study of THA and total knee arthroplasty (TKA) performed at a single institution found significantly higher risk for factors associated with poor outcome including deep infection (hazard ratio [HR] = 2.37; 95% CI: 1.19–4.27) and all-cause revision (HR = 1.78; 95% CI: 1.01–3.13) in smokers.[19] A meta-analysis reviewed 528 abstracts on foot and ankle surgeries for the effect of tobacco use on an array of foot and ankle procedures. All procedures dependent on bone healing – including joint arthrodesis, fracture fixation, and deformity correction at all levels – were adversely impacted by smoking.[20] Smoking negatively impacts both the

objective and subjective outcomes of lumbar and cervical spine surgery. Patients that currently smoke at the time of spinal procedure are more likely to experience pseudarthrosis and postoperative infection and report lower subjective outcome scores.[21] In the patient who smokes and has a long-bone fracture there is an increased risk for nonunion (odds ratio [OR] = 2.32; 95% CI: 1.76–3.01; p <0.001) or delayed healing (30.2 weeks [95% CI: 22.7–37.7] for smokers, 24.1 weeks [95% CI: 17.3–30.9] for nonsmokers).[22] The Lower Extremity Assessment Project (LEAP) study looked at the impact of current and former smoking on limb-threatening open tibia fractures. Current smokers were more than twice as likely to develop infection (OR = 2.22; 95% CI: 1.01–4.91; p = 0.05) and almost four times as likely to develop osteomyelitis (OR = 3.72; 95% CI: 1.25–11.1; p = 0.01). Former smokers' risk for osteomyelitis was lower (OR = 2.80; 95% CI: 0.89–8.83; p = 0.07) than their actively smoking counterparts.[23]

Resolution of clinical scenario

Smoking has been associated with increased risk for postoperative wound complication and infection across all surgical subspecialties. However, patients that smoke are particularly susceptible to procedures reliant on osseous healing for a good outcome. This includes the osseointegration of the bone–implant interface in arthroplasty and osseous healing necessary in successful joint arthrodesis, osteotomy or deformity correction, and fracture care. Smoking is associated with increased rates of nonunion.

Question 2: In patients undergoing orthopedic procedures, does smoking cessation, compared to persistent smoking, decrease the likelihood of a poor outcome?

Rationale

In the clinical scenario presented, we described a healthy young patient that smokes at the time of a limb-threatening open fracture. If she were to stop smoking before her definitive procedure, would that change her expected outcome? The evidence is mixed.

Clinical comment

Across all surgical specialties there are good data to support that having longer periods of smoking cessation at least four weeks prior to a procedure decreases the incidence of total complications, including postoperative wound healing and pulmonary complications.[15]

Findings

A meta-analysis of randomized trials evaluated the effect of smoking cessation on postoperative complications across a range of surgical subspecialties. Trials with >4 weeks of preoperative smoking cessation showed significantly larger risk reduction than trials <4 weeks (relative risk reduction = 20%, RR = 0.80; 95% CI: 3.0–33.0; p = 0.02). Patients that quit 2–4 weeks before procedure had a similar risk profile to those that continued smoking.[24] Another meta-analysis reviewed all cohort and randomized controlled trials (RCTs) that reported postoperative complications in patients that quit smoking within six

months prior to undergoing general surgical procedures. Using a random effects model, ex-smokers were compared with current smokers.[25] Patients that quit smoking >4 weeks prior to surgery significantly lowered their risk for respiratory and wound healing complications. A multicenter, single-blinded, controlled trial randomized 105 daily smokers with acute fractures requiring acute intervention into control and intervention groups. The intervention group was given a standardized smoking cessation program for six weeks. Patients not included in the intervention arm had a significantly increased risk for postoperative complications, such as wound infection, pulmonary complication, skin breakdown, and urinary tract infection (OR = 2.51; 95% CI: 0.96–6.9).[26] Based on these reviews, it seems safe to conclude that discontinuing smoking >4 weeks before an elective surgical procedure brings wound healing and pulmonary complication rates closer to those of individuals without a smoking history and discontinuing smoking at the time of acute injury can minimize complications.

The temporal relationship between smoking cessation and surgery is still more uncertain with regards to bone healing. Animal studies have examined the chronology of smoking cessation and found a dose-dependent response between the earlier cessation of nicotine exposure after surgery and increasing spinal fusion rates.[27] A meta-analysis of human subjects undergoing spinal fusion showed smoking cessation four weeks prior to surgery could lower the rate of pseudarthrosis to a level closer to that of nonsmokers.[28] The LEAP study looked at patients who were never smokers, former smokers, and current smokers at the time of a unilateral open tibia fracture and their time to fracture healing.[23] Former smokers were defined as those that had smoked >100 lifetime cigarettes but were not currently smoking. Even when adjusted for

covariates, at two-year follow-up current smokers were 37% less likely to be united than nonsmokers (p = 0.01) and previous smokers were 32% less likely to be healed than nonsmokers (p = 0.02). While the exact chronology of smoking cessation was not examined, the authors concluded even former smokers were subject to the lingering effects of past smoking on bone healing.

Resolution of clinical scenario

Current smokers are at increased risk for wound and pulmonary complications at the time of surgery. Smoking cessation interventions at least four weeks prior to elective procedures or at the time of acute injury decrease the risk for complications. While studies on the effect of timing of smoking cessation on bone healing are limited, there may be some benefit in overall risk reduction, including fracture healing, even if the detrimental effects on bone healing may linger over a longer period.

Question 3: In orthopedic patients, are certain modalities, compared to others, more effective at initiating smoking cessation in orthopedic patients?

Rationale

Unfortunately, despite the well-recognized negative impact of smoking on orthopedic patients, there is surprisingly little evidence supporting modalities affecting smoking cessation. In general, options include counseling and with nicotine replacement therapy (NRT) or other pharmacologic options, such as varenicline.

Clinical comment

Compared to the general population, patients that smoke are more likely to be less knowledgeable of its negative health effects.[4] There are promising data to support perioperative smoking cessation counseling.

Findings

An RCT of smokers who received cessation counseling while hospitalized for acute fracture found that a brief educational intervention temporarily changed attitudes toward smoking.[29] In a study of smokers scheduled to undergo arthroplasty, a preoperative counseling intervention maintained a quit rate of 22% at one year following surgery versus 3% in a control group.[30] A separate study of smokers scheduled to undergo hip and knee arthroplasty randomized them into a control or smoking intervention group. Patients with intervention that successfully quit smoking 6–8 weeks prior to surgery showed a reduction in complication rate compared to those in the control group.[31] Elective surgery may offer sufficient motivation to reduce smoking rates, and preoperative interventions have shown benefit by reducing complication rates. However, what about the fracture patient in the clinical vignette at the beginning of this chapter? The urgent nature of her care does not allow for preoperative intervention. A single-center cross-sectional cohort study of 112 fracture patients that smoked found 48% expressed an interest in smoking cessation and 11% increased their interest in quitting smoking at the time of their injury.[4] The addition of cessation counseling may increase these rates. Of 41 smokers being treated with a circular frame external fixation for acute lower extremity injury, 56% were smokers at the time of injury and were educated on the negative impacts of smoking. Eighty-seven percent of patients were unaware of the negative effects of

smoking at the time of intervention. After counseling, 74% felt it increased their likelihood of smoking cessation and 48% successfully quit by the end of the study period.[32] The period immediately following acute injury appears to be a critical period for counseling and education regarding smoking to decrease its health burden.

Adjunctive support measures for those trying to quit or decrease smoking currently include NRT and pharmacologic support. Nicotine replacement substances may have benefit in those with strong physiologic addiction.[33] There is strong evidence that NRT enhances the efficacy of tobacco use interventions.[34] Preclinical studies support no increased risk for healing or cardiopulmonary related complications secondary to NRT, and clinical studies show a reduction in postoperative complications when NRT leads to successful smoking cessation. Other pharmacologic options supporting smoking cessation include pharmacologic behavior modifiers such as antidepressants. The most commonly prescribed is varenicline, a partial agonist of nicotinic acetylcholine receptors. In a randomized, placebo-controlled, double-blind trial of smokers willing to reduce tobacco consumption, a group of 760 patients prescribed varenicline had a smoking abstinence rate by one year of 27.0% versus 9.9% for the 750-patient placebo group; relative risk (RR = 2.7; 95% CI: 2.1–3.5).[35] Based on available studies, the most effective way to help patients cease smoking is a combination of active, guided counseling combined with NRT.

While it may be difficult or time consuming in the clinic or inpatient setting for the orthopedic surgeon to formally provide counseling for the patient without any training, there are free options available to patients that the surgeon can refer the patient to easily. The US National Tobacco Quitline (1-800-QUIT-NOW) is a publicly available,

federally funded, state executed tobacco control program. Awareness and use of this program remain low, with many physicians unaware of available services.[36] While brief, physician-guided education and support has some utility, a proactive telephone counseling service offers many superior benefits including accessibility and reduced time constraints. Many of the state-based quitlines offer free NRT in addition to the provided counseling. Physicians and providers may refer patients to the quitline via either facsimile, email or directly through the electronic medical record. This will initiate a series of phone calls from the quitline to the patient at various times to initiate the service. There is also evidence supporting a dose-dependent response to quit rates with increased number of calls to the 1-800-QUIT-NOW hotline increasing chances of quitting compared to standard self-help materials or brief advice.[37]

Resolution of clinical scenario

Orthopedic surgeons can play an important role in smoking cessation by offering education, support, and encouragement. Elective procedures and acute injuries offer important timepoints to discuss smoking cessation with patients. Patients awaiting elective procedures should be counseled to discontinue smoking at least four weeks before their scheduled procedure. Although there is no time to allow cessation prior to surgery in acute orthopedic trauma, patients with acute injury have a critical window when they may be more receptive to smoking cessation counseling. Additional evidence-supported resources are available, including NRT, behavioral modifying pharmacologic, and the 1-800-QUIT-NOW national hotline. A multimodal approach yields the highest chance of smoking cessation.

Summary of answers

- Smokers are at increased risk for wound and pulmonary complications at the time of surgery.
- Tobacco exposure negatively affects bone healing, increases nonunion and delayed union rates, and can be expected to decrease subjective outcome scores in any procedure reliant on bone healing.
- Smoking discontinuation >4 weeks before an elective procedure reliably decreases pulmonary and wound complication rates to levels approaching those of nonsmokers.
- More research is needed to support the timing of smoking cessation in regard to its effect on bone healing.
- There is strong evidence to support the merits of smoking cessation counseling, especially when planning for elective procedures or in the immediate aftermath of an acute injury.
- Physicians and health professionals can aid patients actively trying to quit smoking by offering advice and support. Nicotine replacement, pharmacologic support, and utilization of available resources, including the National Tobacco Quitline, in combination with physician-guided counseling offers the highest chance of successful smoking cessation.

12 Perioperative Medical Management

Jennifer Muniak MD, Susan M. Friedman MD MPH, Joseph A. Nicholas MD MPH, and Daniel A. Mendelson MD MSc
University of Rochester School of Medicine and Dentistry, Rochester, NY, USA

Top three questions

1. In patients presenting with a fragility hip fracture, does routine preoperative echocardiography, compared to no echocardiography, improve survival?
2. In fragility fracture patients, does orthopedic and medical co-management, compared to usual care, improve outcomes such as length of stay, mortality, and readmission?
3. In fragility fracture patients undergoing surgery, does early surgery, when compared to delayed surgery, have an effect on mortality risk?

Question 1: In patients presenting with a fragility hip fracture, does routine preoperative echocardiography, compared to no echocardiography, improve survival?

Rationale

Wide practice variations exist with regard to obtaining preoperative echocardiograms for the purposes of cardiac risk stratification. It is necessary to establish whether patients undergoing fragility hip fracture surgery benefit from this test as part of a standard preoperative evaluation.

Clinical comment

Preoperative testing, if appropriately utilized, has the potential to improve patient outcomes. However, in some contexts, echocardiography and other tests can cause iatrogenic harm. In cases when surgical intervention is considered urgent, testing can lead to surgical delay. Additionally, many fragility fracture patients are medically complicated by chronic cardiovascular conditions, and abnormal test results may trigger intensive perioperative monitoring (raising risk of delirium, limiting mobility) and medication prescribing that can be harmful in the acute fracture setting.

Available literature and quality of the evidence

There are three retrospective cohorts deemed relevant and of acceptable quality to answer this question (level III).

Findings

A retrospective review of patients treated surgically for hip fracture found transthoracic echocardiography (TTE) prior to hip fracture was not associated with improvements in hospital mortality (3.8% vs 1.8%, p = 0.18), 30-day mortality (6.9% vs 6.6%, p = 0.90), or one-year mortality (20.6% vs 20.1%, p = 0.89).[1] Similarly, another retrospective review of fragility fracture patients (>65 years old) found that inpatient mortality was not statistically different between patients who did or did not undergo TTE prior to surgical repair (2.4% vs 3%, p =

0.493).[2] A third retrospective trial found that one-year mortality was not significantly affected by perioperative TTE (p = 0.137) in older adults with similar cardiac risk profiles undergoing hip fracture repair.[3] Notably, all these trials also measured surgical timing, and echocardiography was associatxed with delay to surgical intervention.

Resolution of clinical scenario

- Echocardiogram prior to hip fracture surgery rarely changes management but often will result in delay of surgery.
- Short- and long-term mortality are not improved by routine echocardiography prior to hip fracture surgery.

Question 2: In fragility fracture patients, does orthopedic and medical co-management, compared to usual care, improve outcomes such as length of stay, mortality, and readmission?

Rationale

In an effort to improve clinical outcomes for patients who experience a fragility hip fracture, there is a growing trend for geriatricians or hospitalists to co-manage the patient alongside orthopedic surgeons. This unique model of care has yielded promising results in several centers.

Clinical comment

Patients with fragility fractures often have multiple medical comorbidities that warrant careful management by care

teams well versed in perioperative geriatric medicine. The expertise of the medical doctor (usually a hospitalist or geriatrician) and their relationship with the orthopedic surgeon has the potential to positively impact clinical outcomes in this frail patient population. Co-management is a distinct relationship between two physicians in which there is shared responsibility for patient care and outcomes. Both teams perform daily rounds, contribute to the plan of care, document, and write orders. Frequent, respectful communication between teams is expected. Most co-management programs include close collaboration and aligning of practice patterns with emergency medicine and anesthesia physicians in addition to the disciplines of nursing, social work, occupational therapists, and physical therapists. Additional features of many high-performing co-management programs include proactive hospital discharge planning, standardized order sets, and ongoing quality improvement.

Available literature and quality of the evidence

Eight studies, all prospective (level II) and retrospective (level III) cohort studies, were deemed to be the highest-quality evidence on this topic.

Findings

A sentinel study in 2008 found that, compared to usual care, co-management of fragility fractures by geriatricians and orthopedists significantly improved length of stay (4.6 vs 8.3 days, $p < 0.001$), rates of postoperative infection (2.3% vs 19.8%, $p < 0.01$), complications (30.6% vs 46.3%, $p = 0.005$) and use of restraints (0% vs 14.1%, $p < 0.001$).[4,5] In-hospital mortality and 30-day readmission rates were also improved (1.6% vs 2.5%, $p = 0.68$, and 9.8% vs 13.2%, $p = 0.35$, respectively), though neither was statistically significant.

Several medical centers have subsequently instituted comprehensive co-management programs for fragility hip fractures and compared outcomes before and after program implementation (i.e. utilizing prospective observation with retrospective, historical controls). Results from five programs are outlined below:

1. A significant reduction in hospital length of stay (6.4–5.5 days, $p = 0.0004$) with stable 30-day readmission rate and time to surgery. Increase in number of patients receiving osteoporosis evaluation and receiving outpatient follow-up in the metabolic bone clinic ($p < 0.001$) and orthopedics clinic ($p = 0.005$).[6]
2. A significant reduction in inpatient length of stay after program implementation (delta = 1.6 days, $p = 0.01$). A nonsignificant improvement in the percentage of patients operated upon within 48 hours (86% vs 96%, $p = 0.15$).[7]
3. A significant increase in the number of hip fracture patients obtaining surgical fixation within 48 hours ($p = 0.013$) and a reduction in the average length of hospitalization (19.3 vs 15.1 days, $p = 0.013$).[8]
4. Significant reductions in length of hospital stay (27.5 vs 21 days, $p < 0.001$), time to surgery (41.8 vs 27.2 hours, $p < 0.001$) and in 30-day mortality (13.2% vs 10.3%, $p = 0.04$).[9]
5. Reduction in hospital length of stay (18.2 vs 11.9 days, $p < 0.001$), decrease in cost per case by $4953 ($p < 0.001$), decrease in time to surgery (45.8 vs 29.7 hours, $p < 0.001$). No significant difference but trend in reduced mortality rate (5.0% vs 2.1%, $p = 0.06$) and readmission rate (4.6% vs 6.0%, $p = 0.56$).[10]

A prospective trial of 400 home-dwelling patients with hip fractures aged 70 and above, randomly assigned the subjects to either a comprehensive geriatric care team or a standard orthopedic ward within the same medical center. Patients in the comprehensive geriatric care arm received structured, interdisciplinary comprehensive geriatric assessment, early discharge planning, early mobilization, and initiation of rehabilitation. This was compared with standard care in an orthopedic ward. The primary outcome was mobility (as measured by the Short Physical Performance Battery) four months after surgery for the fracture. Mean scores on the Short Physical Performance Battery for the comprehensive geriatric care group were significantly higher than those of the orthopedic care group ($p = 0.01$).[11]

A population based cohort study utilizing the Danish Multidisciplinary Hip Fracture Registry studied >11 000 patients aged 65 and above with hip fracture. The subjects were grouped by admission to an integrated orthogeriatric unit versus traditional orthopedics unit. Thirty-day mortality was found to be reduced for patients in the orthogeriatric unit (adjusted odds ratio [OR] 0.69; 95% CI: 0.54–0.88). Length of stay and time to surgery were not significantly different between groups in this study.[12]

Resolution of clinical scenario

Co-management between medical doctors and orthopedic surgeons has multiple benefits for patients with fragility hip fractures, most commonly a reduction in hospital length of stay and reduction in time to surgery. Decreased readmission rates and mortality have also been found with high-performing co-management centers. Variability in patient outcomes is likely reflected in how a co-management program is operationalized.

Question 3: In fragility fracture patients undergoing surgery, does early surgery, when compared to delayed surgery, have an effect on mortality risk?

Rationale

Early surgical repair for hip fracture has become standard in many centers, yet debate remains about the optimal timing of surgical repair, and what constitutes an unacceptable delay, especially in instances when expedited surgery places demands for finite hospital resources such as operating room time.

Clinical comment

Most patients undergoing hip fracture repair are at inherently high risk of perioperative complications and mortality due to frailty, multimorbidity, and advanced age. Delay in time to surgery can add additional avoidable risk, such as increased blood loss at the fracture site leading to hemodynamic instability and anemia, prolonged bedrest leading to skin breakdown and pneumonia, and prolonged periods of severe pain at the fracture site causing delirium and poor sleep. Common reasons for delay in surgical fixation include time spent medically optimizing the patient and lack of operating room availability.

Finding the evidence

Four studies were determined to be the highest-quality evidence (level II) and are reviewed here.

Findings

A 2010 systematic review (level II evidence) included 16 studies totaling 14 171 patients aged 60 and older.[13] In five studies that adjusted for medical complexity, age, and sex, early surgery (defined variably as either <24 hours, <48 hours, or <72 hours) was associated with a significant reduction in all-cause mortality by 19% (risk ratio [RR]: 0.81, 95% confidence interval [CI]: 0.68–0.96). All 16 studies provided unadjusted estimates of mortality, and collectively found that early surgery was associated with a 45% risk reduction of one-year mortality (RR 0.55; 95% CI: 0.40–0.75; p <0.001). Four studies within the systematic review discussed postoperative complications with respect to surgical timing. Early surgery (<24 or <48 hours) was found to result in a 41% risk reduction of postoperative pneumonia compared with delayed surgery (RR 0.59; 95% CI: 0.37–0.93; p = 0.02). Early surgery was associated with a 52% reduction in the incidence of postoperative pressure ulcers (RR 0.48; 95% CI: 0.34–0.69; p <0.001). Surgical timing did not significantly affect rates of thromboembolic events.

No significant mortality benefit to early surgery was found in a 2016 multicenter retrospective cohort study of 243 patients who had sustained fragility fracture of a native hip with median time to surgery of two days.[14] On Kaplan–Meier plotting, no relationship was found between timing of surgery (either <24 hours, 24–48 hours, or >48 hours), and mortality at 3 or 12 months. A higher American Society of Anesthesiologists (ASA) grade, however, was associated with a shorter survival time in this study.

A large, multicenter retrospective cohort study in Italy evaluated mortality risk at one year of 405 037 patients aged 65 and over who had undergone surgery for hip fracture.[15] Those who had surgery within two days of admission were found to have a significantly lower one-year

mortality than those who waited >2 days (HR: 0.83; 95% CI: 0.82–0.85).

Time from fracture to surgery (<12 hours, >12 hours; <36 hours and >36 hours) failed to have a significant effect upon one-year mortality in a prospective observational study of 2916 patients with hip fracture ($p = 0.40$).[16] More patients with high medical complexity as measured by ASA classification (groups IV and V) were in the late surgery group compared with the early surgery groups. Nonsignificant trends for adverse medical complications were found in those who had longer wait times for surgery (i.e. pressure sores, urinary tract infections, thrombosis, and pneumonia).

Resolution of clinical scenario

- Prompt surgical fixation for fragility hip fracture is indicated for patients who are medically optimized. There is a benefit of early surgery upon mortality risk as well as lower risk of common postoperative complications such as pressure ulcers, pneumonia, and delirium.
- To minimize mortality risk, timing of surgical intervention should be within 48 hours of fracture.[17] Some data have failed to show a significant improvement in mortality within the 72-hour window from fracture to OR,[14,16] suggesting that perhaps there is a plateau in the benefit of expedited surgery within this time period. Notably, early surgery was not associated with an increased risk of mortality in these study populations.

Summary of answers

- Routine echocardiogram does not improve outcomes for patients with hip fracture and may lead to unnecessary delays in care. Echocardiogram should be reserved for patients with evidence of new or unstable cardiac conditions that would benefit from cardiac intervention prior to surgery.
- Co-management between medical providers and orthopedic surgeons has the potential to decrease time to surgery, length of stay, mortality, and hospital readmission.
- Prompt surgical fixation of fragility hip fractures (<48 hours from fracture) is indicated for patients who are medically optimized in order to reduce risk of mortality and postoperative complications.

13 Orthobiologics

John A. Buza III MD and Thomas A. Einhorn MD
Department of Orthopedic Surgery, NYU Langone Orthopedic Hospital, NYU Langone Medical Center, New York, NY, USA

Clinical scenario 1

- A 64-year-old male with insulin-dependent diabetes and a 40 pack-year smoking history presents after a motor vehicle accident with an open tibial shaft fracture. The patient undergoes irrigation and debridement and placement of a reamed intramedullary nail.
- One year after presentation, the patient presents with continued pain at the fracture site. On plain radiographs, there is a continued gap at the fracture site with no evidence of cortical bridging.

Clinical scenario 2

- A 55-year-old obese female with chronic debilitating low back and right leg pain is found to have a degenerative spondylolisthesis of L5–S1 with significant stenosis.
- The patient has failed conservative therapy and is indicated for L5–S1 decompression and transforaminal lumbar interbody fusion.

Top three questions

1. In patients with open tibial shaft fractures, does the addition of bone-morphogenetic protein (BMP) at the fracture site during intramedullary nailing reduce the risk of nonunion compared to intramedullary nailing alone?
2. In patients with long-bone nonunions, does the use of BMP during revision surgery improve the rate of union compared to revision surgery alone?
3. In patients undergoing primary spinal fusion, does the use of BMP improve the rate of union compared to the use of iliac crest bone graft?

Question 1: In patients with open tibial shaft fractures, does the addition of bone-morphogenetic protein (BMP) at the fracture site during intramedullary nailing reduce the risk of nonunion compared to intramedullary nailing alone?

Rationale

Delayed fracture healing and nonunion can present a challenging clinical scenario for the treating physician. Recombinant human bone morphogenetic protein-2 ([rh]BMP-2) is the most studied orthobiologic used to enhance fracture healing.

Clinical comment

While the majority of fractures heal uneventfully, it has been reported that 5–10% of fractures either fail to unite or demonstrate a delay in healing, and this risk varies

depending on the bone involved (e.g. higher risk of delayed or nonunion in fractures of the tibia and proximal fifth metatarsal).[1] The concept of *healing* itself is also variably defined, as it can refer to radiographic healing (e.g. complete bridging at all cortices), clinical healing (e.g. no pain, return to activity), or a combination of the two. Therefore, alternative strategies designed to enhance fracture healing and to improve the treatment of delayed unions and nonunions are required. Growth factors, by virtue of their ability to regulate cell behavior, have been studied as a potential therapeutic to enhance fracture healing. The growth factors known to be expressed during fracture healing include BMPs, transforming growth factor (TGF) beta, fibroblast growth factor (FGF), and platelet derived growth factor (PDGF).[2–9] Bone morphogenetic proteins are members of the TGF-β superfamily, and have been most extensively studied in the context of fracture healing.[10] Bone morphogenetic proteins mediate their effect by binding to osteoprogenitor cells, thereby increasing the transcription of osteoinductive genes such as RUNX2 to enhance osteoblast differentiation.[11]

Two different recombinant BMPs have been approved by the Food and Drug Administration (FDA) for clinical use in specific populations: (1) rhBMP-2 (INFUSE® Bone Graft, Medtronic), which may be used for acute open tibial shaft fractures in addition to standard fixation with intramedullary nail, or as an adjunct treatment to single-level anterior interbody lumbar-spinal fusion (L2–S1) in patients with degenerative disc disease, and (2) rhBMP-7 (OP-1 Putty, Stryker) which has received a humanitarian device exemption approval in tibial nonunion when an autograft is not allowed or has failed.[12] While both of these BMPs have been approved for clinical use, their testing and regulation have been different.

Available literature and quality of evidence

There are a number of high-quality studies demonstrating the efficacy of rhBMP-2 in enhancing fracture healing in animal models.[13–15] To date, there are three level I studies evaluating the efficacy of rhBMP-2 in enhancing fracture healing in the setting of open tibial shaft fractures.

Findings

The first randomized controlled trial (RCT) to test the safety and efficacy of rhBMP-2 was the BESTT (BMP-2 Evaluation in Surgery for Tibial Trauma) trial.[16] In this trial, Govender et al. randomized 450 patients with an open tibial shaft fracture to receive either standard of care (intramedullary nail and soft tissue management, n = 150) or the standard of care plus an implant containing rhBMP-2/absorbable collagen sponge (0.75 mg/mL, n = 151 or 1.5 mg/mL, n = 149). The high-dose rhBMP-2 group (1.5 mg/mL) had significantly faster healing rates, lower infection rates (among Gustilo-Anderson type IIIA and IIIB fractures), and a significant reduction in secondary interventions.[16] At 12 months after surgery, 58% of the BMP-2 group were “healed,” compared to 38% of the group treated with intramedullary nail alone (p = 0.001). The study defined *healing* as a combination of radiographic healing and meeting clinical criteria for healing. There were no significant differences in complications or adverse events between treatment groups. Based on the results of this study, the FDA granted premarket approval for rhBMP-2 for the treatment of acute (within 14 days), open tibial shaft fractures. Following the publication of this study, other investigators noted the high proportion of patients in the control group that underwent unreamed intramedullary nailing compared to the study group.[17] Reamed intramedullary nailing has been shown to have a possible

benefit in the treatment of tibial shaft fractures, and was therefore likely a strong confounding variable in the BESTT trial results.[18]

Since the FDA approval of BMP-2 for clinical use, several trials using BMP-2 have had less-promising results. In 2006, Swiontkowski et al. combined the data from the original BESTT trial with a second prospective RCT using the same methodology.[19] The authors evaluated the use of rhBMP-2 in open tibial shaft fractures in two separate subgroups: (1) 131 patients with Gustilo-Anderson type 3A or 3B fractures and (2) 113 patients treated with reamed intramedullary nail.[19] Within each subgroup, a comparison was made between those receiving rhBMP-2 and controls who did not receive rhBMP-2. In the first subgroup, the authors found that there was a significant improvement in the rhBMP-2 groups, including fewer bone-grafting procedures ($p = 0.0005$), fewer patients requiring secondary interventions ($p = 0.0065$), and a lower rate of infection ($p = 0.0234$) compared to the control group.[19] In the second subgroup, there was no difference between those that received rhBMP-2 and those that did not. The authors concluded that rhBMP-2 significantly reduces the frequency of bone grafting in Gustilo-Anderson type 3 fractures, but that this study was not originally designed for subgroup analysis, and therefore the data should be viewed with caution. In addition, the authors stated that, although rhBMP-2 did not have any significant difference in patients that underwent reamed intramedullary nailing, there was a trend toward improvement in the rhBMP-2 group, and therefore larger RCTs should be performed to answer this question.

In 2011, Aro et al. evaluated the efficacy of rhBMP-2 in an RCT of 277 patients with open tibial shaft fractures treated with reamed intramedullary nailing.[17] The authors found no

significant difference in the rate of fracture healing or need for secondary procedures between treatment groups. Of note, there was a trend toward a higher rate of infection in the rhBMP-2 group compared to the control group (19% vs 11%, p = 0.0645; difference in infection risk = 0.09; 95% confidence interva: 0.0 to 0.17). The authors concluded that the healing of open tibial shaft fractures treated with reamed intramedullary nailing was not significantly accelerated by the addition of rhBMP-2. The trend toward an increased rate of infection differed from previous studies which demonstrated a possible decrease in infection rate with use of rhBMP-2, and requires further study.

Another consideration with regards to the use of rhBMP-2 is cost. The use of rhBMP-2 may add anywhere from $5000 to $15 000 to the cost of treatment, depending on the amount of protein needed.[20] Proponents argue that these costs are offset by savings related to decreased operative time, lack of a bone grafting procedure, quicker hospital discharge, and faster return to work. There is limited evidence to support these claims, and a high risk of bias as the authors received financial support from the BMP manufacturing company.[21,22] A 2007 systematic review of RCTs did find that BMPs were associated with a reduced operating room time, improvement in clinical outcomes, and a shorter hospital stay as compared to autograft.[23] This study evaluated both rhBMP-2 and rhBMP-7, and included acute tibial fractures, nonunions, and spinal procedures. The true cost efficacy of BMP is probably not known at this time. There is a need for more rigorous cost-effectiveness analysis related to the use of BMP.

Resolution of clinical scenario

- rhBMP-2 may assist with the healing of open tibial fractures treated with unreamed nails, but it has shown no effect when reamed intramedullary nailing is performed.
- There is conflicting evidence that BMP improves infection rates.
- The high cost and safety concerns for the use of rhBMP-2 currently limit its utility as a therapeutic in the treatment of open tibial shaft fractures.
- Further research aimed at increasing the clinical efficacy of rhBMP-2, while decreasing the risk of side effects and reducing overall cost, may improve the therapeutic potential of this growth factor.

Question 2: In patients with long-bone nonunions, does the use of BMP during revision surgery improve the rate of union compared to revision surgery alone?

Rationale

Delayed fracture healing and nonunion is commonly treated with autologous bone grafting, which has been shown to enhance fracture healing. Given the increased risk of complications and donor site morbidity with harvesting autograft bone, several studies have evaluated the efficacy of using BMP in treating nonunions.

Clinical comment

Fracture nonunion is a challenging clinical scenario, and the cause of delayed healing is frequently multifactorial. To

enhance fracture healing, autologous bone grafting has traditionally been used, as it not only provides structural support but also contains osteoinductive and osteogenic factors to assist with healing. The major drawback of autologous bone grafting is the donor site morbidity.[24,25] Therefore, several investigators have evaluated the efficacy of BMP in enhancing fracture healing for long-bone nonunions.

Bone morphogenetic protein-7, also known as osteogenic protein-1 (OP-1), is a member of the TFG-β superfamily that has been shown to be involved in fracture healing in experimental models. This molecule demonstrates an increased expression during endochondral ossification, and has been shown to strongly induce osteoblastic differentiation.[6,26] The strong association between fracture healing and BMP-7 expression led to human clinical studies to rescue nonunions, potentially through the stimulation of local osteoprogenitor cells.

Available literature and quality of evidence

Overall, there are few high-quality studies on the use of BMP-7 in treatment of long-bone nonunions. A 2010 Cochrane systematic review identified eight RCTs of the use of rhBMP-7 in fracture healing, however, these studies varied substantially in their methodology and setting.[27] Overall, the quality of the studies was graded “poor,” as most studies were small, did not report methods of randomization or allocation, or were industry sponsored.[27]

Findings

The first clinical trial of BMP-7 was a prospective RCT of 122 patients with 124 tibial nonunions, half of whom had previously been treated with intramedullary nailing.[28] The primary inclusion criterion was a tibial nonunion of at least

nine months' duration, with no evidence of healing in the three months prior to surgery. All patients received standard of care treatment with insertion of an intramedullary rod, and were randomized to receive either rhBMP-7 in a type I collagen carrier (treatment group, n = 63) or autologous bone graft (control group, n = 61).[28] At nine months after surgery, 81% of those treated with rhBMP-7 and 85% of those treated with autogenous bone graft were judged to have been treated successfully (p = 0.524).[28] Using the same time point, 75% of those in the rhBMP-7 group and 84% in the bone graft group had “healed” fractures, as determined by radiographic criteria (p = 0.218). The authors concluded that rhBMP-7 is a safe and effective alternative to bone graft for the treatment of tibial nonunion, without the added donor site morbidity from obtaining autologous bone graft.[28] While the data showed that BMP-7 was safe and effective, they showed no improvement compared with autologous bone grafting. As a result, the FDA did not provide premarket approval for this treatment. Instead, the FDA issued a *humanitarian device exemption*, allowing a limited distribution to 4000 patients per year only at institutions where an institutional review board (IRB) was present to monitor the use of this treatment.

There are a number of other complications associated with BMPs that are related to either the initial inflammatory response induced by the protein (seroma, neuritis, neck swelling) or their osteoinductive properties (heterotopic ossification, transient osteopenia).[29–31]

As a result of these concerns, rhBMP-2 is not approved for use in children, pregnant women, and cancer patients. rhBMP-2 is also contraindicated for use in the cervical spine as a result of severe complications including infection and dysphagia.[32,33] Similar to BMP-2, concerns regarding

patient safety and high cost surround the use of BMP-7. While there are fewer studies on the use of BMP-7 in the treatment of fracture and nonunion compared to BMP-2, similar side effects may occur, such as seroma, significant edema near the application site, and heterotopic ossification.[30,34] Similar to BMP-2, BMP-7 is expensive and the cost-effectiveness of this treatment modality is not known.

Resolution of clinical scenario

- In early studies, rhBMP-7 was shown to be equally effective as autologous bone grafting in the treatment of tibial nonunion in the context of intramedullary (IM) nail fixation as a secondary intervention.
- A variety of studies have demonstrated promising results for the use of rhBMP-7 in other long-bone nonunions, but the true cost and potential complications associated with this growth factor treatment are not known.
- Further high-quality evidence is needed to elucidate the future role of rhBMP-7 in the treatment of long-bone nonunions.

Question 3: In patients undergoing primary spinal fusion, does the use of BMP improve the rate of union compared to the use of iliac crest bone graft?

Rationale

Lumbar spinal fusion has been shown to significantly relieve pain and improve function in patients with degenerative lumbar spondylolisthesis. The risk of pseudarthrosis in patients undergoing spine fusion with iliac crest bone graft (ICBG) is estimated to be as high as 12%, with advancing age being a risk factor for this complication.[35] The use of BMP to enhance spinal fusion has been studied extensively.

Clinical comment

Pain and disability from degenerative spine disease, particularly low back pain, is a tremendous burden on both patients and society. Treatment of this disorder is typically conservative, although fusion of the spine is an option for patients who have failed conservative management. This can be accomplished from an anterior, posterior, or combined approach, and stability and fusion can be accomplished with or without the use of instrumentation. The gold standard to enhance fusion is autograft in the form of ICBG (ICBG), although there is significant morbidity associated with harvesting it.[36] Additional drawbacks of ICBG include increased operative time, blood loss, and postoperative pain.[36] In an effort to decrease the need of autologous graft, orthobiologics including BMP-2, have been used with increasing frequency.

Available literature and quality of evidence

Animal studies have demonstrated the efficacy of rhBMP-2 in spinal fusion.[37–42] There are a number of high-quality RCTs comparing the use of BMP-2 with ICBG in patient's undergoing lumbar spinal fusion.[43–49]

Findings

In 2002, Boden et al. first evaluated the efficacy of rhBMP-2 in enhancing posterolateral spinal fusion.[49] In this study, 25 patients were randomized in a 1 : 2 : 2 ratio to instrumented posterior fusion supplemented with autograft, instrumented posterior fusion with the addition of BMP-2, or BMP-2 alone without instrumentation.[49] The patients treated with BMP-2 (with or without instrumentation) achieved 100% rate of fusion at one-year follow-up, compared to only 40% of those patients treated with instrumentation and autograft ($p = 0.004$). The promising results of this pilot study led to a larger randomized study comparing rhBMP-2 in an absorbable collagen sponge carrier versus ICBG in combination with a structural allograft dowel in 131 patients undergoing anterior lumbar interbody fusion (ALIF).[48] At two-year follow-up, the rate of fusion (defined as radiographic healing based on four criteria as assessed by blinded radiologists) was significantly greater in the rhBMP-2 treated patients (98.5% vs 76.1%, $p < 0.001$).[48] The rate of revision surgery was also significantly higher in the control group, with eight patients returning to the operating room as compared to only two patients in the rhBMP-2 group (15% vs 3%, $p < 0.05$).

As the early results of BMP-2 use were promising in enhancing lumbar spinal fusion, novel carrier methods were developed. A modification of the BMP-2 carrier was developed which included a matrix that contained 15% hydroxyapatite and 85% β-tricalcium phosphate particles, and demonstrated improved properties with respect to bone remodeling.[50] Dimar et al. studied the use of this novel carrier in 463 patients who underwent posterolateral instrumented fusion randomized to receive either autogenous ICBG or BMP-2.[45] The authors found that patients in the ICBG group had longer operative times and greater blood loss, although the length of hospital stay was

comparable with the BMP-treated group. The rates of fusion were higher for rhBMP-2 at all time points, with 96% achieving fusion by radiographic parameters compared to 89% at two years ($p = 0.014$). Several other high-quality RCTs have supported the efficacy of BMP-2 in enhancing lumbar spinal fusion compared to ICBG,[44,47] while others have shown that there is no difference in fusion rates between BMP-2 and ICBG.[43]

A cost analysis of BMP-2 use was performed in conjunction with an RCT of patients over 60 years of age who underwent posterolateral lumbar fusion.[51] The investigators found that, compared to patients treated with BMP-2, the final costs at two years were over $2000 higher per patient for those treated with autogenous ICBG. The authors suggested that the increased expenses in the ICBG group may have been related to the nonsignificant increased rate of nonunion and subsequent revision operations.[51]

Resolution of clinical scenario

- High-quality RCTs indicate that rhBMP-2 is effective in achieving fusion and this rate of fusion is superior, or at least equivalent, to that achieved with ICBG.
- rhBMP-2 does not appear to be associated with significantly increased cost or rate of complications compared to ICBG in achieving lumbar spine fusion.

Summary of answers

- rhBMP-2 may enhance fracture healing in open tibial shaft fractures, but has shown no beneficial effect when reamed intramedullary nailing is performed.

- The high cost and safety concerns for the use of rhBMP-2 currently limits its utility as a therapeutic in the treatment of open tibial shaft fractures.
- In early studies, rhBMP-7 has shown to be equally effective as autologous bone grafting in the treatment of tibial nonunion.
- High-quality RCTs indicate that rhBMP-2 is effective in achieving lumbar spine fusion and this rate of fusion is superior, or at least equivalent, to that achieved with ICBG.

Clinical scenario

- A 32-year-old woman presents to your fracture clinic with a displaced clavicle fracture.
- Your physical examination reveals multiple bruises across her chest, back, and arms which are in various stages of healing.
- Radiographs reveal a previous clavicle fracture and a partially united ulna fracture.

- The woman presents with her husband, who appears agitated and will not let her answer medical questions for herself.

Top three questions

1. In adult women with orthopedic injuries who present to fracture clinics, what is the prevalence of intimate partner violence (IPV), and how does this compare to the general population?
2. Do specific educational programs, compared to traditional education, for healthcare professionals improve universal IPV identification and referral to assistance programs?
3. In adult women who present to fracture clinics, are universal IPV identification and assistance interventions, compared to standard practice, effective at improving health outcomes for women?

Question 1: In adult women with orthopedic injuries who present to fracture clinics, what is the prevalence of intimate partner violence (IPV), and how does this compare to the general population?

Rationale

To determine the relevance of IPV (also known as *domestic violence*) to orthopedic practice, it is important to understand how frequently it affects individuals with orthopedic injuries.

Clinical comment

While healthcare professionals (HPCs) have a duty of care to protect all vulnerable patients, the prevalence of IPV amongst orthopedic injury patients is an important factor in determining the amount of resources that fracture clinics should invest to implement IPV identification and assistance programs.

Available literature and quality of the evidence

PRAISE (PRevalence of Abuse and Intimate Partner Violence Surgical Evaluation), a large, multinational, cross-sectional study, is the only study to have been conducted that assesses the prevalence of IPV within women attending fracture clinics.[1] To determine prevalence, women (n = 2945) attending fracture clinics (n = 12) located across Canada, the United States of America, the Netherlands, Denmark, and India were asked to complete an anonymous questionnaire. Additionally, multiple studies have been conducted to assess prevalence in other healthcare settings,[2] as well as the general population.[3] The best available evidence is a systematic review by Sprague et al. which examined IPV prevalence rates across medical and surgical healthcare settings and provided pooled prevalence estimates.[2] This review included 37 studies with a primary aim of determining IPV prevalence rates in adult women presenting to physicians regardless of medical specialty. Studies were conducted in family medicine (n = 15), emergency medicine (n = 12), obstetrics and gynecology (n = 3), internal medicine (n = 3), or multiple specialties (n = 4). Lastly, a large-scale systematic review conducted by the World Health Organization (WHO) examined IPV prevalence in the general population.[3] This review included all representative, population-based studies that examined prevalence of IPV. The study

included data from 185 studies from 86 countries. Because prevalence studies do not address therapeutic research questions, the level of evidence schema is not applicable and is therefore not provided here.[4]

Findings

IPV prevalence in orthopedic populations

The PRAISE study asked women to report experiences with IPV in their lifetime, within the last 12 months, and acutely.[1] For the purpose of this study, IPV was defined as physical, emotional, sexual, psychological, or financial abuse between intimate partners. Results showed that one in three participants experienced IPV at some point in their lifetime (34.6%; 95% confidence interval [CI]: 32.8–36.5%) and one in six experienced IPV within the past year (16.0%; 95% CI: 14.7–17.4%) (Figure 14.1). Additionally, one out of every 50 participants (2.7%; 95% CI: 1.3–2.2%) were attending fracture clinics to receive treatment for an injury sustained as a direct result of IPV (acute prevalence).

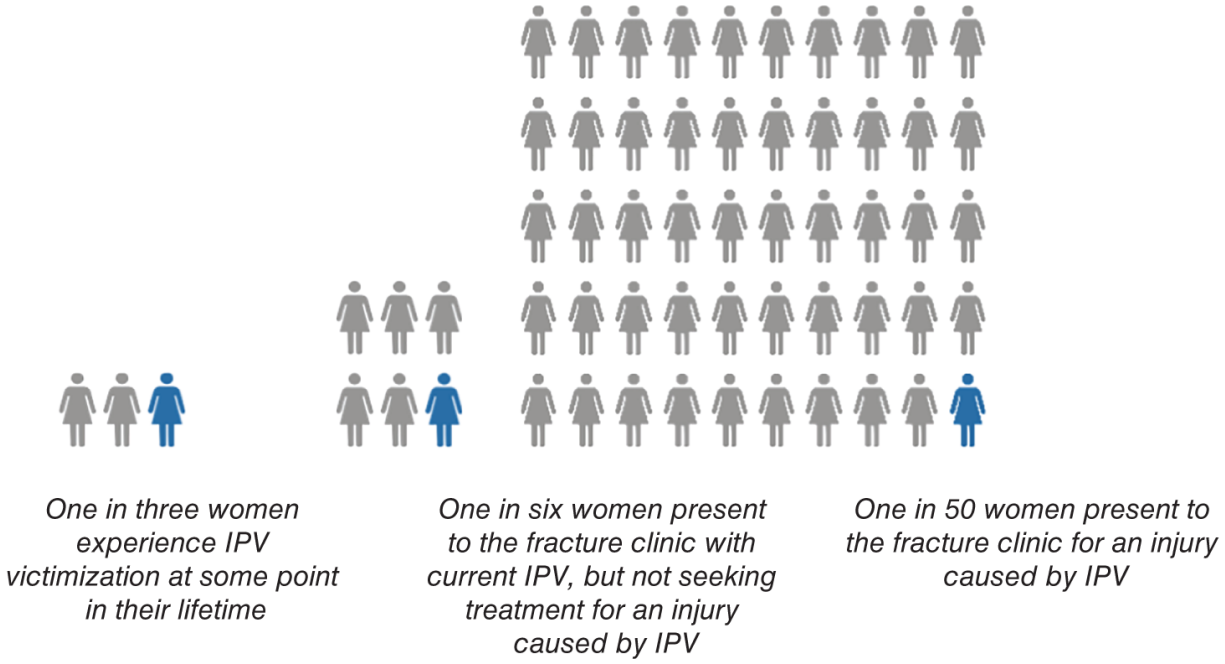

Figure 14.1 Prevalence of IPV in orthopedic populations.

IPV prevalence in other patient populations

The systematic review by Sprague et al. pooled the results of 10 studies conducted in emergency medicine which estimated a lifetime IPV prevalence rate of 38%.[2] Similar results were found in family medicine (40%, n = 12) and slightly higher in other subspecialties including obstetrics and gynecology (59%, n = 4). Pooled 12-month IPV prevalence rates were 20% in both family medicine (n = 8) and emergency medicine (n = 7). Additionally, between 2 and 4% of female patients presenting to emergency medicine settings were found to have injuries that were caused by IPV. There was heterogeneity in how studies defined IPV; however, this did not prevent pooling.

IPV prevalence in the general population

The systematic review by the WHO (2013) pooled the results of 155 population-based studies from 81 countries.[3] The estimated global lifetime prevalence for physical and sexual IPV among women who have been in relationships

was 30% (95% CI: 27.8–32.2%). Regional pooled estimates of prevalence ranged from 16.3% (95% CI: 8.9–23.7%) in East Asia to 65.6% (95% CI: 53.6–77.7%) in Central Sub-Saharan Africa. The pooled estimate for North America was 21.3% (95% CI: 16.2–26.4%) and ranged from 19.3% (95% CI: 15.9–22.7%) to 27.8% (95% CI: 22.7–33.0%) in Europe, depending on location.

Resolution of clinical scenario

- The lifetime prevalence of IPV among orthopedic patients is similar to the global prevalence, but higher than the North American general population prevalence.
- Orthopedic surgeons should be aware of the potential for IPV to be directly affecting the lives of their patients.
- Orthopedic surgeons should consider IPV as a possible cause of injury, or coexisting life circumstance.
- Concerning features in this clinical scenario include recurrent fractures, fractures, and bruises at various stages of healing, and the accompaniment of an agitated and controlling partner.
- The absence of these signs does not indicate the absence of IPV.

Question 2: Do specific educational programs, compared to traditional education, for healthcare professionals improve universal IPV identification and referral to assistance programs?

Rationale

Though orthopedic surgeons and allied HCPs are uniquely positioned to identify and provide critical assistance to women experiencing IPV, they often report barriers to doing so. Previous research has found that education is one key barrier. It is therefore important to understand whether an educational program for HCPs is an appropriate method for improving IPV identification and assistance programs.

Clinical comment

Continuing education that helps HCPs safeguard vulnerable populations is an important part of orthopedic practice. Educational programs that supply HCPs with knowledge about IPV, strategies for improving care, and information on local resources may be helpful for improving existing IPV identification and assistance programs.

Available literature and quality of the evidence

A single pretest–posttest study, EDUCATE (Education on Domestic Violence: Understanding Clinicians' and Traumatologists' Experiences), is available that evaluated the impact of an educational program on 140 orthopedic fracture clinic staff (level III evidence).[5,6] The program focused on teaching HCPs how to identify cases of IPV and provide assistance with an emphasis on practical training and referral to locally available resources. It included specific phrases to use when asking about IPV as well as videos of HCPs demonstrating how to ask about IPV and providing assistance upon disclosure. The study assessed changes in HCPs' knowledge, attitudes, beliefs, and self-reported behaviors (KABB) using the Physician Readiness to Manage IPV Survey (PREMIS) both immediately and

three months after completing the educational program. The PREMIS is a self-administered questionnaire and consists of 10 validated subscales which are scored individually and include: (i) perceived preparation to manage IPV, (ii) perceived knowledge of important IPV issues, (iii) actual knowledge, (iv) preparation, (v) legal requirements, (vi) workplace issues, (vii) self-efficacy, (viii) alcohol/drugs, (ix) victim understanding, and (x) practice issues. Additionally, there are two systematic reviews available on this topic; however, neither review presents a meta-analysis. The first is a systematic review by Waalen et al. which included any study that investigated barriers to provider IPV identification programs or that tested an intervention designed to change provider behaviors around IPV identification.[7] This study included 24 articles, 12 on barriers and 12 on educational interventions. The second is a systematic review by Zaher et al. which included randomized controlled trials (RCTs) of educational interventions among physicians.[8] This review included nine RCTs that described different educational approaches with various outcome measures. Both systematic reviews are considered level II evidence.

Findings

Effect of educational programs for HCPs on IPV identification and assistance

The pretest–posttest study evaluating the EDUCATE program found HCPs had significantly improved scores for KABB on all 10 PREMIS subscales immediately after training (p values ranged from <0.0001 to 0.0056) and on 8 out of the 10 subscales three months after training (all p <0.0001). This suggests that HCPs were better prepared to identify and assist with IPV after completing the educational program. Contrastingly, the systematic review

by Waalen et al. found, based on the 12 studies evaluating educational interventions, that education of HCPs alone had no effect on IPV identification rates.[7] However, when paired with other strategies (i.e. providing specific questions to ask), educational programs were found to have a significant increase on identification rates (no point estimate provided). Other strategies included introducing a protocol for IPV identification and referral or having a designated IPV advocate staff member. Similar results were found in the systematic review by Zaher et al.[8] Of the nine RCTs included in the study, three examined the effects of educational interventions and found an increase in IPV knowledge, but no change in behavior regarding identification of IPV. The other six studies investigated the effects of multifaceted educational interventions and were found to benefit victims of IPV and increase referrals to IPV resources.

Clinical pearls from the EDUCATE study

The EDUCATE program advocates for fracture clinics to take an active role in identifying and providing assistance to women experiencing IPV (Figure 14.2). Table 14.1 includes tips from the EDUCATE program on what to consider when asking patients about IPV. For more information about the EDUCATE program, and IPV in orthopedic patients, please go to www.IPVeducate.com, or the Canadian Orthopaedic Association (COA) or American Academy of Orthopaedic Surgeons (AAOS) IPV position statements.[9,10]

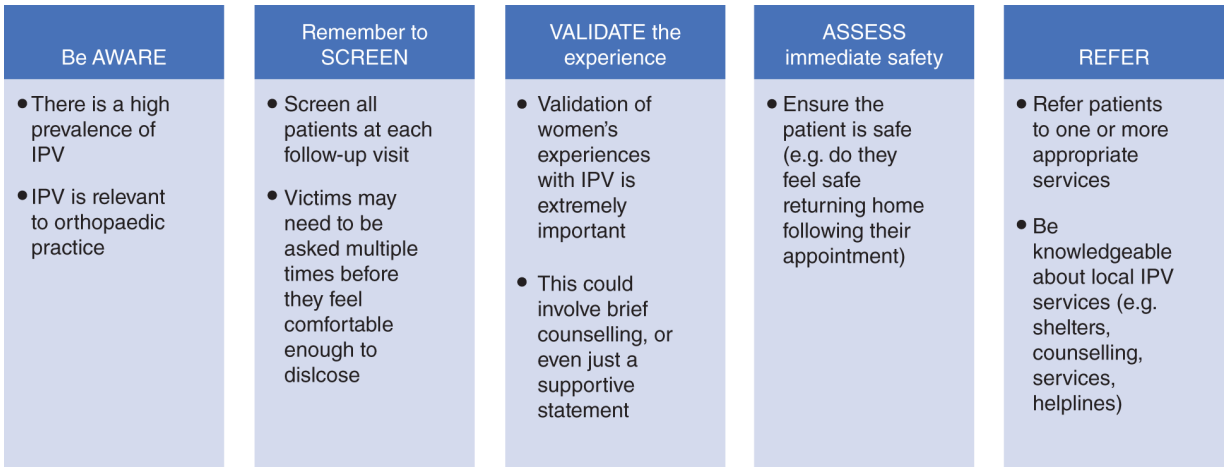

Figure 14.2 Role of the orthopedic surgeon.

Table 14.1 Tips for healthcare providers on asking about IPV from the EDUCATE program.

	Tips for healthcare providers
WHO	• Being a woman is the strongest single predictor for becoming a victim of IPV • IPV affects women of all races/ethnicities, socioeconomic status, age, and relationship status • Some signs of IPV include: frequent injuries, injuries at different stages of recovery, strangulation injury, explanation for mechanisms of injury that do not match the injury pattern, chronic unexplained pain, substance abuse, depression, anxiety • However, not all victims show these signs – the best way to consistently identify IPV is to **ask all female patients**
WHEN	• Ask about IPV at any time during a fracture clinic appointment; mid-appointment may be most appropriate (once rapport has been established) • Develop a routine and conversation starter that is comfortable for you and fits with your practice • Important to ask about IPV at each appointment – women may need to be asked multiple times before they feel comfortable enough to disclose IPV

	Tips for healthcare providers
WHERE	• Ensure environment is safe to ask (i.e. no others present, including partners) • If partners won't leave, you can make a statement that reflects routine practice (even if it's not something you specifically need to have done) i.e. “Mr. Smith at this point in time we need to take Mrs. Smith in for an x-ray. Could you please wait in the waiting room until we call you?”

	Tips for healthcare providers
HOW	• Don't use the words *abused* or *battered* – women may not identify with these labels or recognize their partner's behaviors as abusive • When there are injuries that are suggestive of IPV you could try saying something like: “The injuries you have suggest to me that someone hit you. Is that possible?” “In my experience, often women get these kinds of injuries from someone who has hit them. Has this happened to you?” • When there are injuries not suggestive of IPV, you could try saying something like: “From my experience, I know that being hurt physically or emotionally at home is a problem for many women. Is it a problem for you in any way?” “We know violence in the home affects many women and directly affects health. Have you ever experienced being hurt physically or emotionally at home?” “Violence can be a problem in many women's lives, so I now ask every female patient I see about their safety in their relationships. Do you feel safe in your relationship?”

As the treating physician your role is not to be an expert in delivering IPV interventions. Instead it is important to be aware of IPV, make the effort to identify patients

experiencing IPV, validate their experience, assess safety and refer appropriately.

Resolution of clinical scenario

- Orthopedic surgeons looking for education on IPV should look for programs, such as EDUCATE, that include practical guidance or are combined with IPV identification and assistance programs.
- Education programs consistently improve HCP knowledge regarding IPV.
- There is mixed evidence as to whether these programs also change behavior in terms of referrals to services.

Question 3: In adult women who present to fracture clinics, are universal IPV identification and assistance interventions, compared to standard practice, effective at improving health outcomes for women?

Rationale

To determine whether fracture clinics should routinely ask patients about IPV, it is important to understand if asking about IPV is effective at eliciting a greater number of disclosures. Furthermore, since IPV identification programs should be implemented in conjunction with IPV assistance programs, it is also important to understand if IPV assistance programs are beneficial to patients.

Clinical comment

The high prevalence rate of IPV amongst female orthopedic patients suggests that fracture clinics may be an appropriate setting to identify and help IPV victims. When asking about IPV, it is important for HCPs to be knowledgeable and comfortable with responding appropriately to disclosures and offering appropriate assistance. While fracture clinics may deliver some brief interventions (e.g. referral, brief counselling, immediate safety assessment), other more intensive interventions (e.g. long-term advocacy and counselling, safety planning) may be delivered in a community setting and initiated through a referral from the fracture clinic.

Available literature and quality of the evidence

There have not been specific studies that evaluate IPV identification programs in orthopedic settings; however, one Cochrane systematic review and meta-analysis (level I evidence) by O'Doherty et al. has evaluated the effectiveness of IPV identification programs conducted within healthcare settings.[11] This review included all RCTs and quasi-RCTs published before February 2015 that evaluated the effectiveness of IPV screening by an HPC compared to usual care (or no screening). *Usual care* could refer to a control group which did not receive screening, or a comparator group that received screening by a non-HCP. Eleven eligible trials were identified (n = 13 027) and the overall quality of these studies was low to moderate. One Cochrane systematic review and meta-analysis (level I evidence) has also been published that investigates the effectiveness of IPV assistance programs, though it is not specific to healthcare settings.[12] This review included RCTs that evaluated advocacy-based IPV interventions. *Advocacy interventions* in this context referred to individual or group-based programs if safety planning was included or if they facilitated access to community resources. Comparisons

between brief (<12 hours) and intensive interventions (>12 hours) were made; however, all studies included were very heterogeneous in study methodology, setting, intensity, and abuse severity. Furthermore, the quality of evidence was considered low to moderate for brief advocacy interventions and very low for intensive advocacy interventions.

Findings

Effectiveness of IPV identification programs

O'Doherty et al. included six studies in a meta-analysis which showed that IPV identification programs are effective at increasing the rates of IPV disclosure (relative risk [RR] 2.33; 95% CI 1.39–3.89).[11] Debate also exists as to whether IPV identification programs are effective at increasing referrals to IPV services. O'Doherty et al. reported that based on three studies (n = 1400) there was no evidence that IPV identification programs increase referrals (RR 2.67; 95% CI: 0.99–7.20). Similarly, debate exists as to whether IPV identification programs help to improve health outcomes for women, including recurrent IPV post-identification. Only two studies reported rates of re-victimization and found that there was no reduction in IPV after screening. MacMillan et al. was the only included study in the O'Doherty systematic review that examined the impact of IPV screening on physical health and psychological health (including quality of life, post-traumatic stress disorder, depression, and substance abuse) and found there to be no associated significance.[13] Investigators of the study noted, however, that the results are complicated by a high loss to follow-up rate (43%). Based on these results O'Doherty et al. concluded that there was insufficient evidence to recommend routine screening for IPV. It is important to note that most of the

studies included in the Cochrane review did not include an IPV assistance component, and identification programs alone are unlikely to reduce violence or improve quality of life.[14,15] Furthermore, IPV identification programs have been endorsed by both international and national associations such as the WHO, the COA, and the AAOS.[9,10,16]

IPV identification programs and the potential for harm

Many critics of IPV identification programs argue that although these programs increase rates of IPV disclosures, there is a lack of proven effectiveness in increasing referral rates or health outcomes which may make IPV identification a potentially harmful intervention. Very few studies, however, have investigated harm as an outcome, as pointed out by O'Doherty et al.[11] MacMillan et al.'s study was the only one included in the O'Doherty et al. systematic review that investigated the potential for IPV screening to cause harm to victims.[13] Based on their results, not only did screened women report no harms of screening, but a subscale analysis comparing women exposed to IPV and not exposed to IPV showed no difference between groups and their reports of potential harm of screening.

Effectiveness of IPV assistance programs

One of the primary outcomes of most IPV assistance interventions is the rate of re-victimization. The most rigorous study that has investigated the effectiveness of IPV assistance programs at reducing rates of re-victimization is the systematic review by Rivas et al.[12] Three studies were pooled and found that there was no effect on physical abuse for brief advocacy interventions in 12 months of follow-up (standardized mean difference = 0.00; 95% CI: −0.17–0.16). Pooled results from two

intensive advocacy trials, though, showed a reduction in physical abuse at 24 months (OR 0.39; 95% CI: 0.20–0.77), but not at 12 or 36 months. In addition to evaluating the effectiveness of IPV assistance programs at decreasing rates of re-victimization, many studies have examined the effects of IPV assistance programs on other health outcomes for women. Evaluations of quality of life from the meta-analysis by Rivas et al. suggests that intensive advocacy programs (two studies) may improve the quality of life of women (n = 265) recruited from shelters (mean difference 0.23; 95% CI: 0.00–0.46). Contrastingly, analysis of two brief interventions (n = 149) showed that fewer women developed depression (OR 0.31; 95% CI: 0.15–0.65) with brief advocacy, but that there was no evidence that intensive advocacy is effective at reducing severity of depression at <12 months or two years. In interpreting these results, it is important to consider the appropriateness of the outcomes and follow-up periods used to measure effectiveness. Most outcomes for IPV assistance programs are relatively short (12–24 months). Considering the barriers to leaving abusive relationships (including, but not limited to, safety, custody of children, financial burden, and housing stability), it may take a much longer follow-up to see a decrease in IPV re-victimization or an increase in quality of life.

Resolution of clinical scenario

HPCs should consider asking patients about IPV experiences, and if disclosed they should:

- Respond supportively and offer brief interventions when comfortable.
- Be aware of more intensive interventions available to patients in the community.

- Refer patients to available services.

HPCs should be comfortable using methods to ensure a private and safe environment for asking about IPV and should ask about IPV on multiple occasions, if following a patient serially.

15 Pain Management in Orthopedic Surgery

Vishal Uppal MD FRCA[1], and Harsha Shanthanna MD PhD[2]

[1] Department of Anesthesia, Pain Management and Perioperative Medicine, Faculty of Medicine, Dalhousie University, Halifax, NS, Canada

[2] Department of Anesthesia, McMaster University, Hamilton, ON, Canada

Clinical scenario 1

- A 72-year-old male patient has been managed nonoperatively for years for his right knee osteoarthritis, and is now having worsening pain.
- He undergoes an uneventful total knee arthroplasty (TKA).
- He is treated with multimodal analgesics perioperatively, including patient-controlled analgesia (PCA) followed by short- and long-acting opioids orally.
- Upon discharge postoperative day two, he is given a prescription for anticoagulation orally and oral opioids for pain management.

Clinical scenario 2

At six months after his TKA, the patient continues to have pain that interferes with his daily activities.

He uses slow-release morphine twice a day along with acetaminophen four times daily.

He sometimes uses a cane when the pain is severe.

Due to persisting pain, the patient feels his sleep and quality of life are affected.

Top three questions

1. In adult patients undergoing surgery, which acute perioperative pain management strategies, compared to others, are most effective at managing perioperative pain?
2. In adult patients undergoing surgery, which opioid-sparing strategies, compared to standard care, are most effective?
3. In adult patients undergoing surgery, what is the burden of persistent postoperative pain, and are there any interventions which, compared to usual care, can prevent persistent postsurgical pain?

Question 1: In adult patients undergoing surgery, which acute perioperative pain management strategies, compared to others, are most effective at managing perioperative pain?

Rationale

Total knee arthroplasty (TKA) is associated with significant pain postoperatively.[1] Poorly controlled pain following TKA can not only lead to impaired mobilization and rehabilitation but also increase the likelihood of complications.[2] Severity of acute pain is also known to be

an independent predictor of chronic postsurgical pain after TKA.[3] Ideal perioperative analgesic technique should provide excellent analgesia, limit opioid consumption, and facilitate early mobilization and rehabilitation.

Clinical comment

Broadly, the analgesic options following TKA include pharmacological and nonpharmacological techniques. In clinical practice, these options tend to be used either alone or in combination.

- *Systemic options include*: (1) opioid-based intravenous PCA and (2) multimodal oral analgesia, including acetaminophen, nonsteroidal anti-inflammatory drugs (NSAIDs) +/− opioid analgesics.
- *Regional options include*: (1) local anesthetic infiltration techniques, including periarticular infiltration, intra-articular infiltration, and infiltration between the popliteal artery and the capsule of knee (IPACK); (2) peripheral nerve blocks (+/− continuous catheter techniques), including femoral nerve block (FNB) or adductor canal block (ACB) +/− sciatic nerve block (SNB); and (3) neuraxial techniques, including continuous epidural analgesia and intrathecal morphine.
- *Nonpharmacological options include*: continuous passive motion (CPM), preoperative exercise, cryotherapy, electrotherapy, including transcutaneous electrical nerve stimulation (TENS), and acupuncture.

Available literature and quality of the evidence

As we included systematic reviews and meta-analyses of randomized controlled trials (RCTs) for all interventions except the use of cannabis were level I. Only three studies

were found with regards to cannabis, all of which were level III or IV.

Findings

Intraoperative anesthetic techniques

TKA is commonly performed either under general anesthesia (GA) or neuraxial anesthesia (spinal or epidural). A systematic review involving knee and hip arthroplasty observed that neuraxial anesthesia was associated with shorter hospital length of stay compared to GA, without any other differences.[4] Another systematic review and meta-analysis demonstrated decreased surgical site infections after hip and knee arthroplasty with neuraxial anesthesia compared to GA.[5]

Systemic analgesia

NSAIDS

COX-2 inhibitors are preferred over nonselective NSAIDS because of the lower risk of perioperative bleeding. A meta-analysis of eight small RCTs showed that the perioperative administration of selective COX-2 inhibitors reduces postoperative pain, opioid consumption, and postoperative nausea vomiting (PONV) after TKA without increasing the risk of perioperative bleeding.[6] Furthermore, perioperative use of selective COX-2 may improve postoperative knee function.[6]

Acetaminophen

Two recent systematic reviews show that intravenous acetaminophen added to multimodal analgesia leads to reduced pain and opioid consumption after total joint arthroplasty with few adverse effects.[7],[8] Further, no

difference has been observed between oral and intravenous acetaminophen.[9]

Gabapentinoids (gabapentin and pregabalin)

Although one review with meta-analysis did not find clinically important effect with gabapentin for the management of acute pain following TKA,[10] another review with meta-analysis observed that it decreases opioid requirements at 24 and 48 hours.[11] Small (probably clinically insignificant) analgesic efficacy, antiemetic and opioid-sparing effects of gabapentinoids need to be balanced against a significant increase in the risk of sedation.

Ketamine

There is limited evidence on the use of ketamine for TKA. Three small RCTs showed that adding intraoperative small-dose intravenous ketamine infusion to multimodal analgesic regimen decreased morphine consumption and improved early rehabilitation without increasing the incidence of side effects.[12–14]

Cannabis

As there has been renewed interest in looking at the effect of cannabis on pain and other outcomes in TKA patients, we performed a specific search to identify any such literature. In general, substance abuse increased the risk of complications including infection and prolonged discharge.[15,16] Another retrospective study using the Medicare database suggests that the risk of revision surgery is significantly increased among cannabis users.[17]

Steroids

At least six different groups have reviewed the evidence on use of systemic steroids for TKA.[18–23] The included studies had marked heterogeneity regarding the type and dose of steroid used. The reviews either show an analgesic benefit of steroid use or no difference in pain compared to control patients. In particular, steroid use was associated with reduced pain at rest and activity and lower opioid use during the first 24 hours after operation. Additionally, patients given perioperative steroids had a lower incidence of nausea and vomiting.[19] Generally, no significant adverse effects were observed in the outcomes, such as superficial or deep infections. However, perioperative steroid use was associated with clinically nonsignificant increase in blood glucose for the first six hours. The analgesic benefits of systemic steroids were more apparent in patients undergoing TKA compared to total hip arthroplasty.[18]

Regional analgesia

Femoral nerve block (FNB)

A Cochrane review observed that FNB provided more effective analgesia than PCA opioid alone with less nausea and vomiting, and it was as effective as epidural analgesia.[24] Although continuous FNB can provide superior pain relief and fewer side effects, local infiltration analgesia (LIA) can potentially provide similar outcomes of analgesia with earlier mobilization.[25] More recently, another review with meta-analysis showed that ACB provides equally effective analgesia with early ambulation.[26]

Intrathecal morphine

A meta-analysis showed that FNB provides equal postoperative pain control with similar morphine

consumption compared with intrathecal morphine following TKA, although there were fewer side effects in the FNB groups.[27] Particularly, the incidence of itching in the intrathecal morphine group was higher than in the FNB group.[28] Postoperative urinary retention is also a potential concern.[29]

FNB + SNB

Five different systematic reviews support the analgesic benefits of adding SNB to FNB following TKA. SNB added to FNB reduces postoperative opioid consumption and reduces pain scores after TKA.[30–33] However, SNB is not routinely used in clinical practice, as it interferes with the postoperative assessment of potential nerve injury and impedes early mobilization.[34]

Periarticular local infiltration analgesia (LIA)

There is significant heterogeneity in the mixture and technique of LIA used across the studies which makes the comparisons with other modalities difficult.[35] When compared to placebo, LIA appears to reduce pain scores and opioid consumption in the first 24 hours (but not 48 hours) postoperatively. Another systematic review suggested that intraoperative periarticular but not intra-articular injection may be helpful in pain control up to 24 hours after TKA.[36] Overall, LIA reduces short-term pain compared to placebo and provides improved early postoperative pain relief compared to FNB.[37] Multiple reviews comparing LIA with FNB found that LIA was as effective as FNB in terms of 24- to 48-hour pain scores, total morphine consumption, and range of motion.[25,38–40] However, two systematic reviews found that single-injection FNB was associated with reduced pain upon movement compared with single-injection LIA.[41,42]

Intra-articular local anesthetics

Compared with the placebo group, the single local anesthetic group had a significantly lower pain score at rest, less opioid consumption, and greater range of motion at 24, 48, and 72 hours postoperatively. There were no significant differences in side effects or length of hospital stay.[43] Considering other effective treatment modalities that are available, intra-articular LA is not a popular option.

Adductor canal block (ACB)

- *ACB vs. FNB:* most studies have found no significant differences in pain scores at rest or mobilization at 24 and 48 hours between ACB group and FNB group. While Dong et al. found no significant differences in the strength of quadriceps and adductors between ACB and FNB groups,[44] multiple different systematic reviews have shown early sparing of quadriceps strength and enhanced ambulation ability with ACB.[45–52]
- *ACB vs. LIA*: evidence suggests that LIA is more effective than ACB regarding pain control and opioid use following TKA. However, no clear difference has been observed regarding short-term functional outcomes when the two modalities are compared.[53]
- *ACB + LIA:* evidence suggests that adding ACB to LIA is more effective than single therapy within the first 48 hours following TKA.[54,55] Combining the two modalities was associated with statistically significant lower pain scores, opioid consumption, and more distance walked on postoperative day 1. These differences were not significant on postoperative day 2.[56]

Epidural analgesia

As peripheral nerve blocks[57] and LIA[58] are as effective as epidural analgesia for postoperative pain management in TKA, the role of continuous epidural analgesia is limited considering the higher risk of complications associated with epidural and the common use of anticoagulants for thromboprophylaxis after TKA.

Liposomal bupivacaine (LB)

LB is intended to prolong the action of bupivacaine employed for regional analgesia. It has been shown that LIA with LB is better than placebo for analgesia;[59] it provides similar pain relief as FNB with decreased opioid requirements,[60] and with shorter length of hospital stay than FNB.[61] However, considering that other meta-analyses have shown equivalent analgesia between LIA and FNB (without any LB), its superiority is uncertain.

IPACK

IPACK refers to infiltration between popliteal artery and the capsule of the knee. It is typically performed under ultrasound guidance to achieve pain relief to the posterior aspect of the knee by blocking branches of the tibial, common peroneal, and obturator nerves in the popliteal region. The only RCT comparing LIA group versus IPACK + ACB and modified LIA reported significantly lower pain scores on ambulation than the control group on postoperative days 0, 1, and 2.[62] Patients in the IPACK group were more satisfied and had lower intravenous PCA usage.

Nonpharmacological options

Continuous passive motion (CPM)

A Cochrane review found no benefits of CPM on function, pain, or quality of life after primary TKA.[63] In contrast, CPM is expensive, time consuming, and associated with an increased length of stay.

Preoperative exercise

The evidence suggests that preoperative exercise may slightly improve early postoperative pain and function for patients undergoing joint replacement. However, these effects may not be clinically important considering small effect size and short duration.[64]

Cryotherapy

A Cochrane review concluded that the potential benefits of cryotherapy on blood loss, postoperative pain, and range of motion may be too small to justify its use. Again, the potential inconveniences and expense do not justify its routine use after routine TKA.[65]

Electrotherapy including transcutaneous electrical nerve stimulation (TENS)

A recent meta-analysis suggests that electrotherapy is probably the most effective nonpharmacological intervention. Electrotherapy not only reduces early pain but also changes the long-term trajectory of recovery from pain after TKA.[66] However, its effect on long-term pain is not known.

Acupuncture

Meta-analysis of three studies (230 patients) suggested a significant short-term improvement in pain scores and opioid use with acupuncture use.[66]

Question 2: In adult patients undergoing surgery, which opioid-sparing strategies, compared to standard care, are most effective?

Rationale

Given the current opioid crisis globally and especially in North America, any strategies which can help to minimize perioperative opioid use are important to identify.

Clinical comment

Pain is a common presenting complaint for orthopedic surgery patients; in addition, major orthopedic surgery such as TKA is undoubtedly painful in and of itself given the large incision, extensive dissection, and significant bony work. Thus, opioid-sparing strategies are an important and topical issue in orthopedic surgery.

Available literature and quality of the evidence

Two recent network meta-analyses (NMAs) compare all commonly used analgesic modalities for TKA (level I).

Findings

Comparison of analgesic techniques for TKA

The NMA by Terkawi et al. looked at 170 studies with 17 different options and concluded that the combination of FNB + SNB was the best overall modality regarding analgesia, opioid consumption and rehabilitation profile.[67] However, heterogeneity in measuring rehabilitation precluded them from combining rehabilitation outcomes other than for range of motion and degree of flexion. Thus, it is very likely that the combination of femoral and SNB,

though it provides the best analgesia, may not provide the best condition for active rehabilitation. Dong et al. assessed the outcomes of pain scores, opioid consumption, and length of hospital stay in their NMA of 58 studies.[68] They concluded that continuous FNB is superior to other treatments in decreasing pain scores and opioid requirement. Based on the comparison of individual treatment effectiveness, periarticular infiltration combined with intra-articular infiltration was the best analgesic strategy during the first 6–8 hours after TKA. Periarticular infiltration combined with FNB or epidural was the best during the first postoperative day. The potential to impede rehabilitation and risk of fall is less with intra- and periarticular infiltration and ACB.

Effect of regional analgesia on long-term functional outcome after TKA

There is a lack of evidence on the effect of regional anesthesia on long-term outcomes after TKA. A review of evidence pointed out that more studies are needed to establish the effects of regional analgesia on long-term function and adverse events such as the risk of falls after joint replacement surgery.[69]

Findings

All modalities using LA have the potential for an opioid-sparing effect. However, the choice of a particular modality must be weighed against its risks and should be considered along with nonopioid analgesics as components of multimodal analgesia. FNB, ACB, and LIA provide good analgesia with decreased opioid requirements and are currently preferred at most centers over FNB + SNB. However, ACB and LIA have less potential to impede rehabilitation and hence may facilitate earlier discharge.

Question 3: In adult patients undergoing surgery, what is the burden of persistent postoperative pain, and are there any interventions which, compared to usual care, can prevent persistent postsurgical pain?

Rationale

Despite a technically well-performed surgery, a substantial proportion of patients suffer from persistent postoperative pain and decreased quality of life after TKA. As the number of patients undergoing TKA increases, it is important to address the problem of persistent pain to decrease patient suffering and chances of long-term opioid medication, and to decrease continued healthcare expenses.

Clinical comment

TKA remains the definitive therapy for osteoarthritic knee pain. There is an expectation by most patients to overcome the problem of chronic knee pain with their surgery. Although it is an effective modality of therapy for the majority of patients, 10–34% of patients report persisting pain and functional limitation.[70],[71] Surgical and anesthetic interventions performed during the perioperative period may have a bearing on the incidence and severity of persistent pain.

Relevant background

Epidemiological studies have observed that higher preoperative pain, pre-existing psychological comorbidity in the form of anxiety or depression, pain catastrophizing, and the presence of other musculoskeletal pain conditions

(such as low back pain) increase the chances of persistent pain, apart from the duration and severity of acute postoperative pain.[72] [73]

Available literature and quality of the evidence

As we had two systematic reviews of RCTs (Cochrane) and six individual RCTs (MEDLINE), we rate the evidence as level I.

Findings

There is insufficient evidence to promote the use of regional analgesia for the improvement of long-term functional outcome or pain after elective TKA.[74] One study reported decreased incidence of neuropathic pain six months after TKA with the use of perioperative oral pregabalin; 0% (0 of 113) in the pregabalin group and 5.2% (6 of 115) in the placebo group.[75] However, similar results have not been shown by other studies using pregabalin.[76]

Summary of answers

A variety of systemic, regional, and nonpharmacological pain management modalities exist with differing levels of efficacy and evidence.

For perioperative pain management for elective uncomplicated primary TKA (opioid naive patient), we recommend:

- Spinal anesthesia.
- Aggressive multimodal analgesia with acetaminophen, COX-2 inhibitor, and perioperative systemic steroids.
- ACB +/− catheter.
- LIA +/− IPACK.

For perioperative pain management for elective opioid tolerant primary TKA, we recommend:

- Spinal anesthesia.
- Continue routine opioids (possibly increase dose short term).
- Aggressive multimodal analgesia with acetaminophen, COX-2 inhibitor, and perioperative systemic steroids.
- Continuous FNB or continuous ACB.
- Consider gabapentinoids in the perioperative to postdischarge period.
- Consider ketamine infusion in the perioperative period.
- SNB may be used as a rescue analgesia for uncontrolled pain after TKA.

No analgesics or psychological interventions, used perioperatively, have been shown to influence the incidence or severity of persistent pain after TKA.

Based on the knowledge of potential risk factors, appropriate patient selection, improving pre-existing pain, and psychological comorbidities should be considered to improve long-term pain and functional outcomes.

Observational studies and a clinically reasonable rationale support the potential for decreased chances of persistent pain with better management of acute postoperative pain.

Acknowledgment: we would like to thank Ms. Michelle Fiander (Evidence Synthesis Coordinator, Maritime SPOR SUPPORT Unit-Research Services, Halifax) for helping us with the literature search for case scenario 1.

16 Post-Traumatic Stress Disorder and Depression

Basem Attum MD[1], and William Obremsky[2]
[1] Department of Orthopedic Surgery, University of California, San Diego, CA, USA
[2] Vanderbilt University Medical Center, Vanderbilt Orthopaedic Institute, Nashville, TN, USA

Clinical scenario

- A 32-year-old Latin American presents to the office three months after an open bicondylar tibial plateau fracture via a motor vehicle accident.
- He has been reliving the accident and is anxious and depressed.
- He has been having difficulty sleeping.

Top three questions

1. What are post-traumatic stress disorder (PTSD) and depression, and does their presence, in orthopedic patients, have an impact on postoperative outcomes?
2. How prevalent is PTSD and depression after acute trauma in the orthopedic trauma population?
3. In orthopedic trauma patients with PTSD and/or depression, are there resources that, compared to usual care, improve outcomes?

Question 1: What are post-traumatic stress disorder and depression, and does their presence, in orthopedic patients, have an impact on postoperative outcomes?

Rationale

Identifying the difference between these two psychological disorders is very important for the orthopedic surgeon to comprehensively treat patients.

Clinical comment

PTSD and depression have distinguishing characteristics and potentially affect outcome.

Findings

Orthopedic injuries have a significant impact on society. In 2000, productivity losses from lower extremity injuries alone was $17.5 billion which is 75% more than the losses from nonfatal traumatic brain injuries, 50% more than the losses from nonfatal upper extremity injuries, and 600% more than losses from nonfatal spinal cord injuries.[1]

Treatment of orthopedic trauma injuries is multifaceted. What is often overlooked is the psychological component of recovery. Certain psychological factors such as depression, anxiety, and PTSD can affect outcomes. Zatzick et al. reviewed 101 trauma patients evaluated at admission and again at one year. In this study, PTSD had the strongest association with outcome. Patients with PTSD demonstrated worse outcomes in seven of eight domains of the 36-Item Short-Form Health Survey compared to patients without PTSD.[2]

The first step in management of these patients is to understand these disorders. Depression is a psychiatric disorder characterized by persistent sadness, decreased ability to experience pleasure, and decreased interest in usual activities.[3] Depression can affect outcomes by reducing patient motivation to fully engage in rehabilitation activities.[4] PTSD is a disorder secondary to a traumatic experience or a long-term exposure to a traumatic stress which is characterized by re-experiencing the incident, avoidance, and hypervigilance. The current diagnostic criteria for PTSD is defined by the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5), and includes symptoms from the following categories: intrusion, avoidance, negative alterations in cognition and mood, alteration in arousal, and reactivity.[5]

Half of patients with PTSD go on to develop chronic progression and take approximately three years to remit. A third of the patients will suffer from PTSD-related symptoms for more than 10 years.[6] Clinical presentation and timing of onset is variable. deRoon-Cassini et al. found that patients can present with PTSD symptoms as early as the initial hospital stay. At one to six months postdischarge, some patients developed worsening symptoms, others' symptoms improved, and some had the same severity throughout.[7] When identifying the stressor causing PTSD, patients reported a lack of control over the situation leading up to the traumatic event and/or death of a family member at the scene.[8]

Risk factors, signs, and symptoms

Young age, female sex, poor education, lower socioeconomic class, alcohol abuse, drug abuse, and physical pain have been identified as risk factors for the development of PTSD.[9],[10] A study by Norman et al. on 115

patients evaluated by using the Visual Analog Scale (VAS) at a level one trauma center identified pain as a risk factor for the development of PTSD. An increase of half a standard deviation on the VAS was found to have a fivefold increase at four months and seven-fold increase at eight months postdischarge of developing PTSD.[11] Castillo et al. identified a recurring relationship between pain and associated psychological distress. It was determined that pain and psychological stress could be exacerbated by each other during the chronic stage of trauma. More specifically, it was discovered that pain influenced psychological distress early in the recovery process. At the one-year mark, anxiety in turn affected the level of pain.[12]

Another variable in the development of PTSD is resilience. Clinically, resilience is healthy recovery from extreme stress and trauma.[13],[14] Patients have varying degrees of resilience with several factors involved with its development. Wilson et al. identified seven factors associated with resilience.[13] These included: (i) locus of control (i.e. a sense of efficacy and determination), (ii) self-disclosure of the trauma experience to significant others, (iii) a sense of group identity and sense of self as a positive survivor, (iv) the perception of personal and social resources to aid in coping in the post-traumatic recovery environment, (v) altruistic or prosocial behaviors, (vi) the capacity to find meaning in the traumatic experience and life afterward, and (vii) connection, bonding, and social interaction within a significant community of friends and fellow survivors. King et al., studying Vietnam veterans and PTSD, found that hardy veterans coped better with life than less hardy veterans due to the hardy veterans seeking out and utilizing social support in their local environment to overcome stress.[15]

Question 2: How prevalent is PTSD and depression after acute trauma in the orthopedic trauma population?

Rationale

PTSD and depression are very common in the orthopedic trauma population and have been shown to affect outcome.

Clinical comment

PTSD and depression affect postoperative outcomes. By understanding the prevalence of these psychological disorders in the orthopedic trauma population, surgeons will be more aware of their presence and potentially more likely to screen patients.

Findings

Psychological stress is common in the orthopedic population. In the Lower Extremity Assessment Project (LEAP) study, patients reported elevated levels of psychological distress compared to age- and sex-matched cohorts. One-fifth to one-sixth of the patients reported severe levels of depression, phobia, and anxiety.[16] The National Study on the Costs and Outcomes of Trauma, a multicenter prospective cohort study performed at 69 hospitals in 12 states on 2707 patients, had 20.7% of patients report symptoms of PTSD. Starr et al. used a Revised Civilian Mississippi Scale for Post-traumatic Stress Disorder to measure PTSD symptoms in 580 persons at two level-one trauma centers. Fifty-one percent of these patients met the criteria for PTSD including 57% of those involved in motor vehicle accidents and 65% of the pedestrians struck by a motor vehicle.[17] A prospective cohort on 200 patients with musculoskeletal injuries were

studied to identify the correlation of injury and the development of psychopathology. Patients were evaluated by the General Health Questionnaire and on functional outcomes (measured by Short Form 36 [SF-36], Sickness Impact Profile, and Musculoskeletal Function Assessment). Pre-existing psychological disturbance was seen in 11% of patients but increased to 46% at two months; this later decreased to 22% at six months.[18]

Depression, anxiety, and PTSD are some of the predictors of poor long-term quality of life and reliance of pain medication.[19],[20] The National Study on the Costs and Outcomes of Trauma measured the extent to which patients with PTSD developed functional impairment at 12 months, and the severity of this impairment, through the use of the SF-36 work questionnaire. Patients with PTSD had significantly increased impairments in all functional domains, associated with elevated odds of one or more activities of daily living impairments, a threefold increase of PTSD and five- to sixfold increase of PTSD plus depression.[21]

Lower extremity injuries have a high incidence of PTSD. Crichlow et al. assessed 161 patients 3–12 months postdischarge. A subset of 99 patients with lower extremity injuries reported that 57% of patients had a minimal level of depression, 26% had a moderate level of depression, and 6% had severe levels of depression.[22] A Korean study on 148 men who had one or more long bone fractures found that 27% met the criteria for the diagnosis of PTSD. Lower extremity fracture, multiple extremity fracture, and higher pain VAS were significantly related to the occurrence of PTSD.[23] A Norwegian cohort of patients recovering from orthopedic injuries were one standard deviation below the healthy population with almost one-third of these patients having a diagnosis of PTSD.[24] When looking specifically at

amputations, the number of patients with PTSD is drastically higher. Copuroglu et al. reported that, during the early post-traumatic period, 36.3% of patients were being treated for PTSD; by year five, the percentage drastically rose to 77.2%.[25] PTSD is often seen after motor vehicle accidents and has been shown to persist long after the physical injuries have healed. Studies found that more than 25% of survivors experienced PTSD with even more meeting the subthreshold criteria.[26,27] More than half of the motor vehicle crash survivors with PTSD at one year still had the diagnosis two years later.[28]

Depression has been found in 45% of orthopedic trauma patients with a strong correlation of global disability.[22] Crichlow et al.'s study on 116 patients found a relationship between injury severity and level of depression. In this study, 55% of patients reported minimal depression, 28% experienced moderate depression, and 13% experienced severe depression. Patients with open fractures were 4.6 times more likely to experience depression than patients with closed fractures.[22] Patients with severe lower extremity injury had a 56.6% rate of depression two years after injury.[16]

Williams et al. performed a study looking to estimate the prevalence of PTSD and depression in hand injured patients, and found that 30.2% (32/106) met diagnostic criteria for PTSD, 17.9% (19/106) for depression, and 15.1% (16/106) qualified for both PTSD and depression. This study also found that the association between PTSD and depression was significant ($p < 0.01$). Patients with PTSD had significantly lower scores than those who did not endorse items consistent with PTSD or depression on the SF-36 subscales. In addition, those with both PTSD and depression had significantly lower scores than patients who had neither PTSD nor depression.[29]

Question 3: In orthopedic trauma patients with PTSD and/or depression, are there resources that, compared to usual care, improve outcomes?

Rationale

It is imperative that the treating health provider understand the different resources available to patients. A thorough understanding of how these programs work will assist healthcare providers in directing patients to the appropriate mental health provider.

Clinical comment

Understanding the resources available to patients will help guide them to the appropriate treatment.

Treatment

Cognitive behavioral therapy (CBT) is the mainstay of nonpharmacologic management for PTSD with the focus on changing perception after trauma along with exposure to provocative stimuli in a controlled manner. CBT is also the mainstay of nonpharmacologic treatment for depression.[30] Immediate one-time CBT has not shown to be effective in treating PTSD, though longer-term therapy has shown efficacy. An RCT of 152 patients who underwent four sessions of CBT 5–10 weeks after injury found significantly lower total impact of event scores compared to those not receiving any intervention.[31`] Although CBT has been shown to positively affect outcomes, medication is often used as a supplement. Pharmacologic management for PTSD and depression consists of antidepressants with

selective serotonin reuptake inhibitors (SSRIs) as the most commonly used. Sertraline and fluoxetine are the most commonly used SSRIs. Tricyclic antidepressants, monoamine oxidase inhibitors, and anticonvulsants are also used.[32] It is important to note that the use of benzodiazepines for PTSD has fallen out of favor due to the vulnerability of this patient population to developing addiction.[33]

Trauma collaborative programs – for example the Trauma Collaborative Care (TCC) program – focus on the relationship between a patient and their physician. These programs coordinate resources to patients to address the psychosocial sequelae following trauma. These models focus on the need to empower patients and have them assume more responsibility for their recovery and the need to be proactive. This is implemented by the creation of proactive practice teams which can be molded by training providers to facilitate patient engagement.[34]

The Trauma Survivors Network (TSN) was developed by the American Trauma Society in conjunction with Johns Hopkins University.[35] The TSN is a standardized program which has been used in multiple trauma centers throughout the United States (www.traumasurvivorsnetwork.org). This highly integrative program has been shown to be effective in improving functional outcomes and quality of life. The TSN consists of (i) timely access to information for patients and families via the TSN website, and receipt of the *Trauma Patient and Family Handbook*, which provides information regarding their injury and what to expect during their hospitalization; (ii) peer support provided by visitation of experienced trauma survivors, regular support groups, and an online social networking website; (iii) family education classes; and (iv) a self-management class (NextSteps, offered both online and in person). The goal of

these components is to increase the patient's self-efficacy, support network, and capacity to actively engage in the recovery process.[35]

During the postoperative period, the orthopedic surgeon will often be the only physician that the patient sees on a consistent basis. In order to be able to effectively treat orthopedic trauma patients, the orthopedic surgeon needs to be able to identify PTSD and depression early in the postoperative process. This will not only allow patients to heal from the physical trauma but also help them recover psychologically.

Summary of answers

- Depression and PTSD are common among orthopedic trauma patients.
- The presence of depression and/or PTSD has a negative impact on postoperative/postinjury outcomes.
- Many resources exist for patients who have been through a traumatic experience.
- Orthopedic surgeons should be proactive in assessing for, recognizing, and referring the occurrence of depression and PTSD in their patients.

17 Nutrition and Supplements in Orthopedic Care

Martí Bernaus MD[1], Brad Petrisor MD MSc[2], Sofia Bzovsky MSc[2], and Sheila Sprague PhD[2,3]

[1] Department of Orthopedic Surgery, Hospital Universitari Mútua Terrassa, Barcelona, Spain

[2] Division of Orthopaedic Surgery, Department of Surgery, McMaster University, Hamilton, ON, Canada

[3] Department of Health Research Methods, Evidence, and Impact, McMaster University, Hamilton, ON, Canada

Clinical scenario

Over the weekend, you operatively treat two patients with femoral neck fractures. During rounds on Monday morning, you follow up with the patients with a new surgical resident. You both walk into the first wardroom and differences in body mass index (BMI) and nutrition status between the two patients do not pass unnoticed. One patient is obese and the other shows signs of undernutrition. Your resident then starts asking questions...

Top three questions

1. In orthopedic surgery patients, do vitamin D and calcium supplementation, compared to no supplementation, confer a benefit in terms of fracture risk, fracture healing, or bone mineral density?
2. Among patients undergoing orthopedic surgery, do those with a high BMI have a higher risk of complications compared to those with a normal BMI?

3. Among patients undergoing orthopedic surgery, do those with undernutrition or malnutrition have poorer outcomes compared to those with adequate nutrition?

Question 1: In orthopedic surgery patients, do vitamin D and calcium supplementation, compared to no supplementation, confer a benefit in terms of fracture risk, fracture healing, or bone mineral density?

Rationale

Vitamin D and calcium are well known to be necessary for building and maintaining bone strength and preserving skeletal health across all ages.[1,2] Individuals obtain vitamin D from exposure to sunlight or by consuming foods that contain vitamin D, while calcium is primarily retrieved from dairy products.[1,3] It can be difficult to obtain adequate vitamin D and calcium from these sources alone, especially since sun exposure levels vary depending of the latitude, season, time of day, skin pigmentation, cloud cover, smog, and sunscreen use, so individuals often also derive vitamin D and calcium from supplements.[1,3,4] Although Health Canada recommends that adults take a daily vitamin D supplement of between 600–800 IUs, vitamin D deficiency and insufficiency are prevalent and recognized as worldwide health problems.[1,5] The role of calcium in the pathogenesis of osteoporosis has received increasing attention and the recommended amounts for calcium intake have risen steadily in the past 35 years.[6] This is mainly because calcium deficiency activates bone destruction through bone resorption mechanisms. The use of

prevention therapies, such as vitamin D and calcium supplementation, aims to maintain and improve bone quality and minimize fractures.

Clinical comment

Osteoporosis and osteopenia are highly prevalent among fracture patients.[7] As well, there is uncertainty and a lack of consensus in the use and dosing of vitamin D and calcium supplementation.

Available literature and quality of the evidence

Although the US Institute of Medicine and Health Canada have released dietary reference intakes for vitamin D and calcium. To the best of our knowledge, there are no widely accepted clinical guidelines on supplementation in an orthopedic fracture care practice.[1],[2] Pre-appraised research information was obtained using the OrthoEvidence database of randomized trials. Further, meta-analyses consisting of level I evidence randomized controlled trials (RCTs), level II and III evidence prospective and retrospective comparative studies, as well as level IV evidence case series, and cross-sectional studies, have been published that address our question.[8],[9]

Findings

Vitamin D deficiency in orthopedic patients

Vitamin D deficiency is endemic worldwide in all subsets of orthopedic patients, and osteoporosis is commonly found in those patients with fractures. Although most experts define vitamin D deficiency as levels <20 ng/mL and insufficiency as 21–29 ng/mL, there is no universal agreement for these cutoffs.[10] Based on these definitions, approximately 75% of the general population have serum 25-hydroxyvitamin D

(25[OH]D) levels below 30 ng/mL.[11] One study on orthopedic trauma patients with acute fractures reports overall prevalence rates for combined vitamin D deficiency or insufficiency of 77% and a 39% prevalence rate for vitamin D deficiency alone.[12] It has also been suggested that the prevalence of vitamin D inadequacy, defined by the authors as serum 25(OH)D levels <32 ng/mL, in athletes is prominent.[11]

Vitamin D and calcium supplementation for osteopenia and osteoporosis

Weaver et al. have conducted an updated meta-analysis of vitamin D and calcium supplementation which suggests that the combination of vitamin D and calcium supplementation is statistically significantly associated with reduced fracture risk.[9] Further results from this meta-analysis suggest that supplementation could decrease the relative risk of fractures by 14% (relative risk [RR] = 0.85; 95% confidence interval [CI] 0.73–0.98).[9] However, a meta-analysis by Zhao et al. showed no significant association of calcium or vitamin D (alone or combined) with reduced risk of hip, vertebral, or other fractures in community-dwelling older adults.[13] Also, calcium supplementation alone has not been demonstrated to reduce the rate of fractures in elderly women.[14]

Vitamin D supplementation and fracture healing

Data on the effects of vitamin D and calcium supplementation on fracture healing are limited. Briefly, research suggests that vitamin D supplementation safely increases 25(OH)D serum levels and improves bone mineral density.[8] To date, there has only been one preliminary study, presented as an abstract at a meeting, which reported a trend toward lower nonunion rates in

acute fracture patients receiving vitamin D supplements.[15] Additionally, there is emerging, but inconclusive, evidence that vitamin D levels decrease following a fracture[16–20] and it has been hypothesized that postfracture vitamin D supplementation alone, and possibly in combination with oral calcium supplementation, may improve fracture healing.[21–23] However, although limited, there is some evidence suggesting that dietary calcium intake is associated with cardiovascular risk. Any benefit of calcium supplements on preventing fractures may be outweighed by increased cardiovascular events, more specifically myocardial infarction and stroke.[24] As evidence regarding the use of these therapies has shown inconsistent results, there is a need for more high-quality research to be conducted in this area.

Risks of vitamin D and calcium supplementation

Vitamin D supplementation typically leads to increased levels of serum 25(OH)D. The most well-known risk of increased 25(OH)D is hypercalcemia, which occurs secondary to increased calcium intestinal absorption and bone resorption.[25] However, evidence that excess vitamin D can cause hypercalcemia in generally healthy adults comes from daily intakes of vitamin D >100 000 IU or having levels of serum 25(OH)D exceeding 240 nmol/L (96.15 ng/mL), which is far higher than that necessary to achieve the benefits.[26]

The side effects reported after receiving calcium therapy have been an important drawback for its use. Constipation, excessive abdominal cramping, bloating, upper gastrointestinal (GI) events, GI disease, GI symptoms, and severe diarrhea or abdominal pain were described in a meta-analysis by Lewis et al.[27] More importantly, hospital admissions for GI complaints were higher in calcium-

treated patients (6.8%) compared to those who obtained a placebo (3.6%) (RR = 1.92; 95% CI: 1.21–3.05; p = 0.006).

It has also been reported that the use of calcium supplementation may be associated with increases in urine calcium excretion.[28] In the Women's Health Initiative Calcium/Vitamin D Supplementation Study, there was found to be an increased risk of renal calculi following calcium supplementation.[29]

Regarding cardiovascular events, an RCT of calcium supplementation compared to placebo in healthy postmenopausal women showed a statistically significant increase in the number of women who had a myocardial infarction in the calcium treatment group (RR = 2.24; 95% CI: 1.20–4.17; p = 0.0099).[25] These effects could outweigh benefits that calcium supplements may have on bone health.

Resolution of clinical scenario

- Vitamin D and calcium supplementation is important in the prevention and management of osteoporosis.
- Vitamin D deficiency is common in orthopedic patients.
- It remains unknown whether vitamin D improves fracture healing.

Question 2: Among patients undergoing orthopedic surgery, do those with a high BMI have a higher risk of complications compared to those with a normal BMI?

Rationale

The prevalence of obesity, defined as a BMI of ≥30 kg/m^2, has tripled since 1975, with 650 million adults being reported as obese globally in 2016.[30] Obesity is leading to an increased use of the healthcare system.[31] Obese individuals often have multiple co-morbidities and are therefore at a higher risk for perioperative complications.[32] Co-morbidities associated with obesity include type 2 diabetes mellitus, hypertension, dyslipidemia, cardiovascular disease, stroke, sleep apnea, hyperuricemia, gallbladder disease, gout, osteoarthritis, and certain cancers.[33] Orthopedic patients who are obese may be at a higher risk of both general medical and fracture-related complications. Specific intraoperative and perioperative challenges and complications have also been associated with obesity, including the requirement of special surgical equipment, longer operating times, potentially significant anesthetic issues, as well as a longer postoperative length of stay.[34] From a biomechanical point of view, postoperative rehabilitation may prove difficult as well, as there may be an increase in stress on orthopedic implants with subsequent possible failure of fixation or mechanical failure of the implant itself.[35–38]

Clinical comment

Despite the increase in obesity globally, there are no clinical guidelines for managing overall orthopedic surgical care in obese patients. Therefore, as with any patient undergoing surgical management, it is important to evaluate potential risk factors for both mortality and morbidity while having an understanding of the potential co-morbidities associated with obesity.

Available literature and quality of the evidence

To the best of our knowledge, there are no existing clinical guidelines on this topic. No pre-appraised research information is currently available. Level II–III evidence, consisting of cohort studies, has been used to address this question.

Findings

A study including a general surgical population reported obesity rates of up to 30%.[32] In a large longitudinal study of older US men, 68% of all incident clinical fractures and 62% of incident hip fractures occurred in those who were overweight or obese, while 19% of all clinical fractures and 13% of hip fractures occurred in obese men.[39] In the Million Women Study in the UK, almost one-half of all postmenopausal hip fractures occurred in women who were overweight (40%; BMI 25–29.9 kg/m^2) or obese (9%; BMI $\geq 30\ kg/m^2$).[40]

Regarding orthopedic patients, an analysis of the demographic information reported in recent studies, such as the Fixation using Alternative Implants for the Treatment of Hip Fractures (FAITH) trial, indicates that up to 40% of patients undergoing surgical procedures for femoral neck fractures were overweight or obese.[41] A recently completed substudy of the FAITH trial found that for every five-point increase in BMI, participants experienced an average increased risk of 19% for revision surgery (HR = 1.19; 95% CI: 1.02–1.39; p = 0.027) during the 24-month follow-up period.[42]

In patients with multiple system trauma and surgically treated fractures, complications occurred more often in obese patients (38.0% vs 28.4%; p = 0.03). Significantly more infections (11.4% vs 5.50%; p = 0.04) and renal failures occurred in this patient group (5.70% vs 1.38%; p= 0.02), as well, more deep vein thrombosis events were

identified.[43] In another study, reoperation for implant failure, nonunion, or infection was 4.68 (95% CI: 2.03–10.76) times more likely to occur in patients with BMI >30 kg/m^2.[44]

Another study comparing thresholds for obesity in trauma patients states that the greatest rise in morbidity and mortality was seen among patients with a BMI >35.[45] The mortality of patients with a BMI >35 (obese patients) was 10.7% vs 4.1% for patients with a BMI <35 (lean patients; p = 0.003). Highest mortality rates were seen among patients with a BMI of ≥35. This study also indicates that patients with BMIs between 30 and 35 have similar outcomes to leaner patients (BMI <30).

Although the BMI scale is a convenient method for quantifying the amount of tissue mass in an individual, it does not take into account muscle mass, bone density, overall body composition, racial and sex differences, or changes that occur with age. These confounding variables, which also include socioeconomic status, comorbidities, and geographic region may potentially affect BMI and outcomes in studies resulting in important bias, deeming it an imperfect tool for outcome predictions in patients with obesity.[46] Similarly, these confounding variables may have the ability to distort the association between BMI and outcomes of interest when examining the trauma, surgical, and orthopedic population.

Resolution of clinical scenario

- Overweight and obese patients are a notable and growing group of patients undergoing surgical orthopedic trauma procedures.
- Patients with a higher BMI have typically reported a greater number of complications for important

outcomes, including serious adverse events and revision surgery.

- Ensuring that the perioperative risks and short- and long-term complications for these patients are considered preoperatively is important to minimize increased healthcare costs attributable to complications.

Question 3: Among patients undergoing orthopedic surgery, do those with undernutrition or malnutrition have poorer outcomes compared to those with adequate nutrition?

Rationale

According to the World Health Organization, undernutrition is defined by poor anthropometric status, and is mainly a consequence of inadequate diet and frequent infection, leading to deficiencies in calories, protein, vitamins, and minerals.[47] *Malnutrition* refers to deficiencies, excesses, or imbalances in a person's intake of energy and/or nutrients.[48]

It is estimated that at least 23–33% of patients undergoing orthopedic surgery are malnourished or at risk for malnutrition upon admission.[49] Often, these patients continue to be at risk of undernutrition and malnutrition following their surgical procedures. Previous research suggests that being undernourished may lead to an increase in the development of postoperative medical complications and slower recovery.[50]

Clinical comment

Malnutrition status could be a marker for other comorbidities which are more important in determining outcomes. Making links between nutritional status and recovery is complicated by the fact that markers of dietary protein depletion measured in blood – such as albumin, prealbumin, and transferrin – are partly affected by fluid shifts and responses to injury and infection.[51] Other more direct markers of nutritional status include mid-upper-arm circumference, triceps skinfold, and weight in relation to height (BMI).

Available literature and quality of the evidence

Level II evidence RCT, quasi-RCTs, and prospective cohort studies of nutritional interventions are available to address this question.

Findings

Prevalence

At least one-third of orthopedic trauma patients of all ages that are admitted to a hospital are malnourished, and if left untreated, many of these patients will continue to decline nutritionally, which may adversely impact their recovery and increase their risk of complications and readmission.[52] Furthermore, nutrient deficiencies are highly prevalent in obese patients. In particular, the prevalence of vitamin D insufficiency in obese individuals ranges from 80 to 90%.[53] These patients should ideally undergo a nutritional consultation before elective surgery procedures in order to determine how their nutritional status may impact their recovery process.

Clinical management

Effective management of malnutrition requires collaboration among multiple clinical disciplines including physicians, nurses, dietitians, and pharmacists.[54]

Incidence of complications

A prospective cohort study including 1055 traumatology and orthopedic patients admitted to a level I trauma center aimed to evaluate the relationship between malnutrition and clinical outcomes.[55] Although this study did not focus strictly on orthopedic patients, the overall findings suggested that patients at risk of malnutrition had suboptimal clinical outcomes. Patients at risk of malnutrition showed statistically significant prolonged hospital stay (18.2 ± 11.7 vs 13.7 ± 11.1 days; Spearman's rank correlation, $R = 0.273$; $p < 0.05$), and delayed postoperative mobilization (4.0 ± 4.9 vs 2.2 ± 2.9 days; Spearman's rank correlation, $R = 0.281$; $p < 0.05$). In patients being at risk for malnutrition, the incidence of adverse events was statistically significantly higher compared to that of patients with normal nutritional status (37.2 vs 21.1%; $p < 0.001$). Adverse events were defined as death, infections, wound healing disorders, further operations, thrombosis, and other adverse events (postoperative anemia, postoperative electrolyte imbalance with therapeutic necessity, or treatment specific complications).

Several studies have also evaluated the impact of malnutrition on fracture healing. In spite of fractures eventually healing in the malnourished patient, there is evidence to suggest that both the quality and strength of the healed bone are reduced.[56] Findings have also proposed that perioperative malnutrition may be related to increased rates of pneumonia, urinary tract infections, wound infections, and sepsis.[57] Not only do these complications lead to overwhelming situations for both

patients and their families, but hospitals and insurance companies may incur additional financial burdens from these events.[57] To minimize the negative outcomes associated with undernourishment, prompt identification of malnourished or underweight orthopedic patients, as well as early initiation of specialized nutrition intervention, may help.[57]

Resolution of clinical scenario

- High prevalence of undernutrition in orthopedic surgery patients.
- Risk of undernutrition following orthopedic surgery.
- Malnutrition is associated with higher complication rates in traumatology and orthopedic patients.

Summary of answers

- Although available data suggest that the combination of vitamin D and calcium supplementation is associated with a reduced risk of fractures in females between the ages of 58 and 88, there is emerging evidence to suggest that oral calcium supplements alone may be associated with an increased risk of cardiovascular events.
- Higher BMI ratios seem to be associated with increased risks of short- and long-term operative complications.
- In patients being at risk for malnutrition, the incidence of adverse events was statistically significantly higher compared to that of patients with normal nutritional status.

III Joint Reconstruction

18 Outpatient Total Joint Arthroplasty

Michael Pollock BSc MSc[1], and Brent Lanting MD[2]
[1] University of Limerick, Limerick, Ireland
[2] Division of Orthopaedic Surgery, Department of Surgery, University Hospital, London Health Sciences Centre, Western University, London, ON, Canada

Clinical scenario

- A patient without significant co-morbidities undergoing a primary total joint arthroplasty (TJA).
- The patient has sufficient caregiver support at home.
- The patient lives close to the operating hospital in case of emergency.

Top three questions

1. In eligible patients undergoing TJA, does performing the procedure and discharging the patient on the same day of the operation result in an additional risk of serious adverse events or readmissions compared to the same procedures performed on an inpatient basis?
2. In eligible patients undergoing TJA, does performing the procedure on an outpatient basis result in cost savings compared to the same procedures performed on an inpatient basis?
3. In patients undergoing an outpatient TJA, what factors are necessary to ensure a successful procedure compared to the general population undergoing TJA?

Question 1: In eligible patients undergoing TJA, does performing the procedure and discharging the patient on the same day of the operation result in an additional risk of serious adverse events or readmissions compared to the same procedures performed on an inpatient basis?

Rationale

The primary concern with performing outpatient TJA is patient safety. As readmission rates are increasingly used as a performance indicator, there is concern that outpatient surgery may increase these rates. If TJA are going to be performed on an outpatient basis, it is imperative to ensure there are no additional risks of serious adverse events compared to the same procedures performed on an inpatient basis.

Clinical comment

The major deterrent for outpatient TJA is patient safety. Proponents against outpatient joint replacements advocate that the majority of complications following surgery occur within the time-frame of the typical hospital stay.[1] There is a fear that outpatient TJA will lead to additional adverse events and an increase in hospital readmissions. However, the majority of literature illustrates that outpatient joint replacements can be safely performed with comparable complication rates to similar inpatient procedures.

Available literature and quality of the evidence

- Level IV: 1 systematic review.[2]
- Level I: 2 randomized controlled trials (RCTs).[3],[4]
- Level III: 2 large observational studies.[5],[6]

Findings

To assess the safety of performing outpatient total joint arthroplasty recent literature has quantified the rate of adverse events following outpatient arthroplasty as either acute (intraoperative or immediately perioperative) or postdischarge. A systematic review of outpatient total hip arthroplasty (THA), total knee arthroplasty (TKA), and unicompartmental knee arthroplasty (UKA) reported that the rate of acute adverse events ranged from 0 to 25%, whereas the rate of postdischarge adverse events ranged from 0 to 7%.[2] More importantly, this review reported that outpatient procedures did not lead to a higher complication rate compared to inpatient procedures.[2]

Two RCTs allocated study participants undergoing a THA to be either discharged on the day of surgery (outpatient) or admitted to the hospital overnight following surgery (inpatient).[3],[4] In both RCTs, there were no significant differences in rates of adverse events between study arms.[3],[4] Similarly, two large retrospective reviews concluded that outpatient THA can be safely performed in appropriately selected patients.[5],[6] Courtney et al. conducted a retrospective review of the National Surgical Quality Improvement Program (NSQIP) records between 2011 and 2014 pertaining to outpatient TJA.[5] They found that of the 169 406 patients who underwent a primary TKA or THA 1220 were performed on an outpatient basis (0.7%). Outpatient TJA alone did not increase the risk of

readmission (odds ratio [OR] = 0.652; 95% confidence interval [CI]: 0.243–1.746; p = 0.395) or reoperation (OR 1.168; 95% CI: 0.374–3.651; p = 0.789). Furthermore, they found that outpatient TJA was a negative independent risk factor for complications (OR: 0.459; 95% CI: 0.371–0.567; p <0.001).[5] Nelson et al. conducted a similar study retrospectively reviewing 63 844 THAs between 2004 and 2015 tracked by NSQIP.[6] Of these patients, 420 (0.66%) were performed as an outpatient. These authors reported that outpatients had no difference in any of the adverse events evaluated other than blood transfusion, which was less for the outpatient group compared to the inpatient group (3.69% vs 9.06%; p <0.001).[6] This evidence supports the notion that outpatient TJA can be performed safely in appropriately selected patients. Li et al. remark that the essential components of a successful outpatient TJA program include proper patient selection, preoperative patient/family education, perioperative multidisciplinary coordination and opioid-sparing analgesia, and early and effective postdischarge planning.[7]

Resolution of clinical scenario

- The available literature illustrates comparable complication rates between outpatient arthroplasty and similar inpatient procedures.
- In selected patients, outpatient arthroplasty can be performed safely and effectively.

Question 2: In eligible patients undergoing TJA, does performing the procedure on an outpatient basis result in cost savings compared to the same procedures performed on an inpatient basis?

Rationale

A significant portion of the cost associated with TJA is attributed to overnight admission. With the constraint on healthcare resources, developing a successful outpatient joint replacement pathway opens up the potential for substantial cost savings from the perspective of the Ministry of Health, the institution, and society.

Clinical comment

Outpatient discharge protocols remove most of the associated inpatient costs of the procedures leading to an overall reduced cost. Reducing the cost of healthcare improves access to services for both patients and healthcare centers.

Available literature and quality of the evidence

- Level I: 1 RCT.[3]
- Level III: 1 systematic review[8] and 4 economic analyses.[9–12]

Findings

One of the benefits of the movement toward outpatient arthroplasty is the potential for considerable cost savings. Pollock et al. conducted a cost-minimization analysis in

London, Canada and compared outpatient THAs with inpatient (next-day discharge) THAs.[3] The authors showed that the outpatient group was significantly less expensive than even an enhanced recovery pathway from the perspectives of the hospital (CAD$5170 vs CAD$4403) and the Ministry of Health (CAD$6752 vs CAD $5890), primarily because of a shorter length of stay, less time in the postanesthetic recovery unit, and less time following discharge from the recovery unit.

A systematic review of outpatient orthopedic surgeries performed by Crawford et al. found seven studies addressing cost with an overall savings between 17.6 and 57.6% for outpatient procedures relative to standard discharge protocols.[8] Of the seven studies included in the review, three investigated hip or knee arthroplasty. In 2014, Aynardi et al. conducted an economic analysis in Pennsylvania and illustrated that the overall cost in an outpatient setting (US$24,529) was significantly lower than the same procedures performed in an inpatient setting (US$31,327) ($p = 0.0001$).[9] In 2005, Bertin conducted an economic analysis in Maryland and found that the total average cost for an outpatient THA, including preoperative, intraoperative, and postoperative charges, was approximately US$2500 less than for the inpatients.[10] Finally, Lovald et al. retrospectively reviewed the Medicare 5% Limited Data Set to identify patients with TKAs between 1997 and 2009 and found a mean savings of US$8527 in outpatient TKAs compared to the reference group, which stayed in the hospital for an average of three to four days postoperatively.[11] More recently, Huang et al. conducted a cost-minimization analysis in Ottawa, Canada between 2012 and 2013 and looked at costs between same-day discharge TKA and standard inpatient TKA.[12] They found same-day discharge to be less costly in every case-control

match and found a median savings of 30% for those undergoing same-day discharge.[12]

Resolution of clinical scenario

- Overall, there is a consensus in the literature that outpatient discharge protocols provide significant cost savings for TJA.

Question 3: In patients undergoing an outpatient TJA, what factors are necessary to ensure a successful procedure compared to the general population undergoing TJA?

Rationale

It is important to understand that outpatient joint replacements are not appropriate for all patients and all care centers. Rather, there are a combination of factors that are required to ensure successful procedures. Before outpatient total joint replacements can be more widely adopted, it is imperative to illustrate these factors.

Clinical comment

To successfully achieve outpatient joint replacements, a combination of factors are necessary, including careful patient selection, a multidisciplinary team-based approach, appropriate preoperative education, and perioperative pain management. Furthermore, optimal surgical techniques are essential to facilitate same-day discharge.

Available literature and quality of the evidence

- Level IV: 2 systematic review.[2],[13]
- Level II: 1 prospective study.[14]

Findings

Appropriate patient characteristics are essential to ensure safe and successful arthroplasty in an outpatient setting. Current literature advises that outpatient TJA protocols place restrictions on age, body mass index (BMI), and severity of comorbidities.[2] Kort et al. performed a review of the literature to determine the patient selection criteria for outpatient TJA and found that there was no general consensus.[13] However, the authors reported that ideal patients for these outpatient procedures are those willing to go home the same day of surgery, with a low American Society of Anesthesiologists (ASA) classification (<III), age <75, and sufficient support at home.[13] Furthermore, extensive pre-existing comorbidities are a contraindication for outpatient procedures. In Denmark, Gromov et al. conducted a prospective two-center study investigating the feasibility of outpatient arthroplasty in unselected patients to identify the proportion of patients suitable for these procedures. They found that social network support, safe mobilization, and improved blood saving strategies are crucial to optimize the number of patients eligible for same day discharge.[14] Outpatient TJA is not possible without the proper education and motivation from the patient and their caregiver.

Beyond optimal patient selection, a multifactorial approach is crucial for outpatient TJA to be safely performed. This includes improved analgesia, early physiotherapy, and advanced surgical techniques.[2] These improved surgical techniques limit muscle damage and blood loss, which leads to less pain, quicker recovery, and rapid mobilization following surgery.[2] Pollock et al. reported that surgical

techniques varied across the outpatient total joint replacement literature, which is encouraging so that surgeons can be reassured that there are numerous techniques that can be safely and effectively performed without having to change their practice drastically.[2] Furthermore, the literature illustrates that there needs to be optimal coordination between surgeons, physiotherapists, occupational therapists, nurses, and anesthesiologists to ensure everyone involved is working together to provide the best and most efficient care possible.[2]

Resolution of clinical scenario

- For successful outpatient THA surgery, a number of studies conclude that careful patient selection is necessary (e.g. restrictions on age, BMI, and severity of comorbidities).
- Successful accelerated clinical pathways feature a multidisciplinary approach involving a range of healthcare professionals.
- Patients and their caregivers must be motivated for outpatient pathways to be effective.

Summary of answers

- In selected patients, outpatient joint replacements can be performed safely and effectively.
- In appropriate patients, orthopedic surgeons can perform outpatient total joint replacements at a signification reduction in final cost compared to inpatient procedures in similar patients.
- For successful outpatient surgery, careful patient selection is necessary (e.g. restrictions on age, BMI,

and severity of comorbidities).

[3] Division of Orthopaedic Surgery, Department of Surgery, University of Calgary, Calgary, AB, Canada

Introduction

There has been a resurgence of interest in the preservation of the native hip joint. The development of new techniques in pelvic osteotomies[1,2] for hip dysplasia and subsequently the introduction of the concept of femoroacetabular impingement (FAI)[3–5] have led to an increase in both open and arthroscopic procedures used in the management of hip pathology in young adults. In this chapter, we aim to review the available evidence for certain hip-preserving procedures in the orthopedic literature. Table 19.1 lists the common causes of hip pain in young adult patients.

Clinical scenario

- A 22-year-old female patient is reporting progressive pain in her right hip over the last six months.
- She also has occasional catching sensation in her right hip and she feels that her hip clicks as well. She does not have any medical co-morbidities.

Top three questions

1. In patients with femoroacetabular impingement, does hip preservation surgery, compared to nonoperative treatment, result in better functional outcomes?
2. In young adults with acetabular dysplasia, does periacetabular osteotomy, compared to conservative care, result in better functional outcomes?
3. Among patients with mild or borderline acetabular dysplasia, does hip arthroscopy, compared to conservative care, produce better functional outcomes?

Question 1: In patients with femoroacetabular impingement, does hip preservation surgery, compared to nonoperative treatment, result in better functional outcomes?

Rationale

The concept of FAI was introduced by Ganz and associates in 2003 as a cause for osteoarthritis of the hip.[3] The classic types of FAI include cam deformity, and pincer and mixed impingement.[3] The treatment of FAI includes nonsurgical (personalized hip therapy) and surgical methods. Personalized hip therapy provides muscle control, strength around the hip, and movement patterns, which can lead to the avoidance of hip impingement.[6] The surgical management has been described through both open[7–9] and arthroscopic procedures,[10–12] which allows resection of the bony impingement, treatment of the labral tears, and management of articular chondral lesions. Hip arthroscopy has equal or better outcomes compared to open surgical techniques and is associated with a lower incidence of major complications.[13] In a systematic review comparing

the results of open surgical dislocation, mini-open technique, and hip arthroscopy, the authors found a higher incidence of complications with open surgical dislocation primarily because of trochanteric osteotomy related issues. The mini-open procedure had a significantly higher incidence of iatrogenic injury of the lateral femoral cutaneous nerve.[13]

Table 19.1 Common causes of hip pain in young adult patients.

A. Intra-articular
Capsulolabral 1. Labral tears 2. Capsular laxity 3. Adhesive capsulitis
Ligamentous Ligamentum teres tear
Articular cartilage 1. Arthritis (osteoarthritis, inflammatory arthritis, post-traumatic, septic arthritis) 2. Articular cartilage injury
Synovium 1. Synovial chondromatosis 2. Pigmented villonodular synovitis (PVNS)
Osseous 1. Acetabular under-coverage (dysplasia) 2. Acetabular over-coverage (pincer impingement) 3. Femoroacetabular impingement 4. Osteonecrosis 5. Perthes disease 6. Slipped capital femoral epiphysis

7. Osteoid osteoma and other neoplastic causes 8. Stress fracture 9. Transient osteoporosis
B. Extra-articular
Muscular 1. Adductor muscle strain 2. Abductor tear 3. Iliopsoas tendinitis 4. Piriformis syndrome 5. Proximal hamstrings avulsion/tear
Impingement Ischiofemoral impingement
Osseous 1. Avulsion fracture (e.g. anterior superior iliac spine) 2. Sacroiliac injuries 3. Neoplastic
Athletic pubalgia
C. Referred pain
Lumbar spine
Genito-urinary system
Pathology of abdominal organ or abdominal wall (e.g. inguinal hernia)

Clinical comment

Both hip arthroscopy and personalized hip therapy are successful methods in the management of FAI; however, hip arthroscopy can result in greater improvements of patients' symptoms in the short term.

Available literature and quality of the evidence

- Level I: 1 study (hip arthroscopy versus physical therapy).
- Level IV: 1 meta-analysis of level III and IV evidence.

Findings

Griffin et al. compared the clinical effectiveness of hip arthroscopy versus the best conservative care for patients with FAI in a multicenter trial (UK FASHIoN study) conducted in 23 hospitals in the UK.[6] The study was an assessor-blinded randomized controlled trial (RCT) that included 348 patients with symptomatic FAI with no radiographic evidence of osteoarthritis. Patients were allocated to receive either hip arthroscopy or personalized hip therapy (an individualized, supervised, and progressive physiotherapist-led program of conservative care). Their primary outcome was the patient-reported International Hip Outcome Tool (IHOT-33) 12 months after randomization. Both groups showed an improvement of the average IHOT-33; however, the mean difference in IHOT-33 scores was 6.8 (95% confidence interval [CI]: 1.7–12.0) in favor of hip arthroscopy ($p = 0.0093$). The UK FASHIoN study is the first RCT that shows that hip arthroscopy is effective in the treatment of FAI. This study published in 2018 reported only 12 months clinical outcome after randomization and longer-term follow-up is still needed. In a recent meta-analysis of 1981 hips assessing the outcome of hip arthroscopy for FAI (level IV), the reported risk of reoperation was 5.5%, while the risk of clinical

complications was 1.7%. These complications included heterotopic ossification, transient neuropraxia, adhesions, stiffness, wound infection, skin necrosis, and nondisplaced femoral head-neck fracture.[14]

Resolution of clinical scenario

- Patients with FAI can be managed operatively or nonoperatively. Hip arthroscopy has better outcomes at short-term follow up (level I).
- Both hip arthroscopy and open surgical procedures are effective methods in the management of FAI; however, open procedures are associated with a higher incidence of complications (level III, IV).
- Hip arthroscopy for FAI has a reoperation rate of 5.5% and a complication rate of 1.7% (level IV).

Question 2: In young adults with acetabular dysplasia, does periacetabular osteotomy, compared to conservative care, result in better functional outcomes?

Rationale

Acetabular hip dysplasia covers a spectrum of deformities and is considered present when the lateral center-edge angle (LCEA) is <25° and/or the acetabular index (AI) is >10°.[15,16] Symptomatic hip dysplasia is associated with hip pain and functional limitations.[16,17] Moreover, acetabular under-coverage can lead to early secondary osteoarthritis of the hip. The Bernese periacetabular osteotomy (PAO) was proposed as a method of treatment for symptomatic

acetabular dysplasia by Ganz and his colleagues in 1988.[1] This osteotomy has potential advantages of maintaining the posterior column integrity, preserving the acetabular blood supply and enabling multiplanar acetabular reorientation.[18_20]

Clinical comment

Periacetabular osteotomy can be used for the treatment of residual acetabular dysplasia in young adults with closed triradiate cartilage. Periacetabular osteotomies can improve patients' symptoms and function. The hip survivorship after PAO was reported as 86, 60, and 29% over 10-, 20-, and 30-year periods, respectively.[21],[22] This is despite the fact that the original cohort has a significant number of less-than-ideal hips for preservation with osteotomy.

Available literature and quality of the evidence

Multiple level III and IV studies seek to answer this question.

Findings

The longest follow up after PAO for dysplastic hip patients was reported by the Bernese group in 2016.[21] They published a 30-year follow-up report on their first 63 patients (75 hips) who underwent PAO for hip dysplasia between 1984 and 1987. About 24% of this cohort showed preoperative radiographic evidence of osteoarthritis. Their results have shown cumulative survivorship was 29% at 30 years with 71% of the hips converted to total hip arthroplasty, showed progression of osteoarthritis, or patients had a low Merle d'Aubigné-Postel score (<15). Among the factors they have identified to be associated with failure of PAO, they found that patients with

preoperative radiographic evidence of osteoarthritis were 40 years or older, had preoperative low hip scores, and that patients with preoperative signs of impingement are prone to have poor clinical outcome. They also concluded that PAO should be avoided in patients with preoperative advanced degenerative hip changes.

In a large prospective multicenter study, The ANCHOR group reported a good improvement of pain, function, quality of life, overall health, and activity level of patients who underwent PAO for hip dysplasia.[23] Their cohort included 391 patients who had a mean age of 25 years with a minimum two years' follow-up. They found that patients with moderate to severe dysplasia had more improvement compared to those with mild dysplasia.

Resolution of clinical scenario

- There is moderate evidence that PAO can be successful in improving the symptoms of patients with acetabular hip dysplasia (level III).
- Less than one third of dysplastic hips survived after PAO at 30 years follow up (level III).
- Patients older than 40 years, with preoperative signs of osteoarthritis or impingement, can have poor results after PAO (level III).

Question 3: Among patients with mild or borderline acetabular dysplasia, does hip arthroscopy, compared to conservative care, produce better functional outcomes?

Rationale

Mild and borderline acetabular dysplasia is considered in patients with LCEA between 18 and 25°.[24] Although, hip arthroscopy is associated with high failure rates in the setting of moderate and severe dysplasia,[25] the surgical management of symptomatic patients with mild/borderline hip dysplasia is still controversial. Some studies have reported less improvement of patients with mild dysplasia after PAO compared to those with moderate to severe dysplasia.[23] Common hip arthroscopic procedures do not address the primary pathology in hip dysplasia which is the deficient acetabulum; however, they can address the sequalae of the dysplasia such as labral tears, chondral injuries, and capsular laxity.[25–28] Moreover, arthroscopic femoral osteochondroplasty can be done to manage cam impingement which can be associated with hip dysplasia.[25,29]

Clinical comment

The results of the use of hip arthroscopy in the setting of mild hip dysplasia are inconsistent in the orthopedic literature. However, studies have shown symptomatic relief in short- and medium-term follow-up, especially with labral repair and capsular repair/plication in selected patients. Inadequate patient selection, labral debridement, absence of capsular repair/plication, presence of degenerative changes, and severe grades of dysplasia are associated with poor outcome.

Available literature and quality of the evidence

Multiple level III and IV studies are available on this topic.

Findings

Previous studies reported a high failure rate with hip arthroscopy in patients with acetabular dysplasia; however, their cases were associated with debridement of the labrum which is an important stabilizer in dysplastic hips.[30],[31] Grammatopoulos et al. have reported the outcomes of hip arthroscopy in a historical cohort of patients with hip dysplasia and found a higher failure rate (conversion to total hip arthroplasty) with moderate and severe dysplasia; however, they reported approximately 90% survivorship of hips with mild dysplasia over seven years.[25] They have also found a significant clinical improvement in the postoperative patient-reported outcomes for patients with preserved hips after hip arthroscopy. In a retrospective study, Hevesi et al. investigated the midterm results of arthroscopic labral repair in hip dysplasia. They matched a group of dysplastic patients to nondysplastic controls.[32] They did not find differences in the rate of failure or the clinical outcome between both groups at five years' follow-up.

More recently, Maldonado et al. analyzed the risk factors associated with arthroscopic capsular plication in patients with labral tears and borderline hip dysplasia.[33] They found that patients who were older than 35 years had relative risk of 2.25 of failure (95% CI: 1.10–4.60; p = 0.0266) at a minimum of two years postoperatively.

Resolution of clinical scenario

- There is moderate to poor evidence that hip arthroscopy can improve symptoms of patients with mild acetabular dysplasia (level III, IV).
- Labral debridement and large capsulotomies should be avoided when performing hip arthroscopy in patients with mild dysplasia (level III, IV).

Summary of answers

- Over the last decade, more evidence has become available for hip preservation surgery.
- Although there are multiple level III and IV evidence reports that support the use of these procedures, there is still paucity of RCTs in the orthopedic literature.
- In 2018, the first RCT was published on the use of hip arthroscopy in FAI and we believe that more level I evidence will be available soon.

20 The Direct Anterior Approach

Thomas J. Wood MD[1], and Brent Lanting MD MSc[2]
[1] Division of Orthopaedic Surgery, Department of Surgery, McMaster University, Hamilton, ON, Canada
[2] Division of Orthopaedic Surgery, Department of Surgery, University Hospital, London Health Sciences Centre, Western University, London, ON, Canada

Clinical scenario

- A 65-year-old female presents to your clinic after reading about the direct anterior approach (DAA) to total hip arthroplasty (THA).
- She wants to know what the pros and cons are to this approach.

Top three questions

1. In patients requiring THA for arthritis, does a DAA provide early and late functional benefit compared to posterior and lateral approaches?
2. In patients requiring THA for arthritis, does a DAA provide acceptable radiographic alignment compared to other approaches?
3. In patients who undergo THA, does a DAA have a higher complication rate compared to lateral or posterior approaches?

Question 1: In patients requiring THA for arthritis, does a DAA provide early and late functional benefit compared to posterior and lateral approaches?

Rationale

A minimally invasive internervous approach such as an anterior approach to the hip has been thought to result in less muscle damage and earlier recovery. However, controversy exists about the advantages of the anterior approach as many of the early outcome differences are shortlived.[1–3] Thus, it is important to understand the early and late functional outcomes when using a DAA for THA.

Clinical comment

The results of THA performed through a DAA are largely comparable to posterior and lateral approaches and are not considered superior.[1–5] Outcomes are dependent on the volume and experience of the surgeon.[6–9]

Available literature and quality of the evidence

Seven level I prospective randomized controlled trials (RCTs) assessed early functional differences when using the DAA for THA.[210–15]

Findings

Barrett et al. showed early benefit to pain scores, walking distance, and stair climbing but no differences at six months and a year between anterior and posterior approaches.[10] In a study comparing anterior to posterior approaches, time to ambulation without ambulatory aids and voluntary quitting of ambulatory aids was better in the

anterior group; however, no other clinical or radiographic differences were seen.[14] Zhao et al. showed that using an anterior approach resulted in shorter hospital stays, lower self-reported pain and lower muscle damage markers.[13] Functional outcomes based on the Harris Hip Score (HHS), University of California Los Angeles activity score and gait analysis was better at three months for the anterior group but was not different at six months.[13] Similarly, Christensen et al. showed the anterior approach resulted in shorter hospital stays, greater change in pain scores, and discontinuation of assisted devices at an earlier time.[15] There were no functional differences seen at six weeks.[15] Finally, Cheng et al. showed no differences between anterior and posterior approach besides subgroup analysis, which showed the anterior group having shorter hospital stays, less opiate requirements, and smaller wounds.[2]

Two RCTs compared the direct anterior and lateral approaches.[11],[12] Restrepo et al. in a study of 100 patients showed at one year that the anterior approach had significantly better improvement in Short Form 36 (SF-36) and Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC) scores, but at two years were the same.[11] De Anta-Diaz et al. showed that inflammatory biomarkers (IL-6, IL-8, CK) were significantly higher and magnetic resonance imaging (MRI) results at six months showed significantly more fibrosis and atrophy of the abductors in the lateral group.[12] Functional scores at three months and one year were similar in both groups[12] concluding that this early muscle damage in the lateral approach may not be clinically relevant.[12]

Currently, there are limited long-term data evaluating outcomes following a THA through the DAA. In an RCT, Brismar et al. showed no differences in hip function or pain at one or five years following THA from a DAA or lateral

approach.[16] Reichert et al. showed in a level III retrospective study of 171 hips with follow-up between 3.7 and 5.4 years, similar HHS, SF-36, and activity questionnaires comparing anterior and lateral approaches.[1] In an analysis 21 860 THAs in the Norwegian registry, there were no significant differences in revision for any cause and survival between anterior, lateral, and posterior approaches at two and five years.[17] In an analysis of the Dutch registry, 12 274 patients were evaluated including anterior, direct lateral, anterolateral, and posterolateral approaches. Minimal clinical differences were seen between approaches after three months.[18]

Resolution of clinical scenario

- The use of the DAA for THA may enhance early functional performance compared to other approaches.
- There are no long-term differences between the DAA and other approaches for THA.

Question 2: In patients requiring THA for arthritis, does a DAA provide acceptable radiographic alignment compared to other approaches?

Rationale

The importance of component alignment relates to its influence on longevity of the implant as well as functionality.[19]

Clinical comment

It has been hypothesized that component positioning may be more challenging with the DAA.[8] It is therefore important to assess radiographic alignment following THA using a DAA.

Available literature and quality of the evidence

Four level I studies, two level II studies, and one level III study attempt to answer this question.

Findings

Zhao et al. 2017 showed in a level I RCT of 120 patients that an anterior approach had significantly lower variance in anteversion and inclination compared to a posterior approach.[13] Furthermore, Taunton et al. in a level I study of 54 patients showed no difference between limb length and abduction angle when comparing anterior and posterior approaches.[14] Similarly, Barrett et al. in a level I study showed on the six-week postoperative radiographic that more direct anterior cups were within the Lewinnek safe zone; however, this wasn't significant when comparing to the posterior group.[10] Furthermore, the direct anterior group were significantly more likely to have the femoral stem placed in neutral varus/valgus position.[10] There was no evidence of migration and all components achieved osseointegration in both groups.[10] Finally, Cheng et al. in a level I study of 72 patients showed there was no significant radiological positioning differences between DAA and posterior groups.[2] There was more stem subsidence in the anterior group; however, this was not significantly different from the posterior group and these patients stabilized without symptoms or revision.[2]

In a recent systematic review (level II), Lanting et al. showed that surgical approach was not an important variable for implant position, suggesting all approaches are

adequate for exposure.[20] Similarly, Higgins et al. in a level II systematic review showed a greater percentage of acetabular cups placed within the safe zone when using the DAA; however, this was not significant when comparing to the posterior approach.[4]

Moreover, level III studies suggest the DAA with fluoroscopy is more accurate in regards to cup positioning; however, these studies compare to a posterior approach without fluoroscopy.[21–23] One possible explanation is that in the supine position this recreates the functional pelvic orientation facilitating more optimal acetabular positioning.[13,23]

Resolution of clinical scenario

- There are no differences between radiographic outcomes following a THA using a DAA.
- The use of fluoroscopy may play a role in cup positioning.

Question 3: In patients who undergo THA, does a DAA have a higher complication rate compared to lateral or posterior approaches?

Rationale

It is important to understand what unique complications a surgeon faces when using the DAA and compare these to other hip approaches.

Clinical comment

There appears to be a higher rate of early complications when a surgeon starts to use a DAA.[8,9,24–27] Furthermore, it has been shown that surgeons who had performed fewer than 100 cases were twice more likely to have complications in their patients, thus a low-volume surgeon may find this approach to have unacceptable complications.[6,24]

Available literature and quality of the evidence

Nine level I studies and nine level III studies exist that help to answer this question.

Findings

In a level I RCT, the number of adverse events was higher in the DAA group (11%); however, this was not statistically significant compared to the posterior group (5%).[2] This was similar to Barrett et al. 2013 in a level I study, which showed no difference in intraoperative and postoperative complications between anterior and posterior approaches.[10]

Injury to the lateral femoral cutaneous nerve (LFCN) is one of the more common complications when using a DAA for THA.[2] The incidence is highly varied in the literature likely related to how thorough postoperative physical examinations are, ranging from 0 to 80%.[1,2,6,11,28] In two RCTs, the rate of LFCN palsy was 0 and 83%, respectively.[2,11]

A perioperative fracture is potentially a devastating complication often requiring further fixation and or surgical procedures. Possible explanations for perioperative femur fractures when using a DAA include limited exposure for broaching, excessive retraction required to anteriorize the femur, as well as stress on the

greater trochanter from tense posterior soft tissue structures.[26,29] The rate is fairly low, ranging from 0 to 7% in level I and level III studies.[2,11,13,14,30–32] Four RCTs reported on fractures with a total of 172 patients with fractures occurring in five patients (3%), which included two calcar, one nondisplaced greater trochanter, one femoral perforation, and one greater trochanter tip avulsion fracture.[2,11,13,14] Matta et al. in a level III retrospective study reported seven proximal femoral fractures (three calcar, four greater trochanter), two femoral shaft fractures, and three traction-related ankle fractures in 494 patients, with an overall rate of 1.8%.[33] Treatment for this complication depends on location and implant stability but can include restricted weightbearing, cerclage wiring for greater trochanter fractures, and longer stem revisions for perforation or implant instability.[6,33]

Many surgeons have switched approaches due to the fear of dislocation and hip instability.[34] Registry data from two different level III studies of 22 237 and 21 860 patients respectively showed that the anterior and anterior lateral approaches had a lower dislocation rate compared to posterior.[16,35]

Due to the anterior location of the skin incision, this poses unique wound healing considerations as it is under increased shear stress.[26] Skin maceration and abrasion from broaching is not uncommon (around 5%) potentially increasing risk of wound breakdown, infection and reoperation.[15,25,26] Multiple level III studies suggest the rate of deep infection is between 0.5 and 2%.[6,26,32,33,36,37] The increasing number of assistants, operating personnel including a fluoroscopy technician, the movement and positioning of the C-arm above the incision, and the proximity to the groin all make contamination more likely.[25,38,39] In a level I RCT of 77 patients, Barrett et al.

had one patient in the DAA group who had a small dehiscence of the proximal aspect of the wound.[10] In a retrospective cohort study of 4651 patients, Purcell et al. showed no differences in deep infection rates between direct anterior and posterior approaches in patients with greater than or less than BMI of 35.[40]

Resolution of clinical scenario

- Overall complication rates are similar among hip approaches.
- When counselling a patient about a total hip through a DAA, one must discuss LFCN palsy, wound breakdown, and fracture as possible complications.

Summary of answers

- The use of the DAA for THA may enhance early functional performance compared to other approaches.
- There are no long-term differences between the anterior approach and other approaches for THA.
- There are no differences between radiographic outcomes following a THA using a DAA.
- The use of fluoroscopy may play a role in cup positioning.
- Overall, complication rates are similar among hip approaches.
- When counselling a patient about a THA through a DAA, one must discuss LFCN palsy, wound breakdown, and fracture as possible complications.

21 Computer Navigation in Total Hip Arthroplasty

Aamer Malik MD PhD[1], and Lawrence Dorr MD[2]
[1] Department of Orthopaedic Surgery, Hospital Universitario Sagrado Corazon, Barcelona, Spain
[2] LD Dorr Keck Medical Center of USC, Department of Orthopaedics, Los Angeles, CA, USA

Clinical scenario

- An 80-year-old man with back and left hip pain from severe combined osteoarthritis needs total hip arthroplasty (THA).
- He had right THA and suffered an episode of dislocation one year earlier, and is concerned about this happening again.
- Based on pre-operative imaging, the patient is found to have a stiff kyphotic spine with 10° of functional pelvic range of motion from sacral slope 15° standing to a low sacral tilt angle of 5° sitting.
- Computer assisted THA has been recommended for precise implant positioning aiming for a low combined anteversion to reduce risk of anterior dislocation.

Top three questions

1. For patients with combined hip-spine pathologies who require total hip arthroplasty, which evidence-based clinical investigations, compared to others, correctly evaluate their disease?

2. In patients undergoing total hip arthroplasty, which surgical techniques, compared to other techniques, result in optimal implant positioning and biomechanical hip reconstruction to reduce impingement and dislocation?
3. In patients undergoing total hip arthroplasty, does computer navigated surgery, compared to manual techniques, demonstrate superior implant positioning?

Rationale

Despite improved surgical techniques and implant designs, dislocation is still a leading cause for revision total hip surgery, inducing as many as one in five total hip arthroplasty (THA) revisions.[1,2] This is a major concern for the patient and hip surgeon alike. Total hip arthroplasty patients experiencing dislocation require significant healthcare resources to evaluate and manage this complication.[3,4] Ensuring that evidence-based techniques are employed for THA reconstruction will translate into appropriate use of these limited resources.

Clinical comment

Dislocation through implant malposition is a dynamic problem. Many studies have demonstrated that the classic static target numbers as referenced to anatomical landmarks for implant positioning are insufficient to ensure stability, and functional studies of implant positioning are required.[5–13] There is still no consensus towards the ideal target implant position, but data confirms the importance of incorporating pelvic functional tilt with combined femoral and acetabular version and femur first preparation to maximize range of motion (ROM) and minimize the risk of implant impingement and dislocation .[14–19] Patients with combined pelvic-spine deformities are at high risk for bone

on bone impingement despite avoiding implant impingement and require additional workup.

Understanding an algorithm with evidence-based investigations for common causes of impingement and pain in THA ensures that correctable problems are addressed.[5,10,11,20,21]

Available literature and quality of evidence

The quality of literature addressing appropriate investigations for functional implant positioning is highly variable with the vast majority being Grade II-IV evidence, mainly case series or consecutive cohort studies. Dorr et al. analyzed the influence of pelvic mobility to cup position through conventional radiography and recommended standing and sitting anteroposterior (AP) and lateral pelvic radiographs for patients identified as high risk.[8] Lazennec and Sariali used the EOS® radiographic technique which takes simultaneous capture of two full body orthogonal AP and lateral images and provides two- and three-dimensional models using its Stereos® software.[7,22] This allows superior functional analysis of hip-spine deformities and implant position.[23–25]

Findings

Kanawade et al. confirmed the normal range of pelvic motion from sitting to standing is 20–35° with increase in anteinclination upon sitting being 25° inclination and 14° anteversion. Their studies of pelvic tilt confirmed that 20% of patients present with a stiff (≤20°) or hypermobile (≥35°) hip-pelvic motion making them at risk for impingement and dislocation, respectively.[8,26] The particular preoperative mobility of the pelvis predicts the necessary modifications in strategy of implant position to minimize this risk. The fact that nearly 80% of THA are

implanted near their functional position makes THA tolerant to minor errors in positioning and explains the excellent long-term results that it has enjoyed.[27]

Dropout dislocation occurs upon sitting in patients with 1) hypermobility – posterior pelvic tilt upon sitting (as their functional inclination can be near 80–90°) or 2) hips that are shortened upon reconstruction. Intraoperatively, stability against dropout is tested by pushing the hip to its maximal flexion to the chest and observing that it does not dislocate. These patients (mainly females) need the cup at 35–40° inclination and 25° anteversion so that combined anteversion (CAV) is about 40–45° as they are at risk for posterior dislocation. Stiff pelvis (mainly males) with little posterior tilt and low functional anteinclination needs a cup position around 40–45° inclination as they bend forward more (trunk flexion) from sitting to standing and 15° anteversion so that CAV is about 25–30° to minimize risk for anterior dislocation in extension upon standing.[7,8,28,29] Additional measures such as trochanteric transfer may be required to minimize bone on bone impingement.[12,13]

The EOS® system was confirmed to achieve less radiation with accurate and reliable information for measuring spine acetabular, femoral and pelvic variables; it especially improves measurement of femoral offset and anteversion which standard 2D radiographs under-value from external rotation contracture.[22,23,30]

Resolution of clinical scenario

- Level II–IV evidence shows that 20% of patients present with pathologic pelvic-spine mobility at risk for dislocation.
- Level III evidence confirms utility of preoperative functional radiographs or EOS imaging to work up at-

risk patients.

- Level II evidence confirms surgical strategies and modification of implant position are required for at-risk patients.

Question 2: In patients undergoing total hip arthroplasty, which surgical techniques, compared to other techniques, result in optimal implant positioning and biomechanical hip reconstruction to reduce impingement and dislocation?

Rationale

The range and type of pelvic tilt influences functional cup position.[6–8,10] Thus, it is important to understand which surgical techniques allow for the most accurate functional implant positioning.

Clinical comment

Dislocation is the most alarming complication after THA, but pain, accelerated wear or loosening are also related to impingement and are probably clinically underestimated. In cementless THA, femoral anatomy dictates postoperative implant position, with about 20% of femurs in retroversion ≤0° (cam deformity), or ≥20° anteversion (dysplasia) and puts the patient at risk for impingement dislocation.[20,31,32] This was the basis for femur first preparation and the concept of CAV.

At present it is still difficult to quantify the implications of implant malposition on gait and stance,[33,34] but greater

knowledge in this field has opened new research opportunities.

Available literature and quality of the evidence

To analyze anatomy, surgeon perception, impingement and dislocation Dorr et al. studied a series of cohorts of over 200 patients with navigation and postop CT-scans.[20,31,35,36] With cementless femoral implants femur-first was used and cup anteversion was adjusted towards a combined anteversion of 25–45° while incorporating navigated pelvic tilt to try and achieve impingement free range-of-motion between stem and cup (level III and IV studies).[31,35] As discrepancies in definitions of target acetabular positioning in literature was found, laboratory models were developed to try and obtain consensus for reporting implant position, especially acetabular anteversion (level IV).[16,37] Zhu and Maratt et al. in a consecutive series of patients analyzed the influence of pelvic tilt on cup functional position.[14,38]

Renkawitz et al. in an RCT compared navigated femur-first technique with conventional THA to assess clinical functional outcomes (level II).[39] Weber in a prospective study of 135 patients evaluated 6 current definitions of combined anteversion for impingement free range of motion (level II).[40]

Findings

Total hip arthroplasty using the combined anteversion technique with navigation found no dislocations and achieved the targeted combined anteversion in 96% of cases. Dorr et al. confirmed that even experienced hip arthroplasty surgeons with mechanical guides had outliers over 5° in 31% of cases for acetabular inclination, 39% for anteversion and 46% for the femur version.[8,20,31,35–37] Similar results were found from other studies of

postoperative implant position with outliers of up to 50%.[41–43] Implant positioning depending on human experience alone is imprecise and inaccurate.[36,39,44–52]

Weber et al. concluded that standard rules of combined anteversion improved prosthetic range of motion in 90% of cases but failed to prevent combined osseous and prosthetic impingement in up to 40% of cases because of anatomic variants which occur in individuals.[33] Renkawitz also concluded that despite potentially improved implant positioning and hip flexion there were no significant differences with respect to any gait, functional or clinical outcomes at six months and one year of follow-up between the two treatment groups.[39,53]

Through a laboratory model, we found a correlation of 0.8° change in anteversion for every degree of pelvic tilt change, with the greatest change in anteversion in patients with over 10° of tilt.[14] A 10° magnitude of tilt can thus create an absolute error of 8° in judging the cup relative to the coronal position.[14,16,36,37] In our studies, 77 of 477 (16%) hips had an excess of 10° anterior or posterior tilt.[14] Maratt et al. similarly found 17% of patients with tilt ≥10°.[38] Our clinical studies of pelvic tilt later confirmed that about 20% of patients present with a stiff (≤20°) or hypermobile (≥35°) hip-pelvic motion and require adjusted cup positions.[8,54]

The CAV technique for cementless stems can eliminate stem-on-cup impingement but reduction of bone-implant and bone-bone impingement requires correct cementless cup coverage and correct leg-length (LL) and offset restoration.[33,53,55] In normal hips this requires cup center of rotation (COR) to be reamed on average 5 mm medially and 3 mm superiorly for non-cemented cups. In a clinical study of 82 navigated THAs, we confirmed that

reconstruction within 6 mm of anatomic position was achieved in 95% of cases (78/82 hips) for offset and 99% (81/82) of cases for LL.[55] Honl et al. confirmed that mean error in depth of manual reaming is 6.4 mm from anatomic COR.[56] Hips with dysplasia are difficult to maintain in their anatomic position and often require non anatomic cup positions and offset stems. When added stability is required for high risk patients, dual mobility or constrained cups may be indicated.

Resolution of clinical scenario

- Level II–IV evidence shows cementless femoral implant position as potentially at-risk for dislocation in about 20% of cases due to abnormal version.
- Level II evidence has confirmed that femur first preparation and combined anteversion potentially reduce the risk for prosthetic impingement in 90% of cases but do not improve clinical or functional results at one year.
- Level II–IV evidence of bone on bone impingement from anatomic variants occurs in up to 40% of cases and may require use of dual mobility or constrained implants.

Question 3: In patients undergoing total hip arthroplasty, does computer navigated surgery, compared to manual techniques, demonstrate superior implant positioning?

Rationale

The hip surgeon's most common error is malposition of the acetabular component which is independent of expertise or approach.[20],[57],[58] Non-cemented femoral implant position is not consistent and induces errors when standard acetabular position is targeted.[32],[42]

Clinical comment

Standard surgery cannot evaluate pelvic tilt and functional hip position which is greater than expected in about 20% of cases.[8]

Available literature and quality of the evidence

Dorr et al., in a consecutive prospective cohort series of over 200 patients validated their navigation system for precision and bias with postoperative computed tomography (CT) scans (Grade III-IV). Multiple studies on navigation even by pioneers like DiGioia et al. were on limited number of patients or on laboratory models (Grade III–V).[15],[45],[59] There are only 7 prospective randomized trials comparing 255 patients with navigation and 259 patients with freehand cup placement with (level II).

Findings

Dorr et al. confirm that, for all variables analyzed, computer assisted THA (CAS-THA) is more precise (reproducible) with less bias (error) in comparison to experienced surgeons (ES).[8],[20],[31],[35–37] With computer navigated (NAV) cup inclination, bias was 0.03° and precision 4.4°; for anteversion bias was 0.73° and precision 4.1°. Experienced surgeons present a bias of 1.0° and a precision of 11.5° for cup inclination, and a bias of 2.1° and a precision of 12.3° for anteversion.[36] For femoral position the NAV bias was 0.2° with precision of 4.8°, and for ES the bias was 0.3° and precision 16.8°.[31] For combined

anteversion determined by NAV, the bias was 0.2° and precision 4.8°, while for ES estimates the bias was 3.7° and precision 18°.[37] As mentioned earlier, ES have outliers over 5° in 31% of cases for acetabular inclination, 39% for anteversion and 46% for femur version.[8,20,31,35–37]

Multiple groups working with CAS-THA surgery have consistently confirmed these results. A meta-analysis by Gandhi et al. confirmed more precise cup positioning with NAV-THA without increase in complications, except longer operating times.[60] The meta-analysis by Xu et al. confirmed superior cup positioning and leg length reconstruction with NAV but longer operating times.[61] No differences were found in dislocation rates, deep vein thrombosis or functional outcomes at different time points.[61] Snijders conducted a systematic review and meta-analysis to assess the precision and accuracy from all available high-quality RCTs to date.[62] Six out of seven studies concluded a statistically significant difference in precision in anteversion between the NAV group and the freehand group.[46,48,49,52,63–65] Five out of seven studies concluded a statistically significant difference in precision in inclination. There is a significantly better accuracy for the CNAV-THA group than for the freehand group for anteversion ($p = 0.002$) and for inclination ($p = 0.01$). Parrate confirmed at 10-year follow-up that NAV-THA for cup placement did not confer any substantial advantage in function, wear rate, or survivorship.[64]

Resolution of clinical scenario

- Level II–IV studies have confirmed that computer-navigated implant positioning is more precise with less bias than experienced surgeons.

- Level IV evidence studies confirm that navigation provides more functional implant positions by incorporating pelvic tilt.
- Level II evidence at 10-year follow-up shows that navigation for cup placement does not confer any substantial advantage in function, wear rate, or survivorship.

Summary of answers

- About 20% of patients with pathologic spinopelvic mobility and abnormal femoral version are at risk for dislocation.
- Preoperative functional studies are required to identify this subset of patients who require modifications in surgical strategy and implant positioning.
- Femur first and combined anteversion reduce prosthetic impingement between implants but have not been shown to improve clinical or functional results.
- Computer navigation is superior to experienced surgeons in precise and functional implant positioning but has not been demonstrated to confer any substantial advantage in function, wear, or survivorship to date.

22 Highly Crosslinked Polyethylene in Total Hip Arthroplasty

Glen Richardson MD MSc FRCSC, and Michael J. Dunbar MD PhD FRCSC
Division of Orthopaedic Surgery, Department of Surgery, Dalhousie University, Halifax, NS, Canada

Clinical scenario

- A 55-year-old active female presents to an orthopedic surgeon with advanced osteoarthritis in her right hip.
- Her quality of life is significantly affected by the pain and lack of motion in her right hip.
- Conservative treatment options have been exhausted and she is scheduled for a total hip arthroplasty (THA) with the use of ultra-high-molecular-weight polyethylene (UHMWPE).

Top three questions

1. In patients receiving a THA, does highly crosslinked polyethylene (HCLPE) result in a reduction in the wear rate compared to standard UHMWPE?
2. In patients receiving a THA, does HCLPE result in a reduction in osteolysis compared to UHMWPE?
3. In patients with a THA, does the use of HCLPE result in the potential for mechanical failure compared to standard UHMWPE?

Question 1: In patients receiving a THA, does highly crosslinked polyethylene (HCLPE) result in a reduction in the wear rate compared to standard UHMWPE?

Rationale

The purpose of HCLPE is to improve the longevity of THA by decreasing the wear rate of the bearing used during THA. The use of THA in younger and presumably more active patients has led surgeons to be concerned about the wear rate of polyethylene and to seek out expensive alternate bearings such as HCLPE, ceramic on ceramic, or metal on metal. Clearly any change made to polyethylene has the potential for decreasing wear rates but also increasing adverse events.

Clinical comment

The clinical importance of decreasing polyethylene wear rates is significant to THA recipients. The main theory of late failure of THA is that the wear of the bearing generates particulate debris that leads to loosening, mechanical failure, and/or instability of the THA.

Available literature and quality of the evidence

Ten high-quality randomized controlled trials (RCTs), level I, are available to answer this question.

Findings

A considerable amount of research on the topic of THA wear rates has been published. Many of the studies are RCTs to demonstrate the improvement in wear rates with

HCLPE as compared to regular polyethylene. What complicates the interpretation of the literature is that various different types of HCLPE, which use different techniques to achieve crosslinking and eliminating free radicals, have been used in the clinical studies. In order to interpret the substantial amount of reported data on HCLPE, a basic knowledge of the different methods to measure in vivo wear of polyethylene is necessary. There are manual techniques that rely on manual edge detection to calculate the migration of the femoral head.[1] To improve accuracy and reproducibility, computer-aided techniques have been developed.[2,3] The most accurate method of measuring wear is radiostereometric analysis (RSA).[4,5] Studies looking at wear rates require follow up of at least two years, in order to get a true estimate of steady state wear rate because of the effect of plastic deformation, otherwise known as *bedding in* or *creep*.[6–8]

There have been eight papers that have performed RCTs using cobalt chrome femoral heads on HCLPE and have used some form of computer-assisted technique to measure the polyethylene wear.[9–16] Many of the major manufactures of HCLPE are represented in these articles. Marathon (5 Gy), Durasul (9.5 Gy), Longevity (10 Gy), and Crossfire (7.5 Gy) have all demonstrated significant reductions in steady state wear rates compared to UHMWPE. The reduction in wear varies from 55 to 95% and this often is a function of the wear properties of the control group. Importantly, the follow-up was 2 to 10 years confirming the improved wear of HCLPE.

There have been 12 RSA studies, eight of which are level I studies, reported in the literature.[6,17–25] Arcom, E1 Vitamin E poly, Reflection, Durasul, Longevity, and Crossfire HCLPE have all been demonstrated to have significantly

decreased wear rates compared to UHMWPE. The length of follow-up varied from 2 to 13 years.

Resolution of clinical scenario

- HCLPE results in a significant reduction in polyethylene wear in vivo compared with regularly UHMWPE.
- This reduction in wear remains present at follow-up of 13 years.

Question 2: In patients receiving a THA, does HCLPE result in a reduction in osteolysis compared to UHMWPE?

Rationale

There has been concern that the smaller wear particles of THA will lead to an increased risk of osteolysis compared to UHMWPE.[26,27]

Clinical comment

One of the major reasons for revision of THA is the presence of progressive osteolysis (Figure 22.1).[28] Thus, it is important to understand if HCLPE results in reduced osteolysis.

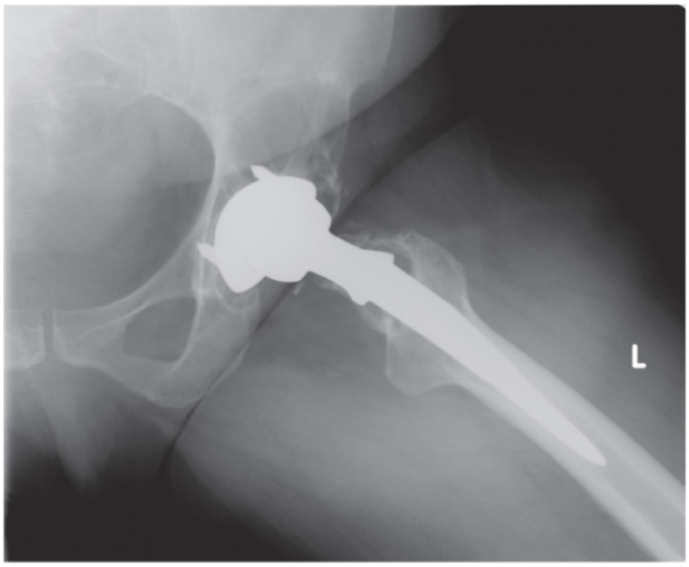
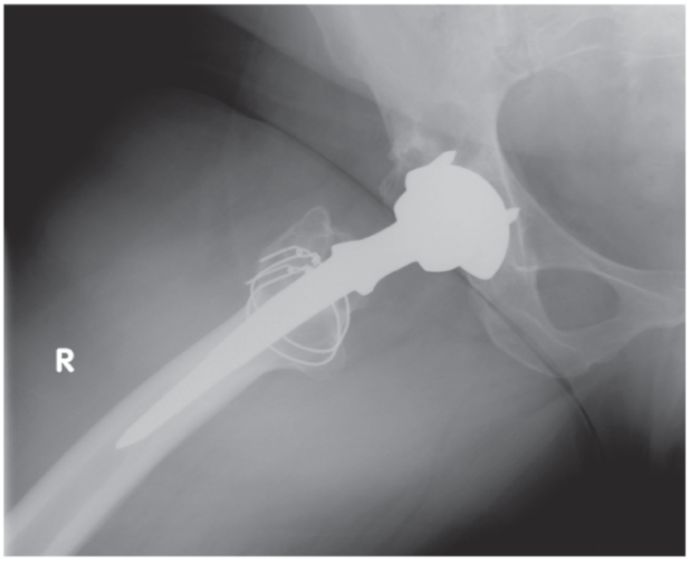
L



L



R

Figure 22.1 AP and lateral views of bilateral hip replacements with UHMWPE demonstrating advanced polyethylene wear and associated osteolysis six years postoperatively in a modestly active female.

Source: Glen Richardson, Michael J. Dunbar.

Available literature and quality of the evidence

There are six level I RCTs and three level III systematic reviews of case-controlled and retrospective studies that aim to answer this question.

Findings

There have been a number of studies that have looked at wear and reported on the incidence of osteolysis as part of an RCT.[9,16,19,29–31] All studies noted a statistically significant decrease in the presence of osteolytic lesions at up to 13 years' follow-up. The method used to evaluate the osteolytic lesions is important, with two studies using the more sensitive technique of CT (computed tomography) scans.[29,31] Both studies noted a significant reduction in the incidence of osteolysis. Ultimately, this is an expected result with yearly wear rates for HCLPE well below the suggested 0.1 mm per year threshold for the formation of osteolytic defects.[32]

Resolution of clinical scenario

- Use of HCLPE demonstrated a significant reduction in the presence of osteolytic lesions.
- Decreased osteolysis is consistent with the low wear rates measured with the use of HCLPE.

Question 3: In patients with a THA, does the use of HCLPE result in the potential for mechanical failure compared to standard UHMWPE?

Rationale

In processing HCLPE the steps taken to increase the cross-linking weaken its mechanical properties and this could result in mechanical failures of the insert.

Clinical comment

The creation of HCLPE results in unfavorable changes with ultimate tensile strength, ductility, modulus, toughness, and crack propagation resistance.[33],[34] There are cases of liner failures reported in the literature, but some of the failures likely were related to implant design.[35]

Available literature and quality of the evidence

Four level IV studies (case series) and three level V (case reports and expert opinion) exist on this question.

Findings

The case reports in the literature only represent small series up to four cases and one report from a voluntary report to the United States Food and Drug Administration of 74 cases.[35–41] The key finding in these analyses is that most failures of HCLPE liners are due to impingement at the areas of the liner that are unsupported and thin, such as elevated rims or locking grooves. It is clear that, with the large number of HCLPE being used, mechanical failure of HCLPE is a rare occurrence.

Resolution of the clinical scenario

- The process of creating HCLPE weakens its mechanical properties.
- There are case reports of HCLPE fractures, almost exclusively at the rim of the liner.
- Avoiding impingement and cup malposition is key to limit this mode of failure.

Summary of answers

- The use of HCLPE consistently demonstrates a reduction in wear rates compared with UHMWPE.
- This reduction in wear is also associated with significantly fewer osteolytic lesions at long-term follow-up.
- Mechanical failure of HCLPE is unusual but there are case reports.
- The fracture of the liner occurs at the rim, where the HCLPE is unsupported and thin due to elevated rims or locking mechanisms.

Clinical scenario

- A 48-year-old healthy male presents with right groin pain that has progressively limited his work and leisure activities over the last two years.
- Clinical examination of the affected hip reveals restricted motion and antalgia while radiographs demonstrate advanced degenerative joint disease.
- The patient is a manual laborer and avid hockey player who is seeking a surgical intervention to restore his function with durable results.

Top three questions

1. In young, active patients with advanced degenerative hip disease, does hip resurfacing result in superior patient-reported outcome measures compared to total hip arthroplasty (THA)?
2. In patients with advanced hip osteoarthritis, does hip resurfacing result in higher revision rates compared to THA?
3. Does more surgeon experience or technique, compared to less surgeon experience or other techniques, impact

the clinical outcome of patients undergoing hip resurfacing?

Question 1: In young, active patients with advanced degenerative hip disease, does hip resurfacing result in superior patient-reported outcome measures compared to total hip arthroplasty (THA)?

Rationale

While THA has consistently demonstrated excellent long-term clinical outcomes in patients suffering from end-stage degenerative joint disease,[1] hip resurfacing has emerged as an alternative option with several potential advantages. By only resurfacing the articulation, a relatively larger head is employed which may improve stability.[2] Furthermore, hip resurfacing maintains more femoral bone stock,[3] thereby facilitating future revision surgery and theoretically preserves each patient's native anatomy and biomechanics, which may result in improved motion and function. This is especially pertinent to young and active patients wishing to return to physically demanding activities. A comparison of patient-reported outcome measures between hip arthroplasty and resurfacing is therefore of paramount interest.

Clinical comment

The theoretical advantages of hip resurfacing must be demonstrated clinically through improved patient-reported outcomes over THA (the current gold standard treatment) before widespread adoption is advocated.

Available literature and quality of the evidence

The majority of studies comparing patient reported outcomes between hip resurfacing and replacement surgery are case-controls (level III) and report mixed results.[4–11] Nonetheless, there are four randomized controlled trials (RCTs) (level I) that compare clinical outcomes between hip resurfacing and replacement in relatively young and active patients. Two of these studies compare resurfacing with contemporary nonmetal-on-metal total hips,[12,13] while the other two studies compare hip resurfacing with metal-on-metal THA.[14,15]

Findings

Focusing our discussion on the available level I evidence, there are two studies that compare hip resurfacing to THA with nonmetal-on-metal articulations. Costa et al. randomized 126 patients to receive either hip arthroplasty or resurfacing and reported similar Oxford Hip Scores (mean 38.2, 95% confidence interval [CI]: 35.3–41.0 vs 40.4, 95% CI: 37.9–42.9, respectively) and Harris Hip Scores (HHS; 82.3, 95% CI: 77.2–87.5 vs 88.4, 95% CI: 84.4–92.4, respectively) at 12-month follow-up.[13] Strengths of this study include: adherence to a standardized preoperative assessment and perioperative care pathway for both groups, blinded measurement and assessment of outcomes, low cross-over rates, excellent follow-up (95%), and the fact that each patient had the allocated surgery according to the preferred technique of the operating surgeon. While clinical outcomes were similar between the two groups, they were limited to a one-year follow-up and may not reflect long-term results between these two interventions. More recently, Haddad and colleagues reported on the long-term results of their randomized trial involving 80 patients treated with either cementless THA or

a Birmingham hip resurfacing.[12] Similar to Costa's study, there was no difference in mean Oxford Hip Scores (37.9 ± 0.6 for replacement vs 40.1 ± 0.4 for resurfacing) nor HHS (96 ± 4.2 for replacement vs 97.1 ± 5.1 for resurfacing) at mean follow-up of 12 years. Nonetheless, the authors report that a higher proportion of patients with a hip resurfacing were running and involved in sport and heavy manual labor after 10 years. The authors suggest an advantageous return to high-level activity in resurfaced patients, perhaps below the sensitivity threshold of the Oxford and HHS. It must be noted, however, that there was a large amount of crossover in this study where only 24 of the 80 patients actually underwent the treatment to which they were randomized.

There are two RCTs comparing hip resurfacing to metal-on-metal THA. Vendittoli et al. randomized 209 hips to undergo resurfacing or replacement with a metal-on-metal bearing using a 28 mm head.[14] They demonstrated a marginally better Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC) score in the resurfacing group (5.7 ± 8.6 for resurfacing vs 9 ± 11.0 for THA) at two-year follow-up. Garbuz et al. randomized 107 patients to either hip resurfacing or a large head metal-on-metal hip arthroplasty.[15] Exceedingly high metal ion levels discovered in the hip arthroplasty group raised concern for trunnionosis and eventually led to the premature termination of the trial. Similar early failures of large head metal-on-metal total hips have been identified from multiple studies and registries leading to the widespread abandonment of these implants.[16]

Resolution of clinical scenario

- Current level I evidence does not support a clear clinical benefit in patient-reported outcome measures

following hip resurfacing in comparison to THA.

- Nonetheless, hip resurfacing as compared to THA may offer advantageous long-term function with respect to specific high-demand actives such as participation in running sports and manual labor.

Question 2: In patients with advanced hip osteoarthritis, does hip resurfacing result in higher revision rates compared to THA?

Rationale

Higher-than-expected revision rates for resurfaced hips have been reported for numerous reasons including femoral neck fractures,[17,18] implant position,[19] and size,[20,21] adverse reactions to metal ions,[22,23] and certain implant designs.[24,25] Given the generally young age and high activity level of this patient population, revision is a major concern – albeit revising a hip resurfacing may be easier than a THA due to preserved femoral bone stock. A critical evaluation of survivorship is therefore necessary to guide surgical indications and appropriate patient selection for successful hip resurfacing.

Clinical comment

Notwithstanding potential clinical benefits of hip resurfacing, the survivorship of these implants in comparison to conventional THA remains a critical concern in the young and active patient.

Available literature and quality of the evidence

Numerous case series, cohort studies, and small single-center RCTs have compared the revision rates between hip resurfacing and replacement as summarized in the systematic review by Marshall et al.[2] and meta-analysis performed by Smith et al.[26] The former reported an average time to revision was 3.0 years for metal-on-metal hip resurfacing (95% CI: 2.95–3.1) versus 7.8 years for THA (95% CI: 7.2–8.3). Similarly, Smith et al. demonstrated a risk ratio for revision of 1.72 (95%CI: 1.20–2.45) with hip resurfacing compared to replacement; however, both Marshall and Smith caution the lack of high-quality data included in these analyses. Few studies reported medium- or long-term follow-up or adequate matching of controls, and included a variety of hip resurfacing implants – some of which have been shown to be far more successful than others. Consequently, we believe the data from national joint registries, which collect detailed information on patients undergoing joint replacement, are the best available data on survivorship and will be used in this section to compare revision rates of hip resurfacing and replacement implants.

Findings

The 2016 annual report of the Australian National Joint Replacement Registry analyzes 498 660 primary and revision hip arthroplasty procedures with up to 15-year follow-up.[27] While the number of hip resurfacing procedures has dropped considerably over the last few years (accounting for only 0.8% of hip arthroplasty procedures in 2016), a total of 16 521 hip resurfacing procedures have been captured and are tracked in the registry. The cumulative percent revision of primary hip resurfacing for patients with osteoarthritis (which accounts for >95% of the hip resurfacing procedures in the registry) is 9.5% (95% CI: 9.0–10.0) at 10 years and 12.9% (95% CI:

11.8–14.0) at 15 years. This is considerably higher in comparison to primary THA, which has a cumulative percent revision of 5.1% (95% CI: 5.0–5.2) at 10 years and 8.0% (95% CI: 7.7–8.3) at 15 years. However, when comparing only male patients younger than 55 years old (the typical candidate for resurfacing[28]) and excluding implants with poor performance, the 10-year revision rates are lower with resurfacing 3.7% (95% CI: 3.1–4.4) compared to replacement 5.4% (95% CI: 5.2–5.6). Prior case series have associated component malpositioning[19] and a small head size[20,21] with increased risk of failure. The registry reiterates the latter, reporting 10-year cumulative percent revision rates of 23.0% (95% CI: 20.6–25.6) and 5.1% (95% CI: 3.8–6.8) for head sizes of ≤44 and >55, respectively (hazard ratio of 3.2; 95% CI: 2.3–4.5). The registry also reports markedly higher failure rates in females (10-year cumulative percent revision of 18.3%; 95% CI: 16.9–19.7 for females vs 6.6%; 95% CI: 6.1–7.1 for males), likely reflecting smaller component sizes in these patients. Finally, the wide range of clinical success of specific resurfacing implants is highlighted in the registry; reporting overall 10-year percent revision from as low as 6.9% (95% CI: 6.4–7.5) for the Birmingham Hip Resurfacing System to as high as 30.1% (95% CI: 27.4–33.1) for the Articular Surface Replacement (which was recalled in 2010). The strengths of these data include the large number of patients included, long-term follow-up, and the fact the majority of the resurfacing implants used were the Birmingham Hip Resurfacing System which has an excellent track record and therefore represents a best-case scenario. The biggest limitation of the Australian data, alike other registries, is that they do not capture detailed level II data (e.g. body mass index, comorbidities, activity-level, surgeon volume) and therefore makes for a potentially biased comparison to patients undergoing THA.

Other national registries such as the Swedish Hip Arthroplasty Register[29] and National Joint Registries (UK)[30] demonstrate similar findings to those described above. The latter reports 10-year revision rates of 8.4% (95% CI: 7.9–8.9) for the Birmingham Hip Resurfacing System, where the leading causes for revision were pain and adverse soft tissue reactions. Interestingly, the registry also reports revision rates following first revision (re-revision), which are 11.5% (95% CI: 10.3–12.9) for hip resurfacing and 13.0% (95% CI: 12.1–13.8) for uncemented hip arthroplasty.

Resolution of clinical scenario

- According to national joint registry data, the long-term revision rates of hip resurfacing are higher than THA except in males younger than 55 years of age where resurfacing has advantageous survivorship.
- Younger age, female sex, small head size, and certain implant designs are all strongly associated with a higher cumulative percent revision following hip resurfacing.
- Following first revision, the risk of subsequent revision is similar between a THA and resurfacing.

Question 3: Does more surgeon experience or technique, compared to less surgeon experience or other techniques, impact the clinical outcome of patients undergoing hip resurfacing?

Rationale

While the concept of hip resurfacing was established as early as the 1940s,[31] technological advances in metal-on-metal bearings[32] enabled an all-metal acetabular component and spawned renewed interest in resurfacing over the last two decades.[28] The adoption of new implants and techniques for resurfacing therefore introduced a new learning curve to surgeons. Subsequently, the clinical outcomes have improved through refinement of implant design, surgical technique, and patient selection, all of which are essential to successful hip resurfacing.

Clinical comment

An understanding of the lessons learned from early experiences with metal-on-metal hip resurfacing and appreciation of the learning curve are critical for surgeons who wish to perform this procedure.

Available literature and quality of the evidence

The clinical success of various hip resurfacing implants is well followed in national joint registries (see above). With regard to surgeon experience, technique, or patient selection, the literature is sparse. The effect of these parameters is limited to several large case series (level IV) as discussed below.[33–37]

Findings

Berend and Lombardi, two experienced high-volume joint surgeons, described their initial experience with hip resurfacing.[33] Following surgeon-to-surgeon training and practice sessions on cadavers, they reported on their first 73 patients who underwent hip resurfacing. There was an 8% prevalence of early failure requiring revision (at mean

follow-up of 25 months). While a high number of patients were lost to follow-up, of the 77% evaluated at a minimum of one year (average, 33 months), only 79% were reported to have a good or excellent result and only 65% were free from pain. Della Valle et al. reported on the first 537 cases performed in the United States using the Birmingham Hip Resurfacing System with 14 component revisions (7.4%) within the first year, including 10 for femoral neck fracture, two for dislocations, and two for acetabular component loosening.[34] These failure rates contrast starkly to those reported by surgeons with a long experience using the same implant such as the series reported by Treacy et al. with a five-year revision rate of only 2%.[37] These series clearly warn of a learning curve associated with the surgeon new to hip resurfacing.

Beyond the initial learning curve of the procedure, refinement of technique has led to improved outcomes in several studies. Mont et al. reported on a series of 1016 hip resurfacings by a group of surgeons who convened after the first 292 cases for an *investigator meeting* where they reviewed their results. The following risk factors for failure were identified:[35]

- Preoperative assessment

  Large or multiple cysts situated near the femoral head-neck junction.

  Poor bone quality.

- Operative/technical factors

  Leaving reamed bone uncovered by femoral component.

  Minimizing the size of the femoral component to conserve acetabular bone.

Leaving the femoral component proud on the femoral head.

Malpositioning of the acetabular shell.

- Postoperative factors

  Noncompliance with postoperative restrictions.

  Weightbearing and traumatic events.

  Malpositioning: acetabular shell <30°, >60°, or femoral component <135°.

The group made a concerted effort to address the above listed risk factors thereafter. Comparing outcomes before and after the meeting, overall complication rates were significantly reduced, notably in the rates of revision for femoral neck fracture (7.2 to 0.8%) and aseptic loosening of the acetabular component (3.4 to 1.9%) with mean follow-up of 33 months. Amstutz et al. elaborated on a series of 1000 patients undergoing resurfacing with the Conserve Plus and demonstrated that improvements of their femoral fixation technique (termed *first*, *second*, and *third generation*) correlate with significant improvements in medium-term implant survivorship: with a hazard ratio of 0.37 (95% CI: 0.17–0.83).[38] Siebel et al. reported similar improvements in revision rates as the number of cases performed increased, dropping from 5% in the first hundred cases to 1% in the third hundred cases.[36] Despite reducing failure rates with experience and refinement of technique in all of the above studies, patient-reported outcomes were similar over time.

Resolution of clinical scenario

- Surgeons who are inexperienced in hip resurfacing should be aware of a potential learning curve and increased risk of implant failures (particularly femoral

neck fracture and aseptic loosening of the acetabular component) during this period of adaptation.

- Experience and a concerted effort to obviate potential sources of failure have led to improved survivorship following hip resurfacing. However, an improvement in patient-reported outcomes has not been found.

Summary of answers

- Experience with contemporary hip resurfacing over the last two decades has tremendously enhanced our knowledge on the indications for surgery, implant design, and operative technique. Today, hip resurfacing remains an option for the younger, active, male patient to provide durable survivorship and a favorable condition for future revisions.
- Although hip resurfacing as compared to THA may offer advantageous long-term function with respect to specific high-demand actives, current level I evidence does not support a clear benefit in patient-reported outcome measures.
- According to national joint registry data, the long-term revision rates of hip resurfacing are higher than THA except in males younger than 55 years of age where resurfacing has advantageous survivorship.
- Younger age, female sex, small head size, and certain implant designs are all strongly associated with a higher cumulative percent revision following hip resurfacing.
- Surgeons who are inexperienced in hip resurfacing should be aware of a potential learning curve and increased risk of implant failures (particularly femoral

neck fracture and aseptic loosening of the acetabular component) during this period of adaptation.

- Experience and a concerted effort to obviate potential sources of failure have led to improved survivorship following hip resurfacing.

24 Metal-on-Metal Hip Arthroplasty

Oliver Marin-Peña MD[1], Olga Pidgaiska MD[2], and Pedro Reis-Campos[3]

[1] Hip Unit, Orthopedic and Traumatology Department, University Hospital Infanta Leonor, Madrid, Spain

[2] Orthopaedics Arthrology and Arthroplasty Department Sytenko Institute of Spine and Joint Pathology, Kharkiv, Ukraine

[3] Orthopedic and Traumatology Department, Hospital Vila Franca de Xira, Portugal

Clinical scenario

- A 40-year-old semiprofessional athlete comes to your clinic with recalcitrant groin pain after failed conservative treatment.
- Radiographs show advanced degenerative changes.
- The patient enquires about a metal-on-metal (MoM) hip resurfacing (HR) because he has many friends with the same type of implant who continue to play sports routinely.

Top three questions

1. In young, active patients undergoing MoM HR, is the revision rate higher than those undergoing metal-on-metal total hip arthroplasty (MoM-THA)?
2. In patients who have undergone MoM HR, does monitoring metal ion levels, compared to no active monitoring, affect outcomes or revision rates?

3. In patients with suspected pseudotumor and systemic toxicity, which diagnostic tests, compared to other tests, are most accurate?

Question 1: In young, active patients undergoing MoM-HR, is the revision rate higher than those undergoing metal-on-metal total hip arthroplasty (MoM-THA)?

Rationale

The indications for MoM-THA are currently limited due to a loss of confidence in certain devices. In analyzing survival rate of MoM hip implants, it is important to differentiate between HR and THA. While some MoM devices associated with recalls have caused concern, other MoM-THA devices continue to have an acceptable rate of success.

Clinical comment

In young patients, MoM-HR is believed to provide slightly better functional outcomes but slightly worse survival rate in the long-term compared with ceramic-on-ceramic (CoC).

Available literature and quality of the evidence

- Level I: 1 meta-analysis.[1]
- Level II: 4 systematic reviews.[2–5]
- Level III: 5 case control retrospective studies.[3_7]
- Level IV: 5 case series.[8_12]

Findings

Two studies that have analyzed 28 mm femoral head MoM-THA found better outcomes compared to 36 mm heads, with a survivorship greater than 90% survivorship at 15.[11,12] National database registries report failure rates with MoM-THA to be two- to threefold higher than THA with non-MoM bearings. In a meta-analysis, MoM was found to have an all-cause revision rate that was higher than CoC.[1] Similarly, in a cohort of 6215 MoM-THA patients versus 7360 CoC THA patients, the revision rate in MoM was higher than CoC bearing cohort. A recent systematic review which included 40 randomized controlled trials (RCTs) confirmed the same conclusion of a lower survival rate of MoM-THA.[3] Higuchi et al. compared MoM and CoC hip arthroplasties and concluded that the incidence of osteolysis was lower in CoC, but that the survival rate was similar in both groups.[3] Another long-term study revealed that patients younger than 50 years of age with MoM HR maintained substantial improvements in health and function beyond 10 years after the surgery.[10]

The Nordic Arthroplasty Register Association analyzed 32 678 cementless stemmed THA. At six-year follow-up, the revision rate was significantly higher for MoM compared to metal-on-polyethylene (MoP) stemmed THA. In contrast, the prevalence of revision due to dislocation was lower for MoM-THA.[4] The Australian Joint Registry demonstrated 5- and 10-year revision rates of 3.3 and 7.4%[5] with stemmed MoM-THA. Seppanen et al. reported an 86% 10-year survival rate of MoM-HR from the Finish registry when all type of centers were analyzed.[7] However, excellent survival rates were reported from certain single centers as high as 97% at 10 years.[8] In patients younger than 45 years of age, survival rate was similar between HR and conventional THA, and HR patients were able to return to a moderate or high activity level.[9] Furthermore, recent systematic review

has suggested some clinical potential advantages of HR against THA[1] but slightly higher revision with lower complications rates.[2]

At the 6th Advanced Hip Resurfacing Course, 67% of surgeons suggested completely abandoning stemmed MoM-THA with large diameter heads.[6] Younger women in combination with larger head size were associated with increased revisions. Moreover, it was described that reoperations were more frequent and occurred earlier for MoM in this high-risk group.[2] However, they recommended that MoM-HR should not be abandoned and should be viewed separately from stemmed MoM-THA with a large diameter head.[6]

Resolution of clinical scenario

- Stemmed MoM-THA, particularly with large femoral heads, should no longer be used.
- There is still a role for MoM-HR in low-risk patients by experienced surgeons.

Question 2: In patients who have undergone MoM-HR, does monitoring metal ion levels, compared to no active monitoring, affect outcomes or revision rates?

Rationale

Metal ion levels of chromium (Cr) and cobalt (Co) in patients with MoM-THA could be increased during follow-up and this issue could be related with THA malfunction and potential complications.

Clinical comment

The authors have in their experience seen asymptomatic young patients with an MoM-THA and minimal radiological changes during routine follow-up visits who have incidentally been noted to have elevated metal ion levels. Optimal monitoring of metal ion levels is unclear.

Available literature and quality of the evidence

- Level II: 3 systematic reviews.[13–15]
- Level III: 12 cohort studies.[16–27]
- Level IV: 5 case series.[628–31]
- Level V: 2 studies.[32,33]

Findings

Metal ions levels and adverse tissue reaction

After MoM hip arthroplasty, patients with blood metal ions levels below international thresholds have a lower risk of adverse reactions to metallic debris.[16] However, some authors have reported that blood metal ions levels are not correlated with intraoperative tissue damage, presence of pseudotumor, or pseudotumor size.[28,29] Another study reported that the synovial fluid metal ions levels were also not correlated with histological severity in MoM hip arthroplasty revisions.[17] Moreover, it's known that the interpretation of the blood metal ions levels can be difficult in patients with systemic renal disease, other metallic implants, or bilateral MoM implants. Thus, the analysis of the blood metal ion levels should be used as complementary information but not as an isolated parameter to establish the need for revision surgery.[18]

Metal ion levels and imaging findings

MacNair et al. found poor correlation between blood metal ion levels and the occurrence of adverse reaction to metal debris (ARMD) on magnetic resonance imaging (MRI) and recommended that the decision to revise implant should be based on imaging and not on blood metal ion levels.[23] Malek et al. demonstrated positive MRI findings combined with high metal ions levels increased detection of a malfunctioning MoM-THA implant.[24] Langton et al. recommended measuring ion values even in asymptomatic patients due to silent osteolysis when Co blood concentration greater than 20 μg/L was present.[25]

Metal ion levels and component malpositioning

Ohtsuru et al. recently reported a positive correlation in cup inclination and metal ion levels.[19] However, another study concluded that the acetabular inclination angle was not a meaningful determinant of higher metal ion levels.[20] Furthermore, RCT data have reported no correlation between acetabular inclination and metal ion levels.[13] Another study analyzed malfunctioning MoM-THA with a mean cup inclination of 45.6° and concluded that there is no relationship between cup inclination and metal ion levels.[34] The 6th Advanced Hip Resurfacing Course established 40° of inclination (±10°) and 15° of anteversion (±10°) as acceptable limits for acetabular positioning.[6] De Haan et al. proposed that metal ion levels increased when cup inclination was >55° compared with <55°. Indeed, functional arc of cover and component design were mentioned as important risk factors.[31] In contrast, a prospective study with unilateral MoM HR concluded that metal ion levels positively correlated with the three-dimensional orientation of the acetabular component and

gender but not body mass index (BMI), femoral head size, or hip type.[14]

Metal ion level threshold

Threshold of seven parts per billion (ppb) had 89% specificity, but only 52% sensitivity for detecting a failed MoM hip prosthesis. At a threshold of 4.97 µg/L sensitivity was 63%, and specificity was 86%.[14] Van Der Straeten et al. reported that the acceptable upper levels for well-functioning devices were: Cr 4.6 µg/L and Co 4.0 µg/L for unilateral implants, and Cr 7.4 µg/L, Co 5.0 µg/L for bilateral MoM-THA.[21] The American Academy of Orthopedic Surgeons (AAOS) defined a cut-off <3 µg/L for the low-risk group, 3–10 µg/L for the medium-risk group, and >10 µg/L for the high-risk group. The European Commission specifies a threshold of 2–7 µg/L for further imaging investigations. The European Federation of National Associations of Orthopedics and Traumatology (EFORT) and the European Hip Society (EHS) have proposed as levels of *without clinical concern* when Cr and Co are <2 µg/L and a level for *clinical concern* within the range of 2–7 µg/L. In 2011, the Dutch Orthopedic Association (NOV) established as normal values <2 µg/L, slightly elevated 2–4 µg/L, elevated above 4 µg/L, and extremely elevated at >20 µg/L.

Metal ion levels and international protocols

The United States Food and Drug Administration (FDA) recommends follow-up every six months, with possible imaging and assessment of metal ions in the blood, but does not recommend a specific metal ion level as a trigger for revision or other medical intervention.

The United Kingdom Medicine and Healthcare products Regulatory Agency (MHRA) recommends routine blood

metal ion testing and cross-sectional imaging. However, a prospective study of 256 asymptomatic patients with unilateral MoM-THA described a significant increase in blood ion values in the first two years. After seven years, there was no significant change in Co values, and there was a decline in Cr value after nine years. The authors concluded that annual metal ions may be unnecessary in asymptomatic patients.[22]

The Agence Francaise de Securité Sanitaire des Produits de Santé does not propose specific ion levels but emphasizes clinical and radiological follow-up.[26],[32],[33] A recent systematic review about the best protocol to detect MoM-THA and MoM-HR failures recommended clinical and imaging follow-up of asymptomatic HR but recommended blood metal ion levels in MoM THA patients.[15]

Resolution of clinical scenario

- There is no consensus in the current literature on threshold levels for metal ions (Cr and Co).
- Metal ion levels should be repeated periodically and their development over time considered.
- Rather than being a single diagnostic tool, metal ions should be assessed in the entire context of the clinical and radiological findings.

Question 3: In patients with suspected pseudotumor and systemic toxicity, which diagnostic tests, compared to other tests, are most accurate?

Rationale

MoM-THA is considered a potential contributor to the local release of metal ions with tissue reaction and the formation of local *pseudotumor*. High blood levels of metal ions could also be related to clinical symptoms and systemic toxicity.

Clinical comment

During routine medium- or long-term follow-up, patients with MoM-THA could present with pain, fatigue, weakness, hypothyroidism, and mild peripheral neurological symptoms. Presence of pseudotumor or systemic toxicity related to increased blood metal ions levels should be considered as a possibility in these cases.

Available literature and quality of the evidence

- Level II: 7 systematic reviews and RCTs.[35–41]
- Level III: 5 cohort studies.[42–46]
- Level IV: Five case series.[947–50]

Findings

Pseudotumors

Many factors are associated with local tissue reaction and pseudotumor formation after MoM-THA. Risk factors include large femoral head size, acetabular malpositioning, female sex, dysplasia, metal hypersensitivity, low BMI, and higher level of activity.[35] Van der Veen et al. reported a pseudotumor incidence of 54% with MoM-THA compared to 22% with MoP-THA. In this cohort, blood Co levels did not exceed acceptable clinical values and no difference was detected between the two groups at the final follow-up.[36]

Local effects of metal ions were local discoloration, tissue necrosis, and pseudotumor formation.[37,47]

Systemic toxicity

Systemic metal toxicity, including cobaltism, was considered a potential complication of MoM arthroplasty that could lead to organ failure.[43] Patients with systemic effects of metal ions commonly present with fatigue, weakness, hypothyroidism, polycythemia, cognitive dysfunction, neuropathy, and encephalopathy.[38,47,48] Patients may also complain about black tongue discoloration and a metallic gustation.[49] Thus, the inspection of the oral mucosa is recommended when blood metal ions levels are elevated. Though a relationship between MoM-THA and cardiac disease had previously been proposed in the literature,[50] a recent well-conducted study of over 50 000 patients demonstrated that MoM-THA was not associated with any cardiac complications.[41]

In a recent systematic review, symptoms associated with cobaltism appeared at a mean of 41 months and involved the cardiovascular system (60%); the audio-vestibular system (52%); the peripheral motor-sensory system (48%); the thyroid (48%); psychological functioning (32%); the visual system (32%); and the hematological, oncological, or immune systems (20%). Blood Co levels (mean 324 µg/L), but not Cr levels, were highly associated with a quantitative measure of overall symptom severity (Pearson's r, 0.81; $p < 0.001$). Surprisingly, revision of failed CoC-THA was the main cause of this cobaltism disease.[38]

Indications for revision of MoM-THA

It is accepted that the presence of a symptomatic MoM-THA, along with elevated metal ions levels, and the

presence of a pseudotumor on an imaging study are an indication for revision surgery.[39] Cup loosening remains the main cause of failed MoM hip arthroplasty.[9] Revision surgery should include a meticulous debridement in order to remove the necrotic tissues associated with pseudotumor.[40] However, pseudotumor recurrence was reported in 9–18% according to some studies.[44],[45] Revision of failed MoM-THA requires conversion to a metal-on-polyethylene or ceramic-on-polyethylene bearing.[46]

Resolution of clinical scenario

- Patients with MoM-THA who present with fatigue, weakness, cognitive dysfunction, or neuropathy should be examined to rule out systemic metal toxicity.
- Blood metal ion levels and imaging studies should be done to investigate pseudotumor presence.
- Patients with symptoms, elevated metal ions levels, and the presence of a pseudotumor on an imaging study may require revision surgery.

Summary of answers

- MoM bearing surfaces for hip arthroplasty and resurfacing have gained a negative reputation due to recalls and concerns with high revision rates.
- MoM-THA with large head size should be avoided altogether.
- MoM bearings should be avoided in females and those with known metal hypersensitivity.
- MoM-HR, particularly in carefully selected patients, does represent an attractive option for younger and more active male patients.

[2] St Michael's Hospital, The University of Toronto, Toronto, ON, Canada

Clinical scenario

- A 57-year-old active woman has progressively developed severe pain in her right hip.
- She has exhausted conservative treatments and is keen to remain active with hobbies including golf and badminton.
- At present she has mild rest pain, frequent sleep disturbance, and walking is limited to half a mile.
- She is unable to perform any sporting activities. She is otherwise fit and well.
- She has done some research and is curious about ceramic versus other bearing surfaces and if ceramic has any unique complications or considerations.

Top three questions

1. In patients undergoing total hip arthroplasty (THA), do ceramic bearing surfaces, compared to metal or polyethylene, result in better outcomes?
2. In patients undergoing THA, are ceramic bearing surfaces, compared to metal or polyethylene,

associated with a unique set of complications?

3. In patients who have undergone THA with ceramic bearing surfaces, compared to metal or polyethylene, are revisions more likely and/or more difficult to perform?

Question 1: In patients undergoing total hip arthroplasty (THA), do ceramic bearing surfaces, compared to metal or polyethylene, result in better outcomes?

Rationale

With over 4.5 million ceramic THAs implanted worldwide before the turn of the last century,[1] and more recently and in its most modern form, over eight million delta ceramic components sold,[2] it is important to understand its place in today's THA landscape.

Clinical comment

THA surgery is one of the most common procedures performed in orthopedic surgery. It is considered one of the most effective orthopedic procedures with excellent long-term survival in the elderly.[3] Metal-on-polyethylene (MoP) replacements are still the traditionally implanted bearings, used initially by Charnley in the 1960s, and still recommended by many today. Long-term survival of this bearing combination is limited by polyethylene wear and related osteolysis.[4] In the younger patient, with longer life expectancy and increased activity, there is an up to tenfold increase in the demands of any replacement bearing.[5] Regarding this, there is an oft-quoted, long-term study of

patients under the age of 51 which demonstrated a failure rate requiring revision arthroplasty of over 25% at 20 years and almost 50% at 27 years.[6] Revision procedures are challenging, a risk to the patient, and of considerable cost to health service providers.[7–10] Alternative bearings and joint replacements have therefore been developed and include ceramic bearings, metal-on-metal (MoM) resurfacings, and highly cross-linked polyethylene, all aiming to prolong the survival of the prosthesis, and prevention of osteolysis and its consequences.

Available literature and quality of the evidence

Randomized controlled trials (RCTs) and meta-analyses are available to answer this question.

Findings

A randomized controlled trial (RCT) comparing 31 ceramic-on-ceramic (CoC) THAs with 30 cobalt chrome on highly cross-linked polyethylene (MoP) revealed no difference in outcome scores between the two groups looking at Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC) and Short Form 36 (SF-36) scores at a follow-up of between 2 and 24 months.[11] Another compared 30 CoC replacements with 26 ceramic-on-plastic (CoP) replacements and reported no significant difference in joint specific outcome scores at a mean follow-up of eight years.[12] A further RCT with a mean follow-up of 35.2 months compared 346 CoC with 168 MoP replacements, and reported equivalent Harris Hip Scores (HHSs) and patient satisfaction.[13] A five-year RCT published in 2005 comparing 213 CoC with 101 MoP hips concluded that CoC articulations were at least equivalent in performance to the MoP design.[14] HHSs were 96.6 in the ceramic and 97 for MoP. An extension of this series, assessing a titanium-

coated ceramic bearing, again identified no difference in HHS with a mean of 96.6 at 4.2 years' follow-up.[15] A subsequent review of the same cohorts at a mean follow-up of eight years again identified no difference in outcome scores.[16] Finally, a minimum two-year follow-up RCT compared 250 CoC articulations with 250 CoP hips showed no difference in clinical outcome.[17]

Three meta-analyses[18–20] all published in 2015 included in excess of 5000 patients and failed to show a significant clinical difference, be this CoC, CoP, or MoP.[20] The authors concluded that other factors, including cost, be considered rather than clinical outcomes. Furthermore, 10 RCTs, all published from 2005 to 2013, showed no statistical difference in survival or patient outcomes.[12,17,21–28] However, some of these trials did confirm radiographic changes with slight increased wear in the CoP compared to the CoC. A Canadian study identified this wear to be three times that of CoC,[21] and one further study identified significant wear but no clinical sequelae in the CoP prosthesis at 10 years.[12]

Despite so much data suggesting no clinical difference but some radiographic deterioration, several papers deserve specific mention of practical significance to our patient. Petsatodis et al. undertook a study of 100 young patients (mean age 46) who had undergone a CoC THA and showed that at 10 and subsequently 20 years a very satisfactory result with only six requiring revision, these due to loose ceramic chips.[29] Another studied 100 patients (mean age 45), each of whom underwent CoC and CoP in bilateral replacements.[24] Patients were reviewed after 12.4 years (mean) with, in effect, each patient acting as their own control. There was no difference in clinical outcomes at their latest follow-up. These data appear to support the view that there may be some deterioration on scientific

review but no difference in patient satisfaction or clinical outcome.

Ceramics have continually improved over the years. First-generation alumina ceramics (1974–1988) were characterized by low density, high porosity, and large grain size, and did not perform well with early series reporting high failure rates, but not directly due to the alumina itself. The main failures were aseptic loosening of the femoral stem[30],[31] or of the monoblock acetabular system[32] with reported fracture rates of 3–13%.[33]

Second- and third-generation alumina ceramics (1988–1994 and 1994–present, respectively) are characterized by a reduced grain size with increased alumina purity with the addition of calcium oxide (CaO) or magnesium oxide (MgO) materials.[34] With third-generation ceramics there has been further improvements with hot isostatic pressing, laser etching (avoiding surface stress risers), and proof testing.[33] Prior to proof testing, ceramic components were subject to a finished product audit in which only a sample from each batch was subject to testing.

Despite these improvements there continues a search for a ceramic material to satisfy increasingly more challenging patient demands. These changes include smaller components, additional sizes, along with even greater reliability and longevity. Known as a *fourth-generation ceramic*, BIOLOX delta (CeramTec AG, Plochingen, Germany) is a combination of both the major subsets of ceramic, an alumina matrix with zirconia particles homogeneously dispersed and encapsulated increasing the fracture toughness.[33]

Ceramics may be used as an alternative to a metal head in a conventional hard-on-soft bearing against polyethylene. With a lower Ra (the mathematical average of all deviations

from the mean line of the surface profile) and improved wettability, this combination has the potential to provide a low wear alternative to either stainless steel or cobalt chrome. Ceramic may also be used as a more modern hard-on-hard bearing against either a ceramic liner or, as a more recently introduced, ceramic-on-metal (CoM) bearing surface.[35–37] Advantages with hard-on-hard bearings is the potential for fluid film lubrication, an exceptionally low wear rate, and avoiding osteolytic polyethylene debris. Using hard-on-hard bearings also allows the use of large heads, which if used with a conventional polyethylene option would create excessive volumetric wear. CoC options also avoid the production of metal ions, which are released and may complicate MoM and CoM alternatives.[35–38]

Using a MoP articulation also offers the surgeon access to multiple head sizes and modular neck lengths spanning 20 mm. On the acetabular side, in addition to multiple inner diameter options, there is also the availability of lateralized liners, elevated rims, and anteverted, eccentric, and constrained liners. In contrast most CoC systems have only one head size per cup diameter, with three or four head lengths spanning 10 mm or less. These alternatives for equalizing leg lengths and maximizing stability are two crucial goals of THA.[8] Numerous liners and head options assist in achieving these goals. Any loss of these options may currently be the most substantial disadvantage of CoC THA.

Resolution of clinical scenario

- Overall, there is some evidence to suggest lower wear rates with ceramic-bearing surfaces.
- There is little evidence to demonstrate clinical benefit in most patients, and cost is a major consideration.

- There is evidence to demonstrate excellent results with ceramic surfaces in young patients.

Question 2: In patients undergoing THA, are ceramic bearing surfaces, compared to metal or polyethylene, associated with a unique set of complications?

Rationale

Being the second hardest material, after diamond, wear-resistant benefits must be weighed against the unique disadvantage risks of fracture and squeaking.

Clinical comment

Some issues unique to ceramic bearings include stripe wear, osteolysis, fracture, and squeaking.

Available literature and quality of the evidence

RCTs, as well as retrospective cohort studies and case series, are available to answer this question.

Findings

Stripe wear

Stripe wear is the term given to a localized crescent-shaped area of surface alteration of a ceramic femoral head.[32] Its cause is not fully understood. The resultant damage to the surface takes the form of grain fracture or pullout with resultant loose bodies and a roughened surface. This roughened area may then be the precursor of more extensive wear.[8]

Osteolysis

A short-term RCT comparing CoC and metal on cross-linked polyethylene reported no osteolysis at 24 months in either group,[11] not unexpected as even with conventional polyethylene hips wear-related osteolysis is not a short- or even medium-term complication. In a longer-term study, with mean follow-up of eight years, cortical erosions were reported in 4 of 287 (1.4%) alumina ceramic hips and 25 of 82 (30.5%) control MoP hips.[16] Within this latter group, one patient required revision of cup and liner for osteolysis at 10.5 years and another had a liner exchange at 52 months for polyethylene wear and osteolysis at eight years.[16] This report followed an earlier five-year follow-up of the cohorts with osteolysis recorded in 1.4% of 213 alumina hips and 14% of the 101 control MoP hips.[14]

One important retrospective review of 103 THAs deserves mention where ceramic implants reported a rate of osteolysis far higher than that found in other RCTs. At a mean follow-up of 92 months femoral osteolysis was reported in 23 hips (22%) with 10 requiring revision for loosening.[39] Tissue retrieved at revision confirmed abundant wear particles with the authors concluding ceramic particles can stimulate foreign body response and periprosthetic osteolysis. This was the first published series of patients with a CoC articulation demonstrating such a high level of osteolysis. However, the prosthesis used in this study was subsequently withdrawn from the USA due to high failure rates.[40]

Numerous medium- and long-term retrospective studies and reviews have shown limited or no evidence of osteolysis in modern well-functioning ceramic articulations.[41–45]

Fracture

Fracture is a catastrophic complication of a ceramic articulation requiring immediate revision. Benefits of low wear articulations need to outweigh specific risks associated with the bearing.

Early in the production of ceramics, fracture rate was as high as 13.4% for those manufactured before 1990, with catastrophic consequences.[46] The same paper reported the fracture rate of ceramic BIOLOX femoral heads as 0.026% for first generation, 0.014% for second, and 0.004% for femoral heads manufactured after 1994 based on data collected from over two million femoral heads. Sedel's review of the 30-year history of alumina suggests the risk of fracture is 1 in 2000 for a 10-year period.[42] A further historical review reports 80% of ceramic head fractures occur within the first two years and 90% within the first three years.[17]

Reviewing level I evidence, an RCT comparing MoP with a number of full ceramic options confirmed two fractures at 9.0 and at 6.5 years, in a total cohort of 380 ceramic hips[16] with an overall mean follow-up of eight years. There were also four ceramic chips on insertion of the liner, which were immediately changed to a new liner and shell, none of these required revision.[16]

In order to address the issue of fracture on insertion, a titanium-cased alumina ceramic component was introduced as a fourth group. In a separate publication, this group showed no chips, fractures, or failures at a mean follow-up of 4.2 years in 209 hips.[15] An RCT by Bierbaum et al. involving 514 hips in 458 patients comparing MoP articulations with CoC revealed no fractures in the 346 in the ceramic group with a mean follow-up of 35 months.[13] There was, however, an insertional chip rate of 2.6% (9/346 hips), each identified and replaced at the time of surgery with as yet no sequela. Another large medium-term

study involving 500 hips comparing an equal number of CoC articulations with CoP, at a minimum follow-up of two years, reported no ceramic fractures; one liner chipped on insertion requiring exchange (0.4%).[17] A review of 56 hips at a mean follow-up of eight years reported no ceramic fracture or liner chips in 30 CoC articulations and 26 CoP hips.[12]

Lastly, no fractures were reported at a mean of 50.4 months in 103 hips in 97 patients in a retrospective review.[43] A number of case reports of fracture have been published, one of which from 1995 reviewed the available data from 10 previous published fracture reports. They concluded that, including their own case, common characteristics for fracture included young age at surgery, heavy and active patients, and 8 of the 10 were male.[47],[48]

Squeaking

Squeaking from the site of THA is a phenomenon unique to hard-on-hard bearings, whether MoM or CoC.[49]–[53] The cause is not fully understood and a number of possible etiologies have been postulated including component mismatch, insufficient lubrication, stripe wear, and third body metal debris.[49]

In our review of ceramic meta-analyses, two confirmed squeaking as an occurrence[18],[19] but Wyles et al.[20] failed to report it as an outcome measure. As for RCTs (of which there were 10), squeaking was rarely mentioned and Hamilton in 2009 in 263 patients specifically found squeaking not to have occurred.[22]

Question 3: In patients who have undergone THA with ceramic bearing surfaces, compared to metal or polyethylene, are revisions more likely and/or more difficult to perform?

Rationale

It is important to know if revision rates are different among patients with ceramic bearing surfaces as this is perhaps the single most impactful outcome both from the patient perspective and from a systems perspective.

Clinical comment

As a surgeon, it is important to know if revision surgery is different depending on the bearing surfaces. This is particularly important given that patients may end up seeing a different surgeon for their revision surgery than the one who performed the primary procedure. Thus, even surgeons who do not routinely use ceramic bearings need to be aware of their implications for revision surgery.

Available literature and quality of the evidence

Level I evidence reviewing THA revision is difficult to obtain. Observational and retrospective evidence is available. Five trials (1511 patients total) report postoperative revision rates in comparative randomized studies involving CoC articulations.[11–13,16,17] Three further trials were excluded from analysis as they were previous publications from the same cohort.[14,15,54] The results of pooled statistics are shown in Table 25.1.

Table 25.1 Revision surgery. CoC: ceramic on ceramic, CoP: ceramic on polyethylene, MP: metal on polyethylene, RR: relative risk of revision with ceramic on ceramic compared to alternatives (values <1 favors CoC, >1 favors control).

		Events			
	N	**CoC**	**Control**	**RR**	**95% CI**
CoC vs CoP	475	2/226	7/249	0.309	0.063–1.502
CoC vs MP	1036	14/744	16/292	0.331	0.159–0.687
CoC vs all	1511	16/970	23/541	0.378	0.198–0.721

Findings

Two studies compared CoC articulations with CoP and concluded a reduced risk of revision in the CoC group (risk ratio [RR] = 0.309; 95% confidence interval [CI]: 0.063–1.502).[12,17] Follow-up in these studies varied from a minimum of two years (n = 460) to a median of eight years (n = 55). Two hips required revision in the ceramic group due to recurrent dislocations, while in the control group seven revisions were performed, one for pain of unknown etiology, one loose acetabulum, and five for recurrent dislocation. Within the remaining three studies comparison was made between CoC articulations and MoP in 1036 hips.[11,13,14] Again, a reduced overall risk of revision was observed in the ceramic group (RR = 0.331; 95% CI: 0.159–0.687). Follow-up in these studies ranged from two to eight years (sample size ranged from 61 to 500). Taking all CoC articulations and comparing these with controls revealed a relative risk of revision of 0.378 (n = 1511; 95% CI: 0.198–0.721) for the CoC option.

Revision of any hip replacement is a complex undertaking. Theoretically, the use of ceramic articulations during primary surgery should reduce the frequency of revision

hip replacement. However, when one is required, the absence of osteolysis facilitates revision surgery[45] avoiding the need for bone grafting.[44] Worse, if revision is required following fracture, there will be extensive third body debris within the effective joint space damaging exposed femoral trunnions and acetabular shells. Any delay causes further damage and soft tissue contamination and therefore revision is urgently required. The revision also requires exchange of all components to prevent subsequent bearing exposure to macro- and microscopic ceramic particles.

Allain published a case report and a study on a large series of head fractures.[55],[56] The case report was of a 54-year-old who sustained a traumatic fracture of their femoral head five years after implantation.[55] This was revised to a stainless-steel-on-polyethylene liner. Subsequently, at 11 months the patient developed pain and at 18 months the patient required a second revision. Intraoperatively, the stainless-steel femoral head was deformed and severe metallosis was noted. Histologically, fragments of both stainless steel and alumina ceramic were noted in the soft tissues.

A multicenter review by the same author reviewed 105 revisions for ceramic head fractures.[56] Thirty-one percent went on to require at least one repeat revision with an overall five-year survival rate of only 63%. This rate was worse than most revision series and, in all likelihood, due to retained ceramic particles.[8] Allain's review is the most extensive review available in the literature and makes a number of recommendations.[56] Factors influencing results included whether the cup was changed (57% required re-revision without, 21% with exchange), extent of synovectomy (re-revision in 67% with partial synovectomy, 19% with complete synovectomy), and patient age (54 years in those requiring revision and 63 in those who did

not; p = 0.02). Although definitive conclusions could not be made, this paper does imply that any revision following ceramic fracture should include cup exchange, total synovectomy, and a cobalt chrome or ceramic head.

Lastly, one paper deserves specific mention. Sharma et al. in 2010 published a long-term follow-up of an admittedly small number of THAs for ceramic head fractures.[9] The authors emphasized that ceramic fractures, although increasingly rare with newer ceramics, are associated with ceramic particles penetrating the surrounding tissues. Thus, they undertook and described a radical synovectomy and metal on polyethylene articulation. There were no revisions at 10 years and a yearly wear rate comparable with a matched controlled group of primary metal on polyethylene THAs.

Resolution of clinical scenario

- A revision following ceramic bearing THA is not a simple undertaking.
- The best approach is likely extensive revision, including radical synovectomy and use of an MoP bearing.[8,9]

Summary of answers

- The use of modern ceramic bearings has become significantly safer than when it was first introduced.
- Using the most modern ceramic and testing techniques, a patient receiving a ceramic THA can expect a very low wear articulation, clinical outcome scores at least equivalent to conventional hip replacements, and a low risk of long-term osteolysis.
- Fracture, particularly during insertion remains a risk, as does squeaking which may be an underreported

issue.

- Revision procedures following failed ceramic hip replacements are challenging.
- Retained exceptionally hard fracture debris often necessitates complete component revision with its potential to compromise the long-term survival of the revised hip.

[2] Teknon Medical Center, Barcelona, Spain

Clinical scenario

- A 60-year-old female, without medical history of interest, presents with left groin pain.
- She is an active person who works and plays nonprofessional sports, but now she has a left hip pain that interferes with her activities of daily living.
- Her x-rays reveal advanced osteoarthritis of her left hip.

Top three questions

1. In patients undergoing primary total hip arthroplasty (THA), does a cemented femoral stem, compared to an uncemented femoral stem, provide better function and patient outcomes?
2. In patients undergoing primary THA, does a cemented femoral stem, compared to an uncemented femoral stem, provide longer-term survival?
3. In patients undergoing cemented primary THA, does antibiotic cement, compared to plain cement, effectively prevent infection?

Question 1: In patients undergoing primary total hip arthroplasty (THA), does a cemented femoral stem, compared to an uncemented femoral stem, provide better function and patient outcomes?

Rationale

THA is one of the most common procedures performed in orthopedic surgery. Over the last decade, there has been a trend toward an increasing number of uncemented THA with a subsequent decline in the overall use of cemented implants for primary THA.[1] Hence, this question sought to analyze if patient-reported outcome measures differ depending on the type of fixation. This can be concerning for the patient and surgeon alike because the method of fixation itself may affect patient outcomes.

Clinical comment

The choice of optimal implant fixation in THA – fixation with or without cement – has been the subject of much debate[2] as the method of fixation itself may influence outcomes.[1–3] In cemented joint replacement polymethylmethacrylate (PMMA) is used to fix the prostheses to the bone. In cementless or uncemented joint replacement, hydroxyapatite (HA), porous coatings, or trabecular metal avoid the need for cement as bony in or on-growth occurs. The primary fixation is anatomic/press-fit technique, with secondary biological bone ingrowth producing long-term stable fixation. In hybrid fixation, one component is cemented and the other is uncemented.

Available literature and quality of the evidence

The quality of literature addressing appropriate investigations for cemented versus uncemented in primary THA is highly variable with level I–IV evidence. There are some randomized trials; however, the majority of the outcome studies are multicenter cohort studies or single-center cohort studies.

Findings

Clinical outcomes

The patient's experience in the short-term is important. Multiple studies have demonstrated better pain relief and short-term clinical outcomes, including earlier weight bearing, with cemented THA. Abdulkarim et al., in a meta-analysis of randomized controlled trials (RCTs; mean age 60.5 years, postoperative follow-up mean 4.3 years) comparing cemented and uncemented hips found a significantly improved pain score with cemented fixation compared to uncemented fixation ($p = 0.04$).[3] In contrast, in a study of the Swedish Hip Arthroplasty Register, 3118 patients with uncemented THA due to primary osteoarthritis with complete one-year follow-up were matched with a control group of patients with cemented THA ($n = 3118$). The authors reported that uncemented fixation is associated with better patient-reported outcomes including the EQ-5D, a Visual Analog Scale (VAS) on hip pain, as well as a VAS addressing satisfaction with the outcome of the procedure.[4] Meding et al, found that the 5-, 10-, and 20-year Harris Hip Score (HHS) was not significantly different between cemented and uncemented groups and the 15-year HHS only differed (on average) by four points ($p = 0.0054$). The pain scores were not different at 5, 10, or 15 years, but the 20-year average pain score

were significantly lower (more pain) in the uncemented group ($p < 0.0001$).[5]

Morbidity and mortality

The early postoperative mortality after THA is low and has been decreasing.[1,3] However, cemented fixation is associated with potential perioperative morbidity in the form of bone cement implantation syndrome and even death of the patient. The Finland National Hip Arthroplasty Register analyzed 73 915 patients they found that adjusted perioperative and short-term mortality was similar between patients treated with cemented THA and patients treated with uncemented (odds ratio [OR] = 0.5; 95% confidence interval [CI]: 0.3–1.1) or hybrid (OR = 0.6; 95% CI: 0.3–1.6) THA. The mean age of the patients in that register was 68.3 years old.[6] The Swedish Hip Arthroplasty Register found that, after adjustment for age, gender, co-morbidities, and socioeconomic background, there was a small but statistically significant increased relative risk of death in patients who underwent cemented, but not cementless, THA, up to 14 days after surgery (OR = 1.3; 95% CI :1.11–1.44). Between days 15 and 29, this increased risk of mortality in those with a cemented THA was reverted, and from day 30 after the operation all patients, irrespective of the mode of fixation, had a lower risk of mortality than their controls.[7]

Aseptic loosening

Aseptic loosening is the most common reason for revision, accounting for nearly half of all cases, followed by pain and instability.[8] A known disadvantage of cemented prostheses, however, is the risk of aseptic loosening. Cemented THAs have a significantly higher rate of aseptic loosening when compared to uncemented prostheses.[9] The Health East Joint Registry of USA (6498 THA) found that uncemented

stems were associated with fewer revisions for aseptic loosening in patients <70 years old, but when all-cause revision was considered, neither group demonstrated superior survival (mean follow-up of 6.5 years).[9]

Periprosthetic fracture

Evidence suggests that the increasing usage of uncemented stems may be associated with a higher rate of periprosthetic femoral fracture (PFF) when compared to cemented stems.[10] In a prospective multicenter study found that uncemented femoral components were associated with an increased risk of early PFFs (<90 days; risk ratio [RR] = 4.1; 95% CI: 2.3–7.2), especially in elderly (RR = 1.4 per 10 years; CI: 1.2–1.6), female (RR = 1.6; CI: 1.1–2.2), and osteoporotic patients (RR = 2.8; CI: 1.6–4.8).[10] Also Thien et al. studied the incidence of periprosthetic fracture around the femoral component in cemented and uncemented hips in the two years following implantation. They found a rate of 0.07% for cemented stems and 0.47% for uncemented stems (RR = 8.72; 95% CI: 7.37–10.32; p <0.0005).[11] The National Joint Registry for England, Wales, Northern Ireland and the Isle of Man, using univariate and multivariate Cox models, found an unadjusted hazard ratio (HR) for PFF for cementless compared to cemented stems of 1.43 (95% CI: 1.29–1.58). After adjustment for age, gender, and American Society of Anesthesiologists (ASA) grade, the HR was 1.68 (95% CI: 1.51–1.87). Also, comparing the rate of PFF revision within and beyond the first three months following primary THA in cementless versus cemented stems, the covariate-adjusted HRs were 8.82 (95% CI: 6.89–11.30) and 0.84 (95% CI: 0.49–1.41), respectively.[9]

Resolution of clinical scenario

- Better pain relief and short-term clinical outcomes, including earlier weightbearing have been reported with cemented THA; however, more studies need to focus on this point.
- Perioperative and short-term mortality was similar between patients treated with cemented and uncemented THA.
- There is a higher rate of periprosthetic fracture rates when using uncemented femoral stems; however, cemented THAs have higher rates of aseptic loosening when compared to uncemented THA.

Question 2: In patients undergoing primary THA, does a cemented femoral stem, compared to an uncemented femoral stem, provide longer-term survival?

Rationale

Literature suggests there are differences in survival for cemented as compared to uncemented femoral stems. The survival of uncemented and hybrid implants continues to dramatically improve. For this reason, it is important to evaluate the literature on this topic.

Clinical comment

A number of cementless femoral stems are associated with excellent long-term survivorship. Cementless designs differ from one another in terms of geometry and the means of obtaining initial fixation. Strict classification of stem designs is important in order to compare results among

series.[12] Uncemented designs can be classified based on the following factors:[13]

- *Surfaces and coatings:* for example, porous coated titanium stem, grit blasted implant surface, and HA coating.
- *Size of the stem:* standard length uncemented stems or short uncemented stems.
- *Modularity:* modular stems have another modular interface at the neck/stem junction of the implant. This allows intraoperative flexibility to adjust anteversion/offset and limb lengths.

Available literature and quality of the evidence

The quality of literature addressing appropriate investigations for cemented versus uncemented stems in primary THA is highly variable with levels I–V evidence. The majority of the outcome papers are observational multicenter cohort studies or single-center cohort studies.

Findings

Survivorship between cemented and uncemented stems

The published evidence suggests that cemented fixation still has superior survival among large subgroups of populations studied; however, the survival of uncemented and hybrid implants continues to improve.[2] The National Joint Registry for England, Wales, Northern Ireland and the Isle of Man (992 090 THAs) found an estimated Kaplan–Meier cumulative percentage probability of revision 14 years following a primary THA of 4.88 (4.67–5.10) for cemented hips, compared to 8.94 (8.55–9.35) for uncemented hips, and 5.38 (4.97–5.83) for hybrid fixation.[8] The Swedish (170 413 THAs) and the Irish (1697 THAs)

Hip Arthroplasty Registers also demonstrate superior survivorship of cemented over uncemented THAs with revision free component survival at 10 years of 94% versus 85% ($p < 0.001$) and 98.8% versus 96.8% ($p < 0.001$), respectively. No age or diagnosis group was found to benefit from the use of uncemented THA.[14],[15]

The New Zealand Joint Registry (42 665 THAs) reports that the overall all-cause revision rate is lower in cemented than uncemented THA, although, in contrast to the larger registries above, they found uncemented acetabular components performed better in the medium term (nine years) across all age groups.[16] The combined Nordic Arthroplasty Register Association database (347 899 THAs) found that in patients aged 65–74 and 75 or older the 10-year survival of cemented implants was higher than that of uncemented, hybrid, and reverse-hybrid implants, but in patients aged 55–64, survivorship of cemented and uncemented implants was found to be similar.[17] In a meta-analysis of RCTs, the cemented THA had a higher but statistically non-significant revision rate ($p = 0.14$).[3] Finally, Meding et al., in a review of 1017 primary THAs using the same porous-coated, titanium-alloy, femoral component, found that cemented and uncemented stem survivorship at 20 years was 98.1 and 99.6%, respectively. There was no difference in cemented or uncemented stem survivorship at any time period.[5]

Survivorship between uncemented stems

The Australian Joint Registry has one of the most robust datasets on uncemented implants (200 398 implants) which demonstrates cumulative revision rates at 10 years of 5% (4.9–51), and revision rates at 17 years of 7.5% (7.0, 8.0). They also found that the 10-year cumulative percent revision for total conventional hip replacement using a mini

stem (3706 implants) is 5.9% compared to 5.1% for other femoral stems. There are no differences in the overall rate of revision when a short stem is used; however, the cumulative incidence of loosening for procedures using a short stem is over twice that of other femoral stems at 10 years (2.5 compared to 1.2%).[18]

Comparison of implants that had the same design but were made of different alloys showed no significant difference in the outcomes or rates of thigh pain.[12] Hailer et al. in an analysis of 116 069 THAs in the Nordic Arthroplasty Register Association database found that uncemented HA-coated stems had similar results to those of uncemented stems with porous coating or rough sand-blasted stems. In the unadjusted 10-year survival with the endpoint revision of any component for any reason was 92% (CI: 91.7–92.4) for the group of THAs without HA-coated stems (number at risk after 10 years: 6676) and it was 92.1% (CI: 91.7–92.5) for those with HA-coated stems (number at risk after 10 years: 6464) ($p = 0.3$). They also found that the use of HA coating on stems available both with and without this surface treatment had no clinically relevant effect on their outcome.[19] About the size, Kim et al. reported in their RCT of 200 patients at mean follow-up of 12 years that ultrashort stems showed no differences from conventional cementless stems in terms of validated outcomes scores (mean HHS; $p = 0.189$; mean WOMAC scores; $p = 0.191$; and mean UCLA activity scores; $p = 0.381$) or fixation (revision one hip, 0.5%, in the short-stem group vs one hip, 0.5%, in the conventional group; $p = 1.881$).[19] Future studies of cementless implants should consistently address patient age, activity level, bone type, and deformities so that more definitive conclusions can be drawn about when to use each design.

Resolution of clinical scenario

- Moderate evidence supports that cemented stems still have superior survival among large subgroups of populations studied; however, the survival of uncemented and hybrid implants continues to improve.
- There is no difference between implants that had the same design but were made of different alloys. Uncemented HA-coated stems had similar results to those of uncemented stems with porous coating or rough sand-blasted stems.
- Evidence reveals a moderate difference in the overall rate of revision between short stem and standard length uncemented stems. Long-term survival is still unknown for most of these components.

Question 3: In patients undergoing cemented primary THA, does antibiotic cement, compared to plain cement, effectively prevent infection?

Rationale

Periprosthetic joint infection (PJI) is a major complication of joint replacement. One year after primary THA, around 1% of patients have been revised due to deep infection; superficial surgical site infections (SSIs) are more common and occur in around 3% of cases. The type of fixation (i.e. the use of antibiotic cement) may reduce the risk of PJI and is important to evaluate if differences exist as compared to cementless fixation for femoral stems.

Clinical comment

Perioperative wound contamination during implantation of primary THAs occurs in more than 30% of all operations in

standard and in ultraclean operating theaters. Many THAs are considered to fail due to the presence of clinically unrecognized low-grade infection.[20] Moreover, the outcomes of hip replacement surgery and the survival of implants have improved during the last decades. However, an increase in the risk of revision due to infection after THA has also been reported in recent years.[1],[21],[22]

Available literature and quality of the evidence

The quality of literature addressing the incidence of PJI for cemented versus uncemented femoral stems in primary THA is highly variable with level I–IV evidence. Several RCTs have compared the surgical outcomes of cemented and uncemented THA. However, most of the studies were unable to reach a conclusion on the risk of PJI based on the type of fixation due to the infrequent occurrence of SSI/PJI and low number of subjects in the cohort. Among the RCTs comparing cemented and uncemented THA, no difference has been observed in the rates of PJI.[21]

Findings

Current moderate evidence supports the routine use of antibiotic-laden bone cement (ALBC) in cemented primary THA to reduce the risk of deep PJI especially in patients with immunosuppressive co-morbidities.[22],[23] However, data from the Swedish Hip Arthroplasty Registry between 1992 and 2007 demonstrated that uncemented THA did not present a higher risk of revision due to infection compared to antibiotic-laden cemented THA.[14] In contrast, a higher risk of PJI in THA using bone cement without antibiotics was reported by the Norwegian Arthroplasty Register.[24] This study directly compared the revision rates due to infection in primary uncemented THA with cemented THA with ALBC as well as cemented THA without ALBC. The

results showed that the risk of revision due to infection was the same for uncemented and cemented arthroplasties with ALBC, but higher for cemented arthroplasty without ALBC.[24]

A recent meta-analysis including eight clinical studies (two RCTs and six observational studies) revealed that the incidence of PJI was 0.5% (310/67 531) in the cemented group and 0.3% (47/16 669) in the uncemented group ($p < 0.008$). The use of cement in THA was associated with an increased risk of PJI (OR 1.53; 95% CI: 1.12–2.10; $p < 0.008$).[21] However, the authors could not tell the influence of the type of cement used on the risk of PJI because five of the eight studies included did not specify if they used cement loaded with antibiotics or not. Registry data from large population-based studies (432 168 THAs) appear to show that the risk of revision due to PJI is roughly equal comparing uncemented with cemented fixation. However, using a multivariable Cox analysis, the use of cement without antibiotics and hybrid configurations was found to be risk factors for infection.[25]

Resolution of clinical scenario

- Current weak to moderate evidence supports the use of ALBC in cemented primary THA to reduce the risk of deep PJI, especially in high-risk populations.
- The risk of revision due to infection, in general, was the same for uncemented and cemented arthroplasties with ALBC, but higher for cemented arthroplasties without ALBC.

Summary of answers

- There may be some early benefits to cemented fixation, such as less pain and earlier weightbearing.
- Cemented fixation has unique complications, such as cement embolus, which need to be considered.
- Cemented stems have better long-term survival, though uncemented and hybrid designs are continuing to improve.
- There is no difference in the overall risk of infection between cemented and uncemented THA.
- If deciding to use cement, there is some evidence to suggest a higher risk of infection with plain cement compared to ALBC.

27 Head Size in Total Hip Arthroplasty

Francesc Angles MD[1], Jorge H. Nuñez MD[2] and Pablo Castillón MD[1]

[1] Hospital Mutua de Terrasa. Departament Especialitats Medicoquirúrgiques. Universitat de Barcelona, Spain

[2] Vall d'Hebron University Hospital, Barcelona, Spain

Clinical scenario

- A 68-year-old male presents with his second total hip arthroplasty (THA) dislocation seven months postoperatively.
- Risk factors for hip dislocation were evaluated and the patient was revised, changing the size and position of the cup, as well as exchanging the femoral head for a larger one.
- The patient was satisfied but 12 years postoperatively the x-rays evidence moderate polyethylene wear.

Top three questions

1. In patients undergoing THA, does larger femoral head size, compared to smaller head size, result in improved stability?
2. In patients undergoing THA, do certain bearing couples, compared to others, result in better outcomes depending on femoral head size?
3. In patients undergoing THA, do larger femoral head sizes, compared to smaller sizes, result in greater levels of trunnion corrosion?

Question 1: In patients undergoing THA, does larger femoral head size, compared to smaller head size, result in improved stability?

Rationale

Unstable THA should not be treated with any special device before knowing the etiology of instability. Larger femoral head size improves stability by increasing the jump distance. Routine use of large-diameter femoral heads have become more popular because of the associated improvement in stability.[1]

Clinical comment

Femoral head size has increased over time, from 22 mm heads in the 1960s to 36 mm heads in the last decade. According to the majority of the registries, the most common femoral head diameters are 32 and 36 mm.[2] Femoral head size has also been shown to improve range of motion and function.[3]

Available literature and quality of the evidence

The quality of literature addressing the effect of the bearing surface and the head size is highly variable with level I–IV evidence. There are some randomized trials; however, the majority of the outcome papers are multicenter cohort studies or single-center cohort studies and in vitro studies.

Findings

Larger heads increase impingement-free range of movement between components and have the ability to

offer longer neck options improving the possibility to obtain adequate soft tissues tension.[4] Cinotti et al. reported the effect of head size on impingement in both optimally and nonoptimally positioned acetabular components, and found limited benefits to increasing head size beyond 32 mm.[5]

Howie et al. in a randomized controlled trial (RCT) demonstrated a significantly lower dislocation rate at one year for the 36 mm head group (0.8%) compared to a 28 mm head (4.4%) in primary THA.[6] Another RCT which included 32, 36, and 40 mm heads concluded at five years after surgery that a larger femoral head group had a significantly lower risk for dislocation.[7] Kostensalo et al., with data obtained from the Finnish Arthroplasty Register analyzed 4379 primary THA procedures concluded that 32 mm, 36 mm, and >36 mm were associated with a lower risk of revision due to dislocation compared with 28 mm heads.[8] The Dutch Arthroplasty Register reported a 58% higher risk of revision due to dislocation for THA performed with 22–28 mm head compared with 32 mm.[9] In the setting of the Nordic Arthroplasty Register Association database, Tsikandylakis et al. analyzed 186 231 metal-on-polyethylene THA (head size 28 mm, 32 mm, or 36 mm). They found in an adjusted Cox regression mode that patients with 28 mm heads had a higher risk of revision for dislocation (hazard ratio [HR] = 1.67; 95% confidence interval [CI]: 1.38–1.98) compared with 32 mm, whereas there was no difference between patients with 36 mm (HR = 0.85; 95% CI: 0.70–1.02) and 32 mm heads.[10]

Resolution of clinical scenario

- The use of femoral heads larger than 28 mm may improve THA stability and range of motion in primary THA.

- This improvement has not been shown to increase with femoral heads greater than 36 mm.

Question 2: In patients undergoing THA, do certain bearing couples, compared to others, result in better outcomes depending on femoral head size?

Rationale

Over the last years, the use of large-diameter replacement femoral heads in THA has increased.[2],[11] Large femoral heads provide a wider impingement-free range of motion and also increase the jump distance, improving stability and reducing the risk of dislocation.[12] However, one of the main concerns when it comes to larger femoral heads is the longevity of the bearing surface.

Clinical comment

Bearing wear and head size cannot be examined irrespective of the bearing surface as different materials have different bearing friction properties. The conventional polyethylene has a greater risk of wear, but the relatively recent development of hard-on-hard bearings and the introduction of cross-linked polyethylene has led to the revision of this concept.

Available literature and quality of the evidence

The quality of the literature addressing bearing wear is variable with level I–IV evidence. Most are cohort studies, national hip arthroplasty registries, and in vitro studies.

Findings

Polyethylene bearing

The success of THA has been limited by periprosthetic osteolysis related to particulate polyethylene wear debris, but highly cross-linked polyethylene (XLPE) was developed to decrease polyethylene wear and decrease osteolysis. Engh et al. conducted a prospective, randomized study of 236 patients (XLPE group: 116 patients/non-XLPE group: 114 patients) and concluded that the XLPE liners have a95% wear rate reduction compared with the mean wear rate of the non-XLPE, and the incidence of osteolysis was lower in the XLPE group.[13]

Assuming the outer diameter of the acetabular shell is kept the same, larger diameter bearings require accordingly thinner polyethylene liners. Johnson et al. considered that the minimum thickness could be reduced to 3.9 mm with XLPE,[14] but in another study, by Girard et al., it was concluded that given the current data on wear and fatigue resistance surgeons should comply with the traditional 6 mm thickness, even with XLPE liners.[15] *Wear*, in relation to larger femoral heads, could be linear and volumetric. It has been shown that linear wear rates of less than 0.1 mm per year have been associated with a low incidence of osteolysis, and in long-term clinical studies no differences have been demonstrated in linear wear rates between 26, 28, 32, 36 and 40 mm heads when metal-on-cross-linked polyethylene (MoXLPE) are used.[16],[17] However, surgeons and manufacturers should focus on decreasing volumetric wear. Currently, there is no agreed-on threshold with respect to volumetric wear rates and osteolysis. Cross et al. proposed that a volumetric wear of 40 mm^3/yr could eliminate osteolysis and up to 80 mm^3/yr could be tolerated.[18]

Lachiewicz et al. in 2009 found no association between femoral head size and the linear wear rate, but observed an association between larger (36 and 40 mm) head size and increased volumetric wear rate and total volumetric wear.[19] Authors re-evaluated the previous reported cohort at a mean follow-up of 11 years (range 10–14 years) and they found again that 36–40 mm femoral heads had a higher volumetric wear (median 26.1; 95% CI: 11.3–47.1) than did 26 mm heads (median 3,1; 95% CI: 0.7–12.3), 28 mm heads (median 12.3; 95% CI: 3.0–19.3), and 32 mm heads (median 12.9; 95% CI: 6.6–16.8; p = 0.02).[20] A 13-year report on THA survival from the 2017 Australian Registry report shows that THA with both bigger and smaller than 32 mm MoXLPE bearings have a greater risk of revision compared with 32 mm. Heads smaller than 32 mm were revised due to dislocation more frequently, while heads larger than 32 mm were revised in the majority of cases due to aseptic loosening or fracture, complications that can be associated with wear.[21] Heckmann et al. examined the THA bearing surface trends in the United States from 2007 to 2014. Over this period ceramic-on-polyethylene (CoP) bearing surfaces steadily increased in popularity to become the most popular bearing surface type. Although concerns about fracturing of the femoral head and increased costs had decreased usage of ceramic heads in the 1980s and 1990s, the advent of the delta ceramic with improved material composition, low fracture rates, and low wear rates has again increased the use of CoP bearings.[22] While this has been well established in wear-simulator studies,[23] recent clinical studies have begun to demonstrate clinical differences.[24]

Resolution of clinical scenario

- Bearings >32 mm have increased volumetric wear compared with 32 mm or smaller in MoXLPE THA, but not in ceramic-on-XLPE.
- THA survival is better for 32 mm MoXLPE bearings compared with both bigger and smaller ones.
- The use of the 32 mm head size is recommended when an MoXLPE is used. If bigger head sizes are desired then ceramic heads up to 36–38 mm on XLPE should be considered.

Question 3: In patients undergoing THA, do larger femoral head sizes, compared to smaller sizes, result in greater levels of trunnion corrosion?

Rationale

Trunnionosis is defined as the wear of the femoral head–neck interface and has been acknowledged as a source of THA failure.[25] Several reports indicate a rising awareness of the trunnionosis-related implant failure in the last 10 years.[26] It is estimated that up to 2% of all THA patients can be affected and reports have demonstrated an incidence ranging from 0.7 to 3% of all THA revisions.[21],[27],[28] Hence, this question sought to analyze if the chosen femoral head size can affect trunnion corrosion in THA. This can be concerning for the patient and surgeon alike, because this may affect survival of the THA and patient outcomes. A more complete discussion of trunnionosis can be found in Chapter 29.

Clinical comment

Trunnionosis is a phenomenon that has gained prevalence with newer THA implant designs, particularly when modularity is used.[28] Modularity allows for a better intraoperative restoration of leg length and control of hip offset, but while this enables a more customized fit for the patient, it may have untoward effects. The modularity at times may play a role in increased wear and mechanical insufficiency at the trunnion, ultimately leading to revision.[28,29]

Available literature and quality of the evidence

The quality of literature addressing appropriate investigations for the effect of the wear of the femoral head–neck interface is highly variable with level III–IV evidence. The majority of the outcome papers are multicenter cohort studies or single-center cohort studies.

Findings

Due to galvanic corrosion with mixed metal combinations at the head–neck junction, cobalt-chrome/cobalt-chrome couples are less susceptible to corrosion than cobalt-chrome/titanium or stainless steel couples; this has been evaluated in both in vitro and in vivo settings.[30,31] In a multicenter retrieval analysis of 231 modular hip implants, corrosion was observed in 28% of similar metal couples, compared with 42% in mixed couples.[31] Notably, ceramic femoral heads appear to be much less susceptible to the process of corrosion than those composed of cobalt-chromium (CoCr) alloy.[32–34]

Currently, the evidence is conflicting for the association of head size with trunnion corrosion.[29] Finite element analysis of head–neck junctions demonstrated increased maximum stress on the trunnion as head diameter increased from 28 to 40 mm.[35–37] Bolland et al. in a wear analysis of a series

of 5/17 retrieved large diameter (>40 mm) MoM THAs revealed increased wear at the head–neck junction, but normal wear at the articulating surface suggesting an association between large heads and trunnionosis.[38] Del Balso et al. performed a retrieval analysis of 23 femoral heads of 32 mm diameter matched with 28 mm heads based on time in vivo and head length (−3 to +8 mm). They found that 32 mm femoral heads exhibited greater total fretting scores than 28 mm heads ($p < 0.01$).[35] An analysis of the National Joint Registry for England, *Wales*, *Northern Ireland* and the *Isle* of *Man* data showed a relative risk of adverse reaction to metal debris (ARMD) 2.8 times (95% CI: 1.74–4.36) higher in 36 mm MoP bearings compared with 28 and 32 mm ($p < 0.001$).[27]

However, other studies have refuted an association between trunnionosis and head size. Triantafyllopoulos et al., in 154 MoP THAs retrieved as part of 3282 revision surgeries, found that the fretting and corrosion of the tapers and the trunnions were not affected by head size ($p = 0.247$, $p = 0.471$, $p = 0.837$, and $p = 0.868$, respectively).[39] Cartner et al, in an analysis of 210 femoral heads, found that an increased head size and increased time in vivo did not correlate to higher corrosion scores.[40]

Resolution of clinical scenario

- Based on current evidence, the results suggest that cobalt-chrome/cobalt-chrome couples are less susceptible to corrosion than cobalt-chrome/titanium or stainless steel couples. Also using a ceramic femoral head appears to be much less susceptible to corrosion than those composed of CoCr.
- Currently, evidence is conflicting for the association of head size with trunnion corrosion. Finite element

analysis of head–neck junctions has demonstrated an increased maximum stress on the trunnion as head diameter increased from 28–40 mm. However, recent study has refuted this association.

Summary of answers

- Larger femoral head size (>28 mm) is associated with a lower risk of dislocation.
- Size increases beyond 36 mm do not seem to further reduce dislocation risk.
- Larger head sizes are susceptible to greater volumetric wear rates.
- Femoral head size should be selected carefully in consideration with coupling choice, as different materials have different volumetric wear rates.
- Ceramic is least susceptible to corrosion, followed by CoCr/CoCr, and lastly by CoCr/titanium or steel couplings.
- There is conflicting evidence regarding the impact of head size on trunnion corrosion.

28 Dual Mobility in Total Hip Arthroplasty

Iñaki Mimendia MD, Maria Jurado MD, Ernesto Guerra-Farfán MD, and Victor Barro MD PhD
Vall d'Hebron University Hospital, Barcelona, Spain

Clinical scenario

- A 66-year-old woman presents with a painful left hip since about two years ago, without history of a traumatic event, that is poorly controlled with oral medication and strongly affects her daily activities.
- She had a history of posterior spinopelvic fusion (T12-S1-iliac arthrodesis) one year ago.
- Physical exam shows a walking sagittal spinopelvic imbalance due to bilateral hip flexion and a rigid spinopelvic fusion (Figure 28.1).

Top three questions

1. In patients undergoing primary total hip arthroplasty (THA), do some patient characteristics, compared to others, predict dislocation?
2. In patients undergoing THA, do dual mobility (DM) implants, compared to standard implants, result in a different type of dislocation?
3. In patients undergoing THA, do DM implants, compared to standard implants, have better long-term survival?

Question 1: In patients undergoing primary total hip arthroplasty (THA), do some patient characteristics, compared to others, predict dislocation?

Rationale

Postoperative dislocation is still a common, troublesome complication after THA, being the second most frequent complication[1] and the predominant indication for revision THA in the United States, representing 17–22% of all revision THAs in that country.[2,3] This complication faced by the orthopedic surgeon has a high morbidity, as well as a high economic cost.[4] Identifying patients at risk for dislocation is important, as it can help with preoperative patient education, postoperative prevention measures, and the approach in the management of primary THA instability when planning revision surgery.[5,6]

Clinical comment

The outcome following a first episode of THA dislocation is threefold: first, the patient will have a suboptimal clinical result; second, it will increase the risk of further episodes of instability; and finally, there will be an increased requirement for revision surgery.[7] Therefore, the ideal solution to instability is prevention achieved through optimal surgery.[5] Recognizing adequately the potential causative factors for instability in a patient who is going to undergo a primary THA surgery is crucial.[8]

Available literature and quality of the evidence

Quality of literature addressing appropriate investigations evaluating risk factors for instability after THA is variable with level II–III evidence. There are no randomized trials.

Findings

Due to the multifactorial etiology of hip instability, a detailed assessment of the patient and surgical plan is essential.[6] Patient-specific risk factors for THA instability include female gender, older age, history of previous dislocation, abductor deficiency,[9] American Society of Anesthesiologists (ASA) score of 3 or more, hip fracture, mega or tumor prosthesis,[10] multiple previous surgeries, revision THA,[11] altered neurologic or proprioception around the hip from neurologic or spinal disease, and, importantly, after a recent lumbar fusion surgery. There is a great deal of evidence that spinal fusion alone is a significant risk factor for instability[12],[13] and the most important independent predictor of dislocation within the first six months after surgery.[14],[15] Specific surgical precautions should be taken in this population regarding implant design and orientation, and considering DM implants and surgical approach to reduce the risk of dislocation.[16],[17]

Figure 28.1 Photographs and radiographs of a patient with previous spinopelvic fusion.

Source: Iñaki Mimendia, Maria Jurado, Ernesto Guerra–Farfán, Vicoria Barro.

There is increasing concern over spinal imbalance, acetabular component position, and its relation to dislocation after THA.[13] Restricted pelvic movement due to degenerative disc disease as well as lumbar surgery does not allow the acetabulum to open during flexion of the hip with sitting, needing high inclination and anteversion, and remaining at risk for impingement at the extremes of movement. Advances in positional preoperative imaging (such as standing, sitting, and squatting) help identify high-risk situations and alterations consequently. Stefl et al. suggested that in patients with spinopelvic imbalance the use of DM articulation should be considered.[16]

The soft tissue envelope of the hip joint provides the major secondary stabilizer of the THA. Deficiency of the soft tissue envelope, especially the hip abductors, is also a well-studied risk factor. In this manner, when utilizing the posterior approach, preservation and reattachment of the capsule and external rotators greatly reduces the risk of dislocation.[18],[19]

The surgeon's role in THA stability includes patient selection, choice of surgical approach and implant, technical execution, and experience. Clearly, therefore, the surgeon should understand the design implications of the diverse modular components that constitute the hip prosthesis as a whole.

Resolution of clinical scenario

- A thorough anamnesis on the characteristics of the patient is mandatory to identify the presence of

possible risk factors. This should include gender, age, previous hip surgery, neuromuscular disorders, cerebral dysfunction, poor patient cognition or compliance, lumbar spine disease, and previous lumbar surgery.

- Patients in general should be counseled regarding the risk of THA dislocation, and patients at higher risk should be educated regarding the presence of risk factors that make them particularly high risk for this complication.
- The surgeon performing the surgery must identify patients at high risk and consider all options to minimize the risk of this complication.
- Patients with pathological spinal imbalance and a biological or surgical hip fusion that are at high risk for impingement and THA dislocation may be good candidates for increased constraint such as a DM implant.

Question 2: In patients undergoing THA, do dual mobility (DM) implants, compared to standard implants, result in a different type of dislocation?

Rationale

DM cups consist of a fixed head coupled to a mobile intermediate polyethylene (PE) liner, which articulates with a smooth metal shell. Thus, there is an inner, small diameter articulation, with a capture mechanism between the head and the liner, and a larger, unconstrained, outer articulation.[20] Because there is an additional bearing

interface compared with fixed bearing in THA, DM hips can suffer a unique failure mechanism known as an *intra-prosthetic dislocation* (IPD), in which the inner prosthetic femoral head decouples from the outer PE bearing.[20] IPD is irreducible by closed means and always requires surgical management and DM bearing component revision.

Clinical comment

The most accepted indication of DM is revision surgery; however, with the development of new designs and some promising results, the use of DM in primary hip arthroplasty is increasing, especially in patients with a high risk of dislocation. With poor clinical studies regarding the results of DM in long-term follow-up, IPD is one of the major concerns when using a DM cup in THA.[21] IPD may occur any time after the index procedure. However, the European experience suggests that IPD was predominantly a late complication particularly with conventional PE in the first generation DM designs. Philippot et al. classified three types of IPD, using radiographic and perioperative features: type I, IPD secondary to wear of the PE retentive rim with no evidence of arthrofibrosis or cup loosening; type II, IPD secondary to an extrinsic phenomenon (arthrofibrosis or heterotopic ossifications) as cause for the blockage of the larger articulation, and thus accelerated wear of the PE retentive rim; type III, IPD secondary to cup loosening as cause of wear of the PE retentive rim.[22] Some studies suggest that a high body mass index (BMI), some femoral stem designs, and a large diameter of DM can be predictive factors of IPD.[23]

Available literature and quality of the evidence

Current available literature regarding IPD are from studies with low-quality evidence, mainly case series (level IV).

There are no randomized trials.

Findings

Historically, one of the most common and specific complications in relation to DM implants has been IPD.

Mitchell and colleagues presented in 2017 a historic literature review of IPD in United States.[24] In 2004, Lecuire and colleagues reported seven cases of IPD occurring a mean of 10 years after implantation during the period 1989–1997.[25] In 2013, Philippot and colleagues reported that 81 of 1960 primary THAs performed between 1985 and 1998, developed IPD a mean of nine years after implantation.[22] These IPD cases were attributed to PE wear or outer articulation blockage caused by arthrofibrosis or heterotopic ossification. In 2011, Stigbrand and Ullmark reported three cases in which the DM prosthesis dislocated within one year after implantation. It was suggested that the inner metal head dissociated from the larger PE component after attempted closed reduction for dislocation.[26]

Darrith et al. reviewed 24 studies of DM primary THAs including 10 783 THAs with a mean follow-up of 8.5 years (2–16.5).[21] The second most common complication was IPD, with an incidence of 1.1% (122 hips); however, no cases of IPD were reported for DM primary THAs undertaken after 2007 or for any of those using 28 mm heads. There was a significantly greater incidence of IPD, 3.3% (95% confidence interval [CI]: 2.7–3.9%) in the older series of primary THAs using an inner head size of 22 mm, the causes of which are likely to have been multifactorial. Not only has the quality of the PE liners improved but also the size of the femoral head typically used has increased in diameter.

Resolution of clinical scenario

- IPD is a specific complication of DM and must be considered.
- The latest reviews seem to show a marked decrease of the incidence with the new generations of implants.
- IPD could be in relation to 22 mm heads and PE wear in long-term implanted cases, and inappropriate implantation of DM system in acute cases.

Question 3: In patients undergoing THA, do DM implants, compared to standard implants, have better long-term survival?

Rationale

Dislocation is the most common cause of revision during the first two years after a THA,[27,28] and the most frequent reason for dislocation is implant impingement. For this reason, DM use has been popularized in the last few years in patients with high risk of instability, both in THAs and in revision surgery.[29]

Clinical comment

Surgeons in France began experimenting with the DM concept in the 1970s and 1980s with good results, but IPD and wear were not infrequent problems.[30–33] However, the new designs of DM have been changed in relation to surface coatings, materials, and shape in order to improve these issues. Around the world, interest in DM has been growing since its introduction to the market nearly a decade ago. There are no high-quality prospective studies

in the American or European literature. Although many authors have documented advantages of the DM components in preventing and treating instability,[30–33] there are concerns about the quality of this evidence, the length of follow-up, and the potential for complications unique to these components, such as IPD and accelerated PE wear.[34]

Available literature and quality of the evidence

The current best available evidence in relation of DM in THA consists in a case control study (level III) and case series and prospective and retrospective cohorts (level IV).

In revision surgery of THA the best available evidence consists in one study of level III, retrospective cohort by Jauregui et al., and a systematic review by Darrith et al. (level III).[35] There are no level I studies.

Findings

In terms of DM in primary THA, the most evidence is about first designs of Bousquet DM. Although there is some study about the DM new generation, more evidence is needed.

Vielpeau et al. reported a large series of 668 cases of primary THA.[35] A subgroup of 437 cases with original Bousquet tripolar cups (Novae-1®, Serf, France) with a mean follow-up of 16.5 years was compared with a subset of 231 cases with second-generation cups (Novae E®, Serf, France) with a follow-up of 5.2 years. Revision-free survival was 95.6 and 84.4 % at 5 and 15 years, respectively, for the original Bousquet cups. The second-generation Novae cups showed a five-year survival rate of 99.6 %.

Puch et al. reported a prospective and consecutive series of 119 THAs with a cementless DMC of second-generation (GIROS) were performed in patients aged less than 55

years and 444 in patients aged more than 55 years.[36] The mean follow-up was 11 years (8–15 years). Survivorships (failure of both components or cup loosening) were not different between patients aged less than 55 years and patients aged more than 55 years.

The second-generation DM has increased use in revision surgery, due to the high risk of instability in these patients, and its good results in this term, but there are no level I–II studies at long-term.

Jauregui et al. compared revision THA with DM articulations (n = 60) matched (1 : 2) to patients who had conventional single articulation prostheses, in terms of age, gender, BMI, and Paprosky acetabular defect (n = 120).[36] The DM group had lower dislocation – 1.7% (1 out of 60) vs 5.8% (7 out of 120) – and aseptic loosening rates – 1.7% (1 out of 60) vs 4.2% (5 out of 120) – compared to the control group. There were no significant differences in functional outcomes, activity level, or overall physical and mental health status between the two cohorts.

In a systematic review Darrith et al. analyzed 25 studies of DM revision THAs, including 3008 THAs with a mean follow-up of 5.4 years (2–8 years). A total of 103 (3.4%) had been further revised.[21] The incidence of dislocation was 2.2% (67 THAs), making extra-articular dislocation the most common complication. The rate of aseptic loosening in this group was 1.4% (29 hips) and the rate of IPD was 0.3%.

The new DM generation seems to improve the results of the first original Bousquet system, in terms of survivorship, IPD, and wear. However, we do not have any studies of level I–II or long-term outcomes, so more evidence is needed to extend its use beyond high-risk patients.

Resolution of clinical scenario

- The DM implant is an alternative to keep in mind in cases at high risk for dislocation.
- A few long-term outcome studies of second-generation DM show a higher survivorships, and lower rates of IPD and wear, than first-generation models.
- High-quality, prospective, comparative studies are necessary to broaden the DM use beyond high-risk patients.

Summary of answers

- Patients in general should be counseled regarding the risk of THA dislocation, and patients at higher risk should be educated regarding the presence of risk factors that make them particularly high risk for this complication.
- Intra-prosthetic dislocation is a specific complication of DM and must be considered.
- The DM implant is an alternative to keep in mind in cases at high risk for dislocation.
- A few long-term outcome studies of second-generation DM show a higher survivorships, and lower rates of IPD and wear, than first-generation models.
- High-quality, prospective, comparative studies are necessary to broaden the DM use beyond high-risk patients.

29 Trunnionosis

Christopher Del Balso MBBS MSc, Emil Schemitsch MD, and Brent Lanting MD MSc
Division of Orthopaedic Surgery, Department of Surgery, University Hospital, London Health Sciences Centre, Western University, London, ON, Canada

Clinical scenario

- A 64-year-old female presents with worsening pain in the right groin, abductor weakness, and associated Trendelenburg gait; the patient underwent an uncemented right total hip arthroplasty (THA) with a cobalt-chromium (CoCr) femoral head on highly cross-linked polyethylene three years ago.
- The patient did well following right THA with no issues until six months ago; erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) are within normal limits.
- X-rays reveal subtle lucency about the proximal aspect of the femoral stem; a metal artifact reduction sequence magnetic resonance imaging (MARS-MRI) reveals a large peri-articular encapsulated soft tissue mass; serum metal ion levels are >1 ppb (parts per billion) with increased cobalt (Co) relative to – (Cr).

Top three questions

1. In patients with metal-on-polyethylene (MoP) THA who develop an adverse local tissue reaction (ALTR), does the mechanism by which this occurs differ from that observed in metal-on-metal (MoM) THA?

2. In patients undergoing THA, are there factors which increase the risk of trunnionosis and potential subsequent development of an ALTR in MoP THA when compared to ceramic-on-polyethylene (CoP)?
3. In patients with MoP THA and radiological evidence of an ALTR secondary to trunnionosis, does management differ compared to that of patients with ALTRs from MoM THA?

Question 1: In patients with metal-on-polyethylene (MoP) THA who develop an adverse local tissue reaction (ALTR), does the mechanism by which this occurs differ from that observed in metal-on-metal (MoM) THA?

Rationale

Although ALTRs initially were described to occur in association with MoM articulations, they also have been shown to occur in association with other articulations.[1–4] These include the modular head–neck taper junction as well as modular neck–body taper junctions in MoP THA. In MoM articulations, metal debris is undoubtedly produced at bearing surfaces. However, such debris is also produced at the head–neck taper interface, as demonstrated in studies comparing MoM THA with hip resurfacing.[5,6]

Clinical importance

ALTRs are not simply the result of metal debris produced at the bearing surfaces of MoM THA. Metal debris can be produced at modular head–neck and neck–body taper

junctions. This is a clinical entity referred to as *trunnionosis,* and can occur in MoP THA.

Available literature and quality of the evidence

- Level I: 1 RCT.
- Level III: 1 retrospective cohort study.
- Level IV: 1 case series.

Findings

When comparing large-head MoM THA with MoM hip resurfacing, Garbuz et al. noted increased serum Co and Cr ion levels from baseline in both groups.[6] Excessively high serum Co and Cr levels (at two years) in the large-head MoM THA were shown to not be solely from the bearing surface since the two groups had the same bearing surface. The only plausible explanation for the markedly elevated serum Co and Cr levels relates to the two areas of modularity for the attachment of the femoral head to the stem. In the large-head MoM THA group in this study, the two modular junctions and mismatch of metals between the titanium stem and the Co-Cr alloy adaptor could account for the elevated metal ion levels seen.

In clinical studies of MoP THA designs, metal ion release and ALTRs due to trunnionosis have been reported. A retrospective cohort study by Cooper et al. showed ALTRs can occur in patients with a MoP bearing secondary to corrosion at the modular femoral head–neck taper, and their presentation is similar to the ALTRs seen in patients with a MoM bearing.[1] Elevated serum metal ion levels, particularly a differential elevation of serum Co levels with respect to Cr was shown. Safe levels of serum Co are <1 ppb.[7],[8]

Trunnionosis following MoP THA has been demonstrated in retrieval studies.[3] However, the factors that potentiate trunnionosis are controversial. Both biomechanical and bio-electrochemical factors have been described. The concept of mechanically assisted crevice corrosion (MACC) has also been supported.[9],[10] As described by Goldberg et al., trunnionosis may be enabled by the disruption of the protective oxidative layer on the metal by fretting, potentiating the corrosion of the exposed metal beneath the oxidative layer through an active combination of biochemical and electrochemical methods.[10]

Resolution of clinical scenario

- ALTRs can occur in MoP THA in addition to MoM THA.
- While the bearing surface may be the principle source of metal debris in MoM THA, the taper junction(s) are the source in MoP THA, causing ALTRs and elevated serum metal ion levels (Co > Cr).
- The mechanism by which trunnionosis occurs is MACC.

Question 2: In patients undergoing THA, are there factors which increase the risk of trunnionosis and potential subsequent development of an ALTR in MoP THA when compared to ceramic-on-polyethylene (CoP)?

Rationale

If the factors contributing to the development of trunnionosis are elucidated than the possibility of ALTRs as a result of MACC at metal head–neck and neck–body taper

junctions can be minimized. Alternatively, if trunnionosis occurs solely at metal taper junctions, CoP THA represents a means to avoid the problem altogether.

Clinical importance

In recent years, arthroplasty surgeons have increasingly been utilizing CoP as bearing surfaces to avoid the metal head–neck taper junction implicated in trunnionosis. To date, there has been only a single case report of ALTR secondary to trunnionosis in CoP THA.[11]

Available literature and quality of the evidence

- Level IV: 2 case series.
- Level IV: 2 retrieval studies.

Findings

As ALTRs and trunnionosis are rare entities, the ability to prospectively examine the causative factors is limited. Attempts to date to elucidate these factors are largely based on retrieval studies, case series, and retrospective case cohort studies. Time in vivo consistently has been shown to be a risk factor for trunnionosis.[10,12–14] The biomechanical argument has been supported by studies examining how increased head length, diameter, and offset affect trunnionosis. Increased head length has been shown, in retrieval studies, to increase the severity of corrosion and fretting.[13] Head diameter was also found to be a substantial risk factor for the development of trunnionosis.[14,15] This has been refuted in a report which indicated that head diameter does not contribute to the development of trunnionosis.[12] The role of head diameter is, therefore, unclear.

Both the design and flexural rigidity of the trunnion are purported to play an important role in the development of trunnionosis. A flexible trunnion may allow fretting as well as point loading at the head–neck junction,[16] and stems that have decreased mechanical rigidity have been associated with higher rates of trunnionosis.[10] The relatively shorter mating surface of modern trunnions means the stem trunnion mating surface ends within the head, which leads to edge loading.[17] Edge loading is known to make tribocorrosion more likely to occur. Reports in the literature have indicated that specific trunnion designs have higher rates of fretting and corrosion.[18] The specific feature or combination of features of these trunnions that play a role in the development of trunnionosis is as yet unclear. Increased corrosion is observed with dissimilar head–stem metal combinations.[9,12] In vitro studies do not support this, and therefore the clinical significance is unclear.

There have been issues with implant design, with catastrophic failure having been reported in one particular design.[19,20] Urish et al. reported implant failure in 4.7% of 636 implants at eight years.[19] Catastrophic failure occurred in 18 cases with head–neck taper corrosion in 12 cases. In all failures, MARS-MRI demonstrated large cystic fluid collections typical of ALTR, and pseudotumor was observed in all cases at the time of revision.

The use of ceramic femoral heads as an alternative to CoCr as a means to reduce fretting corrosion is supported in the literature.[21–23] Ceramic does not corrode because it is electrochemically inert. The metal femoral stem mated with a ceramic head remains susceptible to corrosion; however, adverse reactions to metallic debris with CoP THA is exceedingly rare.[11] In a retrieval study, Kurtz et al. demonstrated that taper corrosion was mitigated, although

not completely eliminated, with the use of ceramic heads as compared with Co-Cr heads.[21]

Resolution of clinical scenario

- Factors purported to increase the risk of trunnionosis in MoP THA include increased head length, diameter, offset, stem design, flexural rigidity, and dissimilar head–stem metal combinations.
- Evidence for each of these factors remains limited, and the clinical significance is unclear.
- There are implant designs which have been associated with catastrophic failure and pseudotumor formation.
- Use of ceramic femoral heads in CoP THA can mitigate, although not completely eliminate, taper corrosion.

Question 3: In patients with MoP THA and radiological evidence of an ALTR secondary to trunnionosis, does management differ compared to that of patients with ALTRs from MoM THA?

Rationale

Over the past two to three decades a MoP articulation with a modular head–neck taper has been by far the most common form of total hip replacement implanted worldwide. While believed to be a relatively rare clinical entity, appropriate management for patients with ALTRs secondary to trunnionosis remains unclear.

Clinical importance

Guidelines for the revision of MoP THA in the setting of ALTRs secondary to trunnionosis may assist arthroplasty surgeons in achieving the best possible outcomes for affected patients.

Available literature and quality of evidence

- Level IV: 1 case series, 2 therapeutic studies.

Findings

What surveillance is required for head–neck taper junctions in the setting of MoP THA is unclear. Algorithms for the adequate follow-up and investigation of ALTRs related to MoM THA, including the role of both metal ion analysis and advanced imaging, have been proposed.[24] Trunnionosis arising from MoP THA represents a relatively rare clinical problem. Therefore, routine follow-up, without the need for advanced imaging and/or metal ion analysis, is all that is required for an asymptomatic patient with a well-functioning hip and no radiographic abnormalities. When a patient has hip pain of unknown origin, it might be appropriate to investigate with advanced cross-sectional imaging (i.e. MARS-MRI) and/or metal ion analysis.[1,25] In a retrospective observational study of 3340 revisions for adverse reactions to metal debris and ALTRs, Matharu et al. reported that 7.5% were observed in non-MoM THAs.[26] The authors cautioned that, although revision surgery in non-MoM THAs appears low, this risk is increasing and significantly higher in ceramic-on-ceramic THA and 36 mm MoP THA. Therefore, ALTRs may represent a more significant clinical problem in non-MoM THAs than currently appreciated.

Although there are guidelines for clinically important serum ion levels in patients with MoM THA, guidelines for suspected trunnionosis do not exist. However, Cr levels

may be relatively lower than Co levels in cases of trunnionosis compared with cases of failed MoM total hip replacements.[27]

Treatment algorithms to deal with head–neck trunnionosis and the associated ALTRs are derived from relatively small case series. Engh et al. highlighted the fact that the current treatment protocols for taper corrosion originated from 8 case reports and a single level IV study.[28] Therefore, there is no high-quality (level I or II) evidence to support the proposed algorithms for the treatment of trunnionosis. Most of the regimens designed for the treatment of ALTRs associated with head–neck trunnionosis have originated from the literature on MoM total hip replacement.[6],[29] Soft tissue reactions to metallic debris have been far more common after MoM total hip replacement, and the importance of a thorough debridement of the pseudotumor material, often requiring a subtotal capsulectomy, has been recommended.[6],[29]

In patients with ALTRs in MoP THA secondary to trunnionosis, whether to revise a well-fixed stem in order to remove the potentially damaged male taper junction is of interest. A retrospective review by Goyal et al. demonstrated that there was no difference in survivorship between total hip replacements that were revised to a new metal femoral head in the presence of either high-grade or low-grade head taper corrosion, thus providing strong support for leaving the corroded stem taper in place.[30] Implantation of a new femoral head, in combination with a new acetabular bearing surface, should be performed. The most common bearing replacement combination is a ceramic head, with a titanium adapter sleeve articulating with a highly cross-linked polyethylene insert decreasing the potential for ongoing corrosion and fretting because of

the chemically inert properties of the ceramic material.[1,28,31]

Resolution of clinical scenario

- As trunnionosis in MoP THA is a relatively rare clinical problem, routine follow-up without advanced imaging or metal ion analysis is all that is required for asymptomatic patients.
- In patients with ALTRs secondary to trunnionosis, as with patients with ALTRs from MoM THA, debridement of the pseudotumor with subtotal capsulectomy, femoral stem retention, and implantation of a new ceramic head on highly cross-linked polyethylene insert should be performed.

Summary of answers

- ALTRs can occur in MoP THA in addition to MoM THA.
- While the bearing surface may be the principal source of metal debris in MoM THA, the taper junction(s) are the source in MoP THA, causing ALTRs and elevated serum metal ion levels (Co > Cr).
- The mechanism by which trunnionosis occurs is MACC.
- Factors purported to increase the risk of trunnionosis in MoP THA include increased head length, diameter, offset, stem design, flexural rigidity, and dissimilar head–stem metal combinations.
- Evidence for each of these factors remains limited, and the clinical significance is unclear.
- Use of ceramic femoral heads in CoP THA can mitigate, although not completely eliminate, taper corrosion.

- As trunnionosis in MoP THA is a relatively small clinical problem, routine follow-up without advanced imaging or metal ion analysis is all that is required for asymptomatic patients.
- In patients with ALTRs secondary to trunnionosis, as with patients with ALTRs from MoM THA, debridement of the pseudotumor with subtotal capsulectomy, femoral stem retention, and implantation of a new ceramic head on highly cross-linked polyethylene insert should be performed.

Lisa C. Howard MD, Bas A. Masri MD, Don S. Garbuz MD, and Clive P. Duncan MD
Department of Orthopaedics, University of British Columbia, Vancouver, BC, Canada

Clinical scenario

- An 81-year-old woman with a previous uncemented total hip arthroplasty (THA) presents with severe thigh pain and inability to weight bear after a fall.
- Examination reveals external rotation deformity of the leg, bony crepitus, and tenderness around the proximal and midthigh.
- Radiographs demonstrate a displaced periprosthetic femur fracture.
- Her daughter tells you she has a diagnosis of rheumatoid arthritis and osteoporosis and asks if this predisposes her to this complication.

Top three questions

1. In patients who sustain a periprosthetic femur facture, are there factors that may be predictive of this complication after primary THA?
2. In patients with periprosthetic fractures of the femur, is there a validated classification system that has satisfactory intraobserver and interobserver reliability and validity that aids in therapeutic planning?
3. In patients with Vancouver type B periprosthetic femur fractures, does operative management, compared to

nonoperative management, result in a better clinical outcome?

Question 1: In patients who sustain a periprosthetic femur facture, are there factors that may be predictive of this complication after primary THA?

Rationale

The question of risk factors in periprosthetic fractures is debated extensively in the literature and as such, a review of the current evidence is helpful to identifying these risks as they pertain to this common complication.

Clinical comment

Periprosthetic femur fractures after THA can be a difficult complication to manage. Recognition of features associated with periprosthetic fractures could allow for prophylactic measures to prevent a fracture in the at-risk patient.

Available literature and quality of the evidence

One level II prospective registry study was identified,[1] while the remainder were generally level III,[2–9] including several large database and registry studies.[10–14]

Findings

Gender

A summary of cohort and case-control studies classified as level III evidence noted a tendency of periprosthetic fracture patients to be female gender.[2–5,10–12] A meta-

analysis concluded an odds ratio (OR) of 1.534 (95% confidence interval [CI]: 1.345–1.749, p <0.001), while a Swedish registry study showed a relative risk of 1.6 (95% CI: 1.1–2.3).[6,13] A prospective registry study as well as a retrospective cohort did not conclude gender to be a risk factor.[1,7] Abdel et al. in their retrospective review of 32 644 primary THAs found female gender to be a risk factor of intraoperative (CI: 1.2–1.7; p <0.001) but not postoperative fractures.[14]

Patient age

Several retrospective studies have shown age to be a risk factor for fracture.[7,8,10,12,13] One meta-analysis concluded that age greater than 80 is a risk factor (OR = 4.203; 95% CI: 2.859–6.181; p <0.001)[6] while another prospective cohort study concluded that age is a risk factor with a relative risk of 1.4 for each decade of increasing age (95% CI: 1.2–1.6; p <0.001). In contrast, Lindahl et al. found a significantly higher fracture rate in younger patients (p <0.001),[1] while a large-scale retrospective cohort study did not find age to be a risk factor.[14]

Rheumatoid arthritis

In the prospective Swedish National Registry study, only 6% overall were patients with rheumatoid arthritis. They had an increased prevalence in the periprosthetic fracture group, with an incidence of 11 and 10% in the primary and revision populations, respectively (p <0.001).[1] Zhu et al. in their meta-analysis showed that rheumatoid arthritis is a statistically significant risk factor for periprosthetic fracture (p <0.001).[6]

Osteoporosis and prior fragility fracture

A large-scale prospective cohort study reported osteoporosis to increase fracture risk by 2.8 times (95% CI: 1.6–4.8; p <0.001).[12] Wu et al. found that preoperative osteoporosis was a significant predictor for fracture.[8] In a small case control study, Sarvilinna reported a risk ratio of 4.4 (95% CI: 1.4–14) for periprosthetic fracture if the primary diagnosis for arthroplasty was fracture.[9]

Timing to fracture and implantation method

A large-scale 40-year follow-up retrospective cohort documented the incidence of fracture to be 0.4% at 1 year, 0.8% at 5 years, 1.6% at 10 years, and 3.5% at 20 years.[14] Lindahl et al. reported an average of 7.4 years post primary THA (688 fractures), and 3.9 years post revision hip arthroplasty (361 fractures).[1] The timing of periprosthetic fractures from the index procedure, however, seems to relate in part to the type of prosthesis used. A large prospective cohort study reported that 77% of all prostheses used were uncemented and the incidence of fracture was 2.4% for uncemented and 0.9% for cemented (p <0.001) hips.[12] The Nordic registry reported that fracture risk for uncemented stems was highest in the first six months, while fractures with cemented stems tended to occur later.[13] Abdel et al. found that, overall, uncemented stems had a higher prevalence of fracture at all time points up to 20 years (p <0.001).[14] The reason for early postoperative fractures in uncemented components appears to be related to technical intraoperative errors that lead to fractures in the period of latency before osteointegration.[13],[15] Late postoperative fractures have been associated with loosening and osteolysis.[15],[16] For instance, in the Swedish Hip Arthroplasty Register 70% of implants were noted to be loose prior to periprosthetic fracture.[1]

Resolution of clinical scenario

- Patients who have a history of rheumatoid arthritis, osteoporosis, or previous fragility fracture are at increased risk of periprosthetic hip fracture, whereas those with female gender or increased age are more debated.
- Uncemented stems have a higher risk of fracture in the early postoperative period.
- Femoral component loosening is a risk factor for late periprosthetic fracture.

Question 2: In patients with periprosthetic fractures of the femur, is there a validated classification system that has satisfactory intraobserver and interobserver reliability and validity that aids in therapeutic planning?

Rationale

The Vancouver Classification is the most widely used periprosthetic fracture classification and the evidence behind its use is important to review in the context of this complication.

Clinical comment

The variability of pathology seen in periprosthetic fractures of the femur necessitates an effective classification system to aid in the communication of diagnoses among surgical colleagues and to develop a management plan. The ability

to classify these fractures properly will assist in their management.

Available literature and quality of the evidence

The two studies available to address this question are validation studies.[17],[18]

Findings

A useful classification system incorporates clinical and radiographic information to guide management, allowing for appropriate treatment and comparison of similar fractures.

In 1995, Duncan and Masri published the Vancouver Classification System (VCS), which emphasized the quality of the prosthetic–bone interface (stability) as well the host bone stock in the therapeutic decision-making process.[19],[20] This system divides the femur into three regions regarding the stem: the trochanteric (A), around or just below the stem (B), and distal to that (C). It further subdivides the B type into those with a well-fixed stem (B1), a loose stem (B2), and a loose stem with poor bone stock (B3). The VCS has now been expanded so as to include three fracture types not originally included (D, E, and F), as well as to apply its well-accepted principles to other bones and joints[21],[22] For the purpose of this review, which deals with the femur alone, we will use the VCS.

The VCS has been subjected to reliability and validity testing in both North America and Europe,[17],[18] and is accepted universally. Brady et al. demonstrated reliability of the system when evaluated by experts and nonexperts alike, with intraobserver agreement ranging from 0.73 to 0.83, and interobserver agreement of 0.61 to 0.64 by kappa analysis indicating substantial agreement between observers. Validity was also evaluated revealing substantial

agreement (kappa value of 0.78).[17] It has, however, been subject to criticism, mainly with the reliance of the system on subjective surgeon judgment of implant stability. Failure to differentiate between a type B1 and B2 is associated with higher reoperation rates from implant failure,[23] and therefore distinguishing between B1 and B2 fractures preoperatively, and if this is difficult then checking intraoperative stability of the stem is of great importance.

Resolution of clinical scenario

The VCS for postoperative periprosthetic fractures of the femur is reliable and valid for both experts and nonexperts.

Question 3: In patients with Vancouver type B periprosthetic femur fractures, does operative management, compared to nonoperative management, result in a better clinical outcome?

Rationale

Periprosthetic femur fractures are a recognized complication of arthroplasty with a variety of types and treatment methods. An evidence-based approach to management of these fractures is the main topic of this chapter.

Clinical comment

Periprosthetic fractures are a well-known complication of THA and their management has evolved as implants and techniques have improved. An evidence-based approach to their management is important to improve outcomes.

Available literature and quality of the evidence

One level II prospective study was included,[24] while the remainder of the included evidence is made up of level III or IV studies,[25–31] as well as several systematic reviews and meta-analyses.[32–34]

Findings

Type B1 fractures are located around or adjacent to a stable femoral implant, whereby the fracture has not rendered the implant loose by either debonding a cemented composite beam stem or by involving the primary fixation surface of a cementless stem. It is generally accepted that these fractures should be treated with internal fixation; however, there is debate in the literature as to the more superior fixation method or to the value of adding strut allografts. Moore et al., in their systematic review, showed union with (n = 208) and without (n = 503) an allograft strut was 91.5 and 90.7%, respectively. The time to union was on average 2.5 months longer (95% CI; $p < 0.001$) with the use of an allograft.[32] Furthermore, union with a locking versus nonlocking plate was 91.7 and 92.4% with no difference in the time to union. In contrast, however, another systematic review showed that fractures treated with locking plates (n = 20) compared to nonlocking plates (n = 152) had a statistically significant increased risk to nonunion at 9 versus 3%, respectively ($p = 0.02$).[33] These systematic review results are limited, however, as they only involved level IV studies. However, as internal fixation techniques for periprosthetic fractures have continued to evolve, we cannot simply compare locking versus nonlocking plates as modern devices allow the use of locking screws, nonlocking screws, and cerclage cables using the same plate. The surgeon needs to understand the basic principles of the use of these plates: to allow healing

with callus as opposed to attempting primary bone healing, the bone stock and the presence of an implant make primary bone healing with compression almost impossible.

Revision arthroplasty with a long tapered fluted stem is generally the most accepted treatment for B2/B3 fractures and is associated with good outcomes.[25],[26],[34] The largest retrospective study to date showed a 98% healing rate with the use of a long tapered fluted stem for B2 and B3 fractures with an average Harris Hip Score of 80.[27] In another systematic review,[34] of 343 B2 fractures around both cemented and noncemented stems, 86.8% were treated with revision arthroplasty with or without open reduction and internal fixation (ORIF) while 12.6% were treated with ORIF alone. The re-operation rate for the revision arthroplasty and ORIF alone was 12.8 and 13.1%, respectively. The authors felt the incidence of B2 revisions managed with ORIF was likely underrepresented as the scope of their study did not include misclassified B1 fractures. They concluded that the re-operation rate for B2 fractures managed with ORIF is likely closer to the prospective Swedish registry, which reports a 32% overall re-operation rate for B2 fractures including a 10% re-operation rate of those managed with revision arthroplasty alone and a 23% re-operation rate of those managed with ORIF alone.[24],[34]

With the increasing use of polished tapered cemented stems (also known as *slip taper stems*), it has become apparent that these stems behave differently when subjected to a periprosthetic fracture in comparison to composite beam cemented stems. The polished tapered stems do not have any fixation into the cement mantle, but the cement mantle needs to be fixed to the bone, as the stems are designed to subside into the cement mantle. The composite beam stems, in contrast, are designed to fix to

the cement mantle, which is also required to fix to the host bone. A fracture around a polished tapered stem that does not compromise the fixation at the cement–bone junction, and thus does not lead to stem loosening as long as the bone is reduced and fixed in an anatomic manner so that the cement mantle is restored anatomically. For this reason, these fractures can be classified as B1 fractures. Goudie et al. found that ORIF using a dynamic compression nonlocking plate around polished tapered cemented stems for these fractures resulted in 91% union with nonanatomic reduction predicting failure, emphasizing the above-noted principles.[28] Anatomic restoration of an intact bone–cement mantle allows for controlled subsidence of a polished tapered cemented stem and a revision surgery may be avoided in elderly patients of low demand and significant medical comorbidities.[29],[35] As long as bone stock is reasonable, the fracture is reduced perfectly, and the cement mantle is intact except for the fracture line then these fractures do not require revision of the stem.

Khan et al. in their systematic review of 22 studies showed that 95.8% of Vancouver B3 fractures were treated with revision arthroplasty with or without internal fixation, with the majority being uncemented.[34] The re-operation rate for revision arthroplasty with or without ORIF and ORIF alone were 14.4 and 28.6%, respectively (RR = 1.38; p = 0.63). The revision rates for B2 and B3 fractures treated with uncemented tapered stems was 12.3 and 15.5%, respectively, which is in keeping with the Swedish registry results of 18.5 and 15.5%, respectively.[24] Common reasons for revision include subsidence, re-fracture, and infection.[24],[34] Caution should be used in interpreting these results due to the lower levels of evidence of these studies and due to case heterogeneity.

Using another successful technique, Maury reported on his outcomes of 25 Vancouver B3 fractures treated with allograft prosthetic composites, with the mean postoperative Harris Hip Score at two years of 70.8.[30] Most of their patients were ambulatory (23/24) and pain-free (21/24) at the time of last follow-up. Four of the 25 hips required repeat revision for subsidence and failure. Babis et al., in their long-term study, showed survivorship at 69% with the severity of preoperative bone loss, number of prior revisions >2 and length of the allograft as statistically significant risks for revision.[31] With the current use of either modular or nonmodular tapered stems, the indications for allograft prosthetic composites have been extremely limited in recent years, and the senior authors have not performed this operation for the past 15 years, and it should be considered of historical interest only.

Proximal femoral replacement prostheses, with a reported survivorship of 64% at 12 years, is an option for elderly patients with a limited life expectancy and low functional demands due to a reduced rehabilitation time and immediate weight bearing capacity that these implants allow.[36]

Resolution of clinical scenario

- Vancouver B1 fractures should be treated with open reduction and internal fixation; however, the method of fixation and use of strut allograft remains controversial based on the available literature. The authors recommend the use of a long dedicated periprosthetic fracture plate that allows the use of locking screws, nonlocking screws, and cables in a minimally invasive approach and using indirect reduction technique. Lag screws at the fracture site should be avoided and cables should be used in order to allow healing with

callus. Stable fixation of the proximal and distal fragments needs to be achieved using a combination of locking and nonlocking screws as well as cables with the equivalent of eight cortices in each fragment. The screws should be spaced as far away from the fracture to allow some flexibility at the fracture site to allow for healing with callus. Filling every screw hole with a screw is not recommended as this makes the construct very stiff, and can lead to nonunion. Because the bone is generally osteopenic in these patients, a long plate should be used to protect the entire bone. In general, struts are not recommended, with the exception of transverse fractures at the tip of the stem where rotational control with a plate alone is not possible, and because of the high stress concentration at the tip of the stem.

- Vancouver B2/B3 fractures are ideally managed by long stem revision arthroplasty with or without osteosynthesis. Certain cases involving fractures with a cemented polished tapered implant with a largely intact cement–bone interface and potential for anatomic reduction may be amenable to osteosynthesis alone.
- Other options for Vancouver B3 fractures include allograft composite constructions and proximal femoral replacement. Proximal femoral replacement should be considered in more elderly and low demand patients.

Summary of answers

- Risk factors for periprosthetic fracture include: rheumatoid arthritis, osteoporosis, previous fragility fracture, or the use of uncemented stems.
- The Vancouver Classification System is reliable and valid for periprosthetic hip fractures.

- Treatment depends on Vancouver fracture types, and is dictated by the stability of the implant and the degree of bone loss.

Clinical scenario

- A 59-year-old female is one year out from revision of a left total hip arthroplasty (THA) due to recurrent dislocation.
- She is now nonambulatory due to pain and presents with a draining sinus on her hip.
- Radiographs reveal loosening of the acetabular cup.
- Further diagnostic workup showed an elevated C-reactive protein (CRP: 159 mg/L), erythrocyte sedimentation rate (ESR: 96 mm/h) and a positive aspiration fluid culture for *Enterococcus faecalis* (Figure 31.1).

Top three questions

1. In patients with suspected periprosthetic joint infection (PJI), are novel biomarkers such as alpha-defensin and leukocyte-esterase better screening tests for than ESR, CRP, and synovial fluid polymorphonuclear cells (PMNs)?
2. In patients with late PJI, do two-stage revisions have better rates of infection eradication than one-stage revisions?
3. In patients who have undergone two-stage revision, does an additional course of prophylactic oral antibiotics reduce the rates of reinfection compared to no additional antibiotics?

Question 1: In patients with suspected PJI, are novel biomarkers such as alpha-defensin and leukocyte-esterase better screening tests for than ESR, CRP, and synovial fluid PMNs?

Rationale

Current guidelines recommend a combination of blood tests (ESR, CRP) and synovial fluid analysis for workup of suspected PJI. Recent studies have shown promising results using synovial fluid biomarkers in the diagnosis of PJI.

Clinical comment

PJI affects 1–2% of patients after primary THA,[1],[2] and is responsible for 12.8% of revision THAs.[3] Current guidelines from the Musculoskeletal Infection Society (MSIS) and the International Consensus Group recommend obtaining serum ESR and CRP levels in the workup of all patients with suspected PJI.[4],[5] Despite their universally accepted use, neither test is completely reliable in diagnosing PJI. To improve the accuracy of this diagnosis, several synovial fluid biomarkers have been investigated and shown to outperform traditional tests in diagnosing PJI.[4],[6] Of these, alpha-defensin and leukocyte esterase (LE) have shown promising results.

Alpha-defensin is an antimicrobial peptide released by activated neutrophils that has the ability to adhere to and destroy the bacterial cellular membrane.[7] It is unique to neutrophils found in infected joints, and is not released by neutrophils in aseptic joint inflammations such as gout.[8] There are currently two commercially available methods for measuring alpha-defensin in synovial fluid. The enzyme-linked immunosorbent assay (ELISA)-based alpha-defensin immunoassay measures the fluorescent signal released by tagged antibodies binding to alpha-defensin antigen, and provides a quantitative readout within 24 hours. By contrast, the alpha-defensin lateral flow test is a paper-based platform that detects the presence or absence of alpha-defensin in three drops of a diluted aspirate placed on a test device, and provides a binary readout within 20 minutes.[9] Although these tests are easy to perform, they are much more costly than conventional tests.

LE is an enzyme secreted by activated neutrophils and is currently part of the minor diagnostic criteria of PJI according to MSIS and International Consensus Meeting

guidelines.[10],[11] Its presence in synovial fluid can be detected using colorimetric strip tests.[12] Blood-contaminated synovial fluid samples can interfere with interpretation of the colorimetric strip; however, the use of a centrifuge to separate synovial fluid from contaminant blood can help yield accurate results.[13] Advantages of the LE test include it being quick and easy to perform, as well as the low cost of the colorimetric strip.

Available literature and quality of the evidence

- Level II: 2 systematic review/meta-analyses of prospective cohort studies.[14],[15]
- Level III: 1 systematic review/meta-analysis of level II and III diagnostic studies.[9]
- 3 retrospective cohort studies.[16]–[18]

Findings

A recent systematic review and meta-analysis by Wyatt et al. evaluated the diagnostic accuracy of alpha-defensin (six studies) and LE (five studies) for PJI.[15] The pooled sensitivity and specificity of alpha-defensin were 1.00 (95% confidence interval [CI]: 0.82–1.00) and 0.96 (95% CI: 0.89–0.99), respectively. The pooled sensitivity and specificity of LE were 0.81 (95% CI: 0.49–0.95) and 0.97 (95% CI: 0.82–0.99), respectively. Diagnostic accuracy, as defined by the area under the receiver operating characteristic curve, was 0.99 (95% CI: 0.98–1.00) for alpha-defensin and 0.97 (95% CI: 0.95–0.98) for LE.

Emerging evidence suggests that the alpha-defensin lateral flow test may have lower diagnostic accuracy than its ELISA-based immunoassay counterpart. A 2018 systematic

review comprising 601 patients across seven studies showed the ELISA-based immunoassay to have superior overall diagnostic value compared with the lateral flow test (AUC, 0.98 vs 0.75) with higher sensitivity (96%, 95% CI: 90–98% vs 71%; 95% CI: 55–83%; p <0.001) but no difference in specificity (96%, 95% CI: 93–97% vs 90%; 95% CI: 81–5%; p = 0.060).[9]

A meta-analysis by Berbari et al. evaluated the diagnostic accuracy of serum biomarkers for PJI.[14] Data were pooled from 30 eligible studies. The pooled sensitivity and specificity of ESR were 75% (95% CI: 72–77%) and 70% (95% CI: 68–72%), respectively. The pooled sensitivity and specificity of CRP were 88% (95% CI: 86–90%) and 74% (95% CI: 71–76%), respectively. The diagnostic odds ratio was 7.2 (95%: CI 4.7–10.9; 25 studies) for ESR and 13.1 (95% CI: 7.9–21.7; 23 studies) for CRP.

Shahi et al. evaluated the diagnostic odds ratios (DORs) of five routine laboratory markers for PJI in 4662 revision THAs.[17] The DORs for PJI, from highest to lowest, were LE: 30.06 (95% CI: 17.8–50.7), synovial fluid white blood cell count: 29.4 (95% CI: 20.2–42.8), CRP: 25.6 (95% CI: 19.5–33.7), synovial fluid PMN percentage: 25.5 (95% CI: 17.5–37.0), and ESR: 14.6 (95% CI: 11.5–18.6). The authors concluded that among the minor diagnostic criteria, LE has the best performance.

Tarabichi et al. reviewed the records of 319 patients who had ESR and CRP screening prior to LE testing for diagnosis of PJI.[18] The authors reported that when LE is concordant with ESR and CRP levels it can effectively rule out or diagnose PJI with >95% certainty. When discordant, only stricter LE thresholds (2+ or negative) are adequate to suggest a change in clinical decision-making. In this context, intermediate LE values require further diagnostic testing.

Shahi et al. reported that prior antibiotic administration is associated with lower ESR and CRP values in comparison with no antibiotics, with difference of medians (DOM) of 15 mm/h ($p = 0.018$) and 58 mg/L ($p = 0.038$), respectively, which may lead to increased risk of false negative tests.[16] The same group later reported that alpha defensin levels did not vary significantly with antibiotic administration (DOM 0.68; 95% CI: −0.98–1.26; $p = 0.451$).[19] Alpha defensin was also found to have higher sensitivity (100%; 95% CI: 88.4–100.0%) in diagnosing PJI than ESR (69.0%; 95% CI: 49.17–84.72%; $p = 0.001$) and CRP (79.3%; 95% CI: 60.3–92.0%; $p = 0.009$).

Resolution of clinical scenario

Preliminary studies have shown alpha defensin to be highly sensitive and specific in diagnosing PJI, with superior performance compared to ESR and CRP. Results also appear to remain unaffected by prior antibiotic administration. However, the high cost of the test remains a barrier to its routine use.

The LE strip test is inexpensive and has also shown superior performance in comparison to routine serum biomarkers such as ESR and CRP. Results are most promising when used in conjunction with ESR and CRP.

The 2018 International Consensus Meeting on Musculoskeletal Infection supported the use of the alpha-defensin lateral flow test and the LE test strip in the diagnosis of PJI.[20]

Question 2: In patients with late PJI, do two-stage revisions have better rates of infection eradication than one-stage revisions?

Rationale

Two-stage revision is widely accepted as the standard of care in North America for treating late chronic PJI, while one-stage revision remains a frequent option among European surgeons.

Clinical comment

The goal of any revision for PJI is eradication of infection. This is accomplished through extensive irrigation, debridement, and removal of all implants, cement, and any foreign material present at the time of revision. Reimplantation of a new permanent prosthesis can either be delayed after a course of systemic antibiotics (two-stage) or performed during the same irrigation and debridement procedure (one-stage).

The two-stage approach has long been accepted as the standard of care for management of chronic PJI, and it is considered the only safe method for treating chronic infection when the organism and/or its sensitivities are unknown. Between the first and second stage, the patient requires an extended period of systemic antibiotic therapy in addition to the locally eluted antibiotics from the antibiotic-loaded cement spacer.[21] It has been associated with high morbidity and mortality, pain and disability in the interim period, and sometimes, persistent functional deficit after the final reimplantation procedure.[22–25]

There is increasing interest in the one-stage revision as it may be associated with better functional outcomes and lower overall healthcare costs.[25–27] Cemented components are generally preferred to ensure high levels of local antibiotic elution,[28,29] though reports using a noncemented technique exist.[30,31] Identification of the infecting organism and its antibiotic sensitivity through synovial fluid culture is mandatory in order to establish a targeted antibiotic regimen.[32]

Available literature and quality of the evidence

- Level III: 1 systematic review of retrospective cohort studies.[33]
- Level IV: 2 systematic review/meta-analyses of case series and retrospective cohort studies.[34,35]

Findings

In a systematic review of nine retrospective cohort studies, Leonard et al. did not find a statistically significant difference in infection-free survival between single- and two-stage revisions.[33] Although overall rates of reinfection had a higher trend for one-stage (16.8%) than two-stage (10.6%) revisions, there was also a trend toward better functional outcome in one-stage revision.[36]

In a meta-analysis of 38 one-stage (2536 patients) and 60 two-stage (3288 patients) studies, Kunutsor et al. found similar reinfection rates for the two approaches: 8.2% (95% CI: 6.0–10.8) and 7.9% (95% CI: 6.2–9.7), respectively.[34] Lange et al., in a meta-analysis of 36 noncomparative studies, also found similar reinfection rates between one- and two-stage revisions: 13.1% (95% CI: 10.0–17.1%) and 10.4% (95% CI: 8.5–12.7%), respectively.[35]

Resolution of clinical scenario

The current available evidence fails to demonstrate a significant difference in reinfection rates between the two-stage revision arthroplasty and one-stage exchange arthroplasty for PJI.

The 2018 International Consensus Meeting on Musculoskeletal Infection suggested that one-stage exchange arthroplasty remained a viable option for the management of chronic PJIs. One-stage exchange arthroplasty is contraindicated in patients with signs of systemic sepsis, extensive comorbidities, infection with resistant organisms, culture-negative infections, and poor soft tissue coverage.[37]

Question 3: In patients who have undergone two-stage revision, does an additional course of prophylactic oral antibiotics reduce the rates of reinfection compared to no additional antibiotics?

Rationale

There is a lack of consensus regarding the use of additional prophylactic oral antibiotic therapy following two-stage revision in preventing reinfection.

Clinical comment

Reinfection after two-stage revision for PJI is a devastating complication with reported incidences ranging from 3.2–13%.[38],[39] Treatment of reinfection poses large physical, economic, and emotional burdens on the patient, and is

frequently associated with significant morbidity and poor functional outcomes.

Second-stage reimplantation takes place when the treating medical team feels that the infection is under control. There is currently no consensus regarding the optimal timing for reimplantation. Some authors have suggested reimplantation if the incision has healed and ESR/CRP levels continue to decline following a two-week antibiotic holiday.[21] Intraoperative frozen sections are useful to confirm the eradication of infection,[40] but are not routinely performed at all centers. Despite this, reinfection may occur due to residual bacteria or seeding of the joint at the time of reimplantation. In addition, multiple prior operations on the joint may render patients more susceptible to an early new infection. Administration of oral antibiotics tailored to the original infecting organism(s) after second-stage reimplantation has been proposed as a potential strategy to decrease the rate of reinfection.

Available literature and quality of the evidence

- Level I: 1 randomized controlled trial.[41]
- Level III: 2 retrospective cohort studies.[38],[42]

Findings

At a minimum follow-up of 12 months, Zywiel et al. reported one (4%) reinfection in 28 TKA re-implantations receiving a minimum 28-day course of prophylactic oral antibiotics compared to six (16%) reinfections in 38 patients who did not receive postoperative oral antibiotics.[42] This difference was not statistically significant. On a similar note, Johnson et al. reported no reinfections in 23 THA re-implantations receiving a minimum 14-day course of prophylactic oral antibiotics

compared to six (13.6%; p = 0.087) reinfections in 44 patients who did not receive postoperative oral antibiotics.[38]

Frank et al. reported interim analysis of an ongoing multicenter randomized trial comparing reinfection rates in 59 second-stage hip or knee arthroplasties randomized to receive three months of oral antibiotics post reimplantation versus 48 randomized to receive only routine perioperative antibiotics.[41] At a mean follow-up of 14 months in the antibiotic group and 10 months in the control group, the authors reported a significantly lower reinfection rate in the antibiotic group (3/59; 5% vs 9/49; 19%; hazard ratio, 4.37; 95% CI: 1.297–19.748; p = 0.016).

Resolution of clinical scenario

Preliminary studies with short-term follow-up suggest that prophylactic oral antibiotic therapy after second-stage reimplantation may improve infection-free survival. Further studies with longer-term follow-up are required.

Summary of answers

- Alpha-defensin is a highly sensitive and specific test for diagnosing PJI, with superior performance compared to ESR and CRP. It may be particularly useful in patients with suspected PJI who have been receiving antibiotics prior to workup. Evidence suggests that the lateral flow test has a lower diagnostic accuracy than the ELISA-based immunoassay.
- The LE strip test is inexpensive and has also shown superior performance in comparison to routine serum biomarkers such as ESR and CRP. Results are most promising when used in conjunction with ESR and CRP.

- Although the available evidence fails to demonstrate a significant difference in reinfection rate between two-stage and one-stage revision for PJI, this finding should be treated with caution, as there's a lack of high-quality evidence.
- At short-term follow-up, prophylactic oral antibiotic therapy after second-stage reimplantation may improve infection-free survival.

32 The Painful Total Hip Arthroplasty

Asif A. H. Parkar MBBS[1], Ahmed El-Bakoury MBBS PhD[2], and James N. Powell MD[3]

[1] Queen's Hospital, National Health Service, London, UK

[2] University Hospitals Plymouth NHS Trust, Plymouth, UK

[3] Division of Orthopaedic Surgery, Department of Surgery, University of Calgary, Calgary, AB, Canada

Clinical scenario

- A 70-year-old patient with a total hip arthroplasty (THA) performed eight years ago presents with pain in his hip for the last four months.
- He had unremarkable postoperative recovery and was asymptomatic for the last eight years. He has no significant medical comorbidities.

Table 32.1 Causes of painful THA.

Intrinsic	Extrinsic
Intracapsular Infection Aseptic loosening Osteolysis Instability Impingement Polyethylene debris Trunnionosis/ALTR Metal hypersensitivity Crystalline arthropathy	**Local** Hernia – inguinal, abdominal Hernia – vastus lateralis Hernia – fascia lata Tumor Genito-urinary tract
Extracapsular Iliopsoas tendonitis Trochanteric bursitis Heterotopic ossification Periprosthetic fracture Complex regional pain syndrome	**Remote** Spinal pathology Neuropathy Nerve entrapment Vascular claudication Complex regional pain syndrome

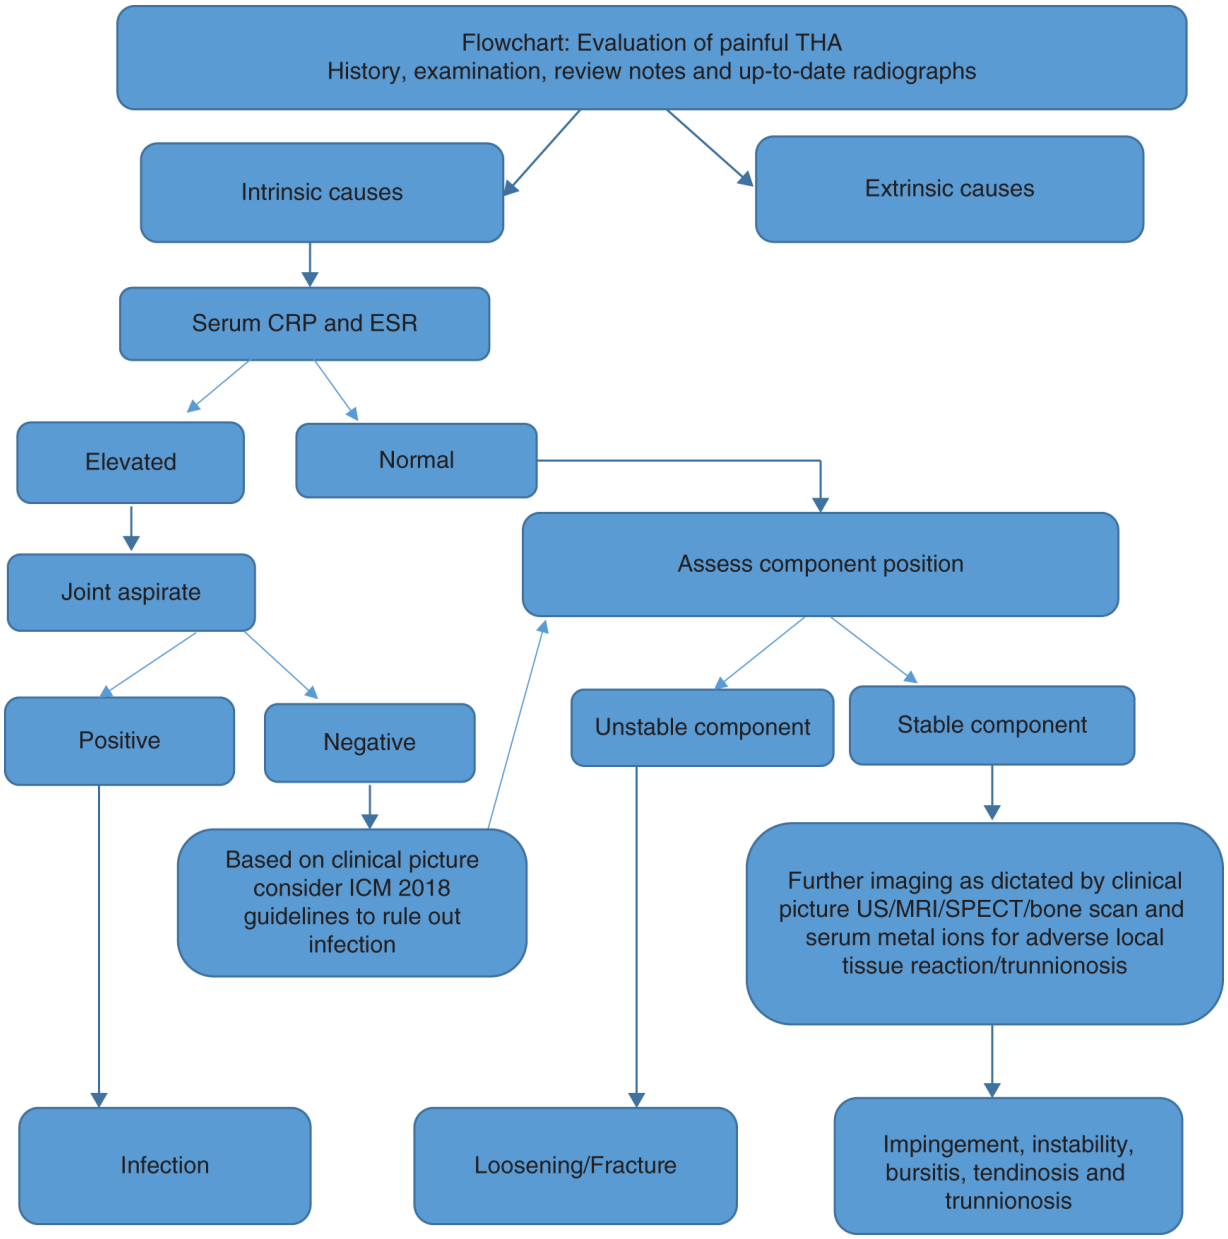

Figure 32.1 Approach to painful THA.

Introduction

Although majority of the patients with THA have a high satisfaction rate, between 7 and 23% of the patients report some dissatisfaction following THA.[1] The aim of this chapter is to provide a systematic evidence-based approach to the evaluation of a painful THA.

Top three questions

1. In patients presenting with a painful THA, what are the key features on history, clinical examination, and investigation, compared to others, that are pertinent to formulating the diagnosis?
2. In patients presenting with a painful THA, which diagnostic tools, compared to others, are most evidence-based to diagnose periprosthetic joint infection (PJI)?
3. In patients presenting with a painful metal-on-polyethylene (MoP) THA, what is the role of metal ion levels, compared to other diagnostic tools, in diagnosing trunnionosis?

Question 1: In patients presenting with a painful THA, what are the key features on history, clinical examination, and investigation, compared to others, that are pertinent to formulating the diagnosis?

Pain following THA is multifactorial. The causes of a painful THA are listed in Table 32.1.[2,3] It is critical to establish the accurate diagnosis with history, clinical examination, and relevant investigations to provide most appropriate nonoperative or operative management.

History

Identifying the precise location of pain is paramount. Groin pain may indicate acetabular pathology and thigh pain

exacerbated by activity may suggest loosening of implant. Buttock pain can be from hip or spinal pathology. Start-up pain may suggest loosening. Local findings such as swelling around the hip may indicate infection or may be due to a pseudotumor. Rest pain warrants investigations for infection or malignancy. It is imperative to question the patient about duration of pain and postoperative recovery after the arthroplasty particularly wound complications and infections.[3]

Clinical examination

Clinical examination should include gait analysis, Trendelenburg sign secondary to abductor muscle weakness; limb length discrepancy; and hip, knee, and spine examination. Progressive shortening of the limb suggests subsidence of femoral component. Active and passive range of movement of the hip with signs of apprehension in extreme positions must be assessed as this may suggest instability. Pain in resisted hip flexion suggests iliopsoas pathology. The hip should be examined for anterior and posterior impingement. This is particularly important in hip resurfacing patients due to a decreased head : neck ratio. Finally, neurovascular examination of the lower limb should be performed and compared with the opposite side.

ALTR: adverse local tissue reaction

Imaging

Plain radiographs play the primary role in the initial evaluation of painful THA and provide baseline imaging for subsequent surveillance. Due to its lower rates of sensitivity and specificity, higher modalities of imaging are often needed to confirm the diagnosis.[4] Hargunani et al. in 2016 have published the role of various imaging modalities

with the pros and cons of each in the evaluation of painful THA.[4] The clinician is often in a position to formulate provisional diagnosis and choose further investigations after clinical assessment and appropriate imaging, plain radiographs being essential. Figure 32.1 demonstrates a systematic and evidence-based method of approaching the most accurate diagnosis during evaluation of painful THA.

US: ultrasound; MRI: magnetic resonance imaging; SPECT CT: single-photon emission computerized tomography?

Question 2: In patients presenting with a painful THA, which diagnostic tools, compared to others, are most evidence-based to diagnose periprosthetic joint infection (PJI)?

Rationale

The Musculoskeletal Infection Society (MSIS) criteria were introduced in 2011 for the diagnosis of PJI of THA and total knee arthroplasty (TKA).[5] This was a revolutionary step in diagnosis and management of PJI with confidence and standardization. These criteria were further modified at the International Consensus Meeting (ICM) in 2013.[6] Since then, further new tests and evidence have evolved, hence the need to update the diagnostic criteria for PJI.

Clinical comment

There is no single test to diagnose PJI with accuracy. This is done by a combination of clinical findings, laboratory results both from peripheral blood and synovial fluid, identification of microorganism, histological evaluation of local tissue, and intraoperative findings.[7]

Available literature and quality of the evidence

- Level II (1 study) and level IV (multiple studies).

Saleh et al. in 2018 have reviewed the evidence looking at serum biomarkers for the diagnosis of PJI.[8] They found that currently C-reactive protein (CRP) and erythrocyte sedimentation rate (ESR) remain the most commonly used biomarkers as other tests have not shown superior sensitivity as first line screening tests for PJI. They have acknowledged increasing interest in the development of newer biomarkers from both serum and synovial fluid and the potential of using genomic and proteomics through messenger RNA in future for diagnosis of PJI.

The MSIS has published characteristics of 43 synovial fluid biomarkers for diagnosis of PJI in a level II study.[9] Out of these 43 they evaluated 16 synovial biomarkers which demonstrated the most consistent results. They reported that out of these 16 synovial biomarkers, five markers – namely human alpha defensin (a-defensin), elastase 2 (ELA-2), bactericidal/permeability-increasing protein (BPI), neutrophil gelatinase-associated lipocalin (NGAL), and lactoferrin – had sensitivity of 100% confidence interval (CI) (88–100%) and a specificity of 100% with 95% CI (94–100%).

Lee et al. published a systematic review and meta-analysis on synovial fluid biomarkers for the diagnosis of PJI.[10] They evaluated 13 synovial biomarkers with high sensitivity to diagnose PJI and reported the superiority of a-defensin over other biomarkers.

- Level: II diagnostic study.

Based on most recent literature and new tests, ICM 2018 proposed and validated new criteria for diagnosis of PJI, as

shown in Table 32.2.[11]

Findings

These criteria to diagnose PJI of the hip and knee were developed after retrospective review of medical records of all the patients undergoing revision THA and TKA at three academic centers between 2001 and 2016. Patients who did not have serum CRP, serum ESR, and/or joint aspiration were excluded. Patients were considered to have PJI if they met the major diagnostic criteria of MSIS and previous ICM.[5,6] Patients who developed PJI within three months from index arthroplasty procedure were defined as acute PJI and were excluded. These criteria were based on current guidelines from the American Academy of Orthopaedic Surgeons (AAOS) and were validated by an external body to avoid the bias.

As per these new criteria listed in the Table 32.2, PJI is diagnosed if at least one of the two major criteria were positive. Major criteria include either two positive cultures of the same organism or sinus tract communicating to the joint or visualization of the prosthesis. In the absence of major criteria, minor criteria based on preoperative diagnosis were evaluated. Minor criteria include elevated levels of serum CRP, D-dimer, ESR, and elevated levels of synovial white blood cells (WBCs), leukocyte esterase (LE), polymorphonuclear (PMN) percentage, CRP, and positive a-defensin. A score of more than six is considered to be positive for PJI. Cases in which the pre-operative score was between two and five were further evaluated for intraoperative variables which include positive histology, positive purulence, and single positive culture with incorporation of pre-operative score. Intraoperative score of more than six was considered positive for PJI.

Table 32.2 Showing new scoring-based criteria from ICM 2018 for diagnosis of PJI.

Major criteria (at least one of the following)			**Decision**
Two positive culture of the same organism			Infected
Sinus tract with evidence of communication to the joint or visualization of the prosthesis			
Preoperative diagnosis			
	Minor criteria	**Score**	**Decision**
Serum	Elevated CRP or D-Dimer	2	≥6 Infected 2–5 possibly infected[a] 0–1 not infected
	Elevated ESR	1	
Synovial	Elevated WBC count or LE	3	
	Positive a-defensin	3	
	Elevated synovial PMN	2	
	Elevated synovial CRP	1	
Intraoperative diagnosis			
Inconclusive preop score or dry tap	**Score**		**Decision**
Preoperative score	—		≥6 Infected 4–5 Inconclusive[b] ≤3 not infected
Positive histology	3		

Positive purulence	3	
Single positive culture	2	

[a] For patients with inconclusive minor criteria, operative criteria can also be used to fulfill definition for PJI.

[b] Consider further molecular diagnostics.

They have advocated to proceed with caution in ALTR, crystal deposition disease, and slow-growing organisms.

The sensitivity for diagnosis of PJI as per the MSIS criteria was reported to be 79.3% with 95% CI (73.–84.4%). This further improved with ICM 2013 criteria as they reported sensitivity of 86.9% with 95% CI (81.8–91.1%). The sensitivity and specificity for the diagnosis of PJI with 2018 criteria was 97.7% with CI 95% (94.7–99.3%) and 99.5% with 95% CI (97.3–99.99%), respectively. This is the first validated evidence-based scoring system for the diagnosis of PJI and has higher level of sensitivity compared to previous scores.[7] The proposed threshold for both serum and synovial markers is shown in Table 32.3.

Table 32.3 Proposed threshold for serum and synovial markers.

Marker	Chronic (>90 days)	Acute (<90 days)
Serum CRP (mg/dL)	1.0	10
Serum D-dimer (ng/mL)	860	860[a]
Serum ESR (mm/h)	30	—
Synovial WBC count (cells/μL)	3000	10 000
Synovial PMN (%)	80	90
Synovial CRP (mg/L)	6.9[a]	6.9
Synovial a-defensin (signal-to-cutoff ratio)	1.0	1.0

[a] Further studies are needed to validate a specific threshold.

Resolution of clinical scenario

- Patient presented with painful THA. History, clinical examination, and plain radiographs did not show any signs of mechanical failure or aseptic loosening.
- The next step was to carry out workup for infection. Accurate diagnosis of PJI is challenging. The patient was investigated as per the new criteria by ICM 2018.
- Patient's score was more than six and the diagnosis of PJI was confirmed.
- This enabled the clinician to undertake appropriate revision arthroplasty.

Question 3: In patients presenting with a painful metal-on-polyethylene (MoP) THA, what is the role of metal ion levels, compared to other diagnostic tools, in diagnosing trunnionosis?

Rationale

Trunnionosis, also known as *taper corrosion*, is one of the complications of modular femoral stems. This term has been widely used in the arthroplasty literature to describe corrosion reaction at the Morse taper of various bearing surfaces. Serum ion levels for trunnionosis in metal-on-metal (MoM) articulation has been investigated extensively in the past. Literature in recent years has shown rising awareness about trunnionosis and role of blood ion levels in MoP articulation due to increasing incidence of trunnionosis-related implant failure.[12] Taper corrosion disrupts the protective oxide layer on the taper. This process is also known as *mechanically assisted crevice corrosion* (MACC). MACC can potentially produce metal ions which can migrate locally causing ALTR or systemically causing systemic metal ion toxicity features.[13] It is estimated that up to 2% of all THA patients might be affected by trunnionosis.[12]

Clinical comments

There are no specific clinical signs to diagnose trunnionosis. This has been reported to present as early as nine months from index procedure.[14] The signs of osteolysis on plain radiographs can be very subtle and variable.

Available literature and quality of the evidence

- Level: III (1 study) and level IV (multiple studies).

Findings

Hussey et al. have published a level III study on MACC in 1352 consecutive patients with MoP THA from a single manufacturer.[15] The inclusion criteria were unexplained pain or osteolysis of >1 cm. They diagnosed trunnionosis based on three criteria:

- Two or more serum metal ion levels showing cobalt (Co) values more than 1.0 parts per billion (ppb) or single test showing Co >1.6 ppb in patients with no other co-exposure.
- Single serum metal ion level showing Co >1.0 ppb in conjunction with metal artifact reduction sequence (MARS) magnetic resonance imaging (MRI) positive for complex fluid collection, pseudotumor, or tissue necrosis.
- Intraoperative findings of ALTR and corrosion at head–neck junction.

They reported 3.2% prevalence of MACC in their study. They also observed that the Zimmer M/L taper stem had higher prevalence 4.9% compared to other stems from the same manufacturer.

Sultan et al. published a systematic review on trunnionosis in MoP THA.[12] They identified following risk factors for trunnionosis.

- Large metal femoral head (36 mm and above).
- More common with metal (Co-Cr) heads compared to ceramic heads.

- Short taper with smaller diameter.
- Stems with stiffer alloys (Co-Cr compared to titanium).
- High body mass index (BMI) and higher functional level of activity.

They have reviewed studies looking at serum metal ion levels in painful MoP THA and have emphasized the disproportionate elevation of serum Co ions versus serum Cr ions. Cooper et al. in 2013 have reported 10 times higher levels of Co vs Cr,[16] while Plummer et al. in 2016 reported five times higher levels of Co vs Cr during their work up for trunnionosis in patients with MoP hips.[17] In the same study Plummer et al. also demonstrated that Co levels of more than 1 ppb was associated with ALTR.

It can be difficult to differentiate between corrosion and PJI as both can have equivocal presentation. In case of nonspecific rise in inflammatory markers, joint aspiration should be carried out. It is reported that automated machines can have false elevation of WBCs in trunnionosis, hence it is recommended to perform manual cell count on the aspirate to avoid false positive results.

Resolution of clinical scenario

- Patient presented with a new onset of unexplained hip pain with a previously well-performing MoP THA.
- History, clinical examination, plain radiographs, serum ESR, CRP, and joint aspiration were inconclusive.
- Patient had serum Co and Cr ions tested which showed disproportionate elevation of Co over Cr. MARS MRI confirmed ALTR and patient had revision arthroplasty.

Summary of answers

- Evaluation of painful THA is challenging. It needs a evidence based systematic approach which helps to narrow down the differential diagnosis and choose appropriate investigations.
- Criteria to diagnose PJI have been evolving with time. ICM 2018 presented the most recent criteria with excellent sensitivity and specificity. These should be considered in clinical practice to evaluate PJI.
- Incidence of trunnionosis is rising. Recent literature has pointed out risk factors for MACC. Unexplained painful MoP THA where infection, aseptic loosening, and iliopsoas tendonitis have been ruled out, warrants trunnionosis work up with serum metal ions.

33 Revision of the Femoral Component

Lisa C. Howard MD, Bas A. Masri MD, Don S. Garbuz MD, and Clive P. Duncan MD
Department of Orthopaedics, University of British Columbia, Vancouver, BC, Canada

Clinical scenario

- A 55-year-old man with a history of a total hip arthroplasty (THA) 15 years ago presents with a 12-month history of left groin pain and progressively declining function.
- Imaging shows extensive bone loss of his proximal femur with subsidence of his femoral stem.

Top three questions

1. In patients undergoing revision arthroplasty with impaction grafting and segmental replacement, what are the technical aspects of impaction, compared to routine technique, that improve clinical outcome?
2. In patients who are undergoing revision THA, how does impaction allografting for femoral revision, compared to no impaction allografting, perform in terms of outcomes?
3. In patients who are undergoing revision THA, how does proximal femoral segmental allografting, compared to other treatments, perform in terms of clinical outcomes?

Question 1: In patients undergoing revision arthroplasty with impaction grafting and segmental replacement, what are the technical aspects of impaction, compared to routine technique, that improve clinical outcome?

Rationale

Impaction and proximal segmental femoral allografting are options for revision arthroplasty in the setting of significant bone loss, thus understanding the technical aspects of these procedures is critical to optimize functional outcome.

Available literature and quality of the evidence

The majority of the available evidence is level IV[1–5] with two level III studies.[6,7] Expert opinion (level V) was also frequently found.

Clinical comment

Impaction and proximal segmental femoral allografting are both technically challenging procedures that should be performed by experienced surgeons. It is critical that the surgeon understand both the technical and the potential intraoperative pitfalls such that the outcome can be maximized while complications and patient morbidity are minimized.

Findings

Impaction allografting

The principle of impaction grafting is to restore cavitary meta-diaphyseal bone loss with morselized allograft to support a cemented stem (Figures 33.1 and 33.2). Poor-quality cement mantle (≤2 mm) appears to influence migration of the femoral stem.[6] The greatest migration, typically into varus and retroversion, occurs in the first three months and is attributed to further graft compaction and a poor cement mantle,[6,8] which is often due to poor instrumentation.[2,3,6] Furthermore, cement mantle defects may cause progressive migration during creeping substitution.[2] Masterson et al. in their study of multiple stem techniques documented concerns with the quality of the cement mantle due to inadequate instrumentation.[9] The Exeter system lead to absence of cement in 50% of Gruen zones, which was attributed to the trial impactors being shorter and more sharply tapered, which created an inadequate cavity. The CPT and Harris Precoat systems led to an absence of 21 and 18%, respectively. In a later study, design improvements in a commercially available system utilized with Exeter stems allowed an improvement of 23.4% of Gruen zones absent of cement.[10]

Vigorous pressurization of the cement can lead to its contact with the endosteal bone, which improves overall stability of the construct, but also potentially impacts revascularization and remodeling.[11] Adequate size of the graft particles to achieve interfragmentary stability[12] and quality of graft impaction are also important to prevent subsidence and poor outcome.[4,6] Ultimately, a combination of construct stability and graft incorporation and remodeling must be obtained. When an extended trochanteric osteotomy (ETO) is performed, the ETO is closed first prior to impaction. With older designs, a cortical only strut allograft was used to reinforce the

osteotomy. However, with the advent of long stems for impaction allografting this is no longer necessary.[7]

Tight allograft packing is critical, which may lead to intraoperative fractures. Adequate exposure, prophylactic cerclage wire or cable fixation, and avoidance of bending stresses and torque within the femur at the time of impaction are important.[7] In addition, bone defects can be reinforced with specialized wire mesh or with cortical only allograft struts (Figure 33.1). A variety of instrument systems have been introduced to help standardize the impaction technique and assess stability.[13] Longer stems with or without additional fixation may be required for added stability and should bypass weakened regions by two cortical diameters.[7]

Figure 33.1 Intraoperative photographing showing a revision THA with impaction allografting along with a cortical strut graft and mesh for a proximal femoral defect.

Figure 33.2 Postoperative AP radiograph of the proximal femur showing the revision of a failed THA with impaction allografting and a cortical strut graft for a proximal femoral defect.

Proximal femoral allografting

The surgical technique for proximal segmental femoral allografts is demanding and is typically reserved for selected cases of Paprosky type IIIB and IV defects. Possible surgical approaches that may be used include either a trochanteric slide,[14] which may reduce trochanteric migration, or a trochanteric splitting osteotomy.[15] The length of the allograft required depends on the degree of bone loss, stability, and leg length assessment which is determined from preoperative templating and intraoperative assessment. Soft tissue should be preserved as much as possible and every effort should be made to preserve the greater trochanter.

Allograft bone is biologically inactive and cannot grow into cementless implants; therefore, the prosthesis should be cemented into the allograft.[5,16] The distal aspect of the stem can be cemented or uncemented; however, care should be taken to ensure that no cement remains at the host bone/allograft junction. Additionally, autogenous reamings from the acetabulum, or from the resected proximal femoral bone, can be utilized along the allograft–host junction to facilitate union. The canal of the allograft should not be over-reamed so as to preserve its strength. If the host canal is larger, as is often the case, a telescoping method can be used,[17] during which the smaller allograft segment is *telescoped* into the large and vacuous distal host femur. The addition of a step cut or oblique cut with cable reinforcement, plate fixation, strut allografts, and distal press fit stems aim to improve the stability of the

construct to promote union.[16] However, if plate fixation is chosen, the portion lying on the allograft should not be fixed with screws, but instead by cables, so as to avoid fatigue fractures. Proximal femur remnants, with their intact soft tissue attachments can then be wrapped around the construct to provide improved soft tissue attachments (Figure 33.3), and to provide a vascularized graft around the allograft–host junction.

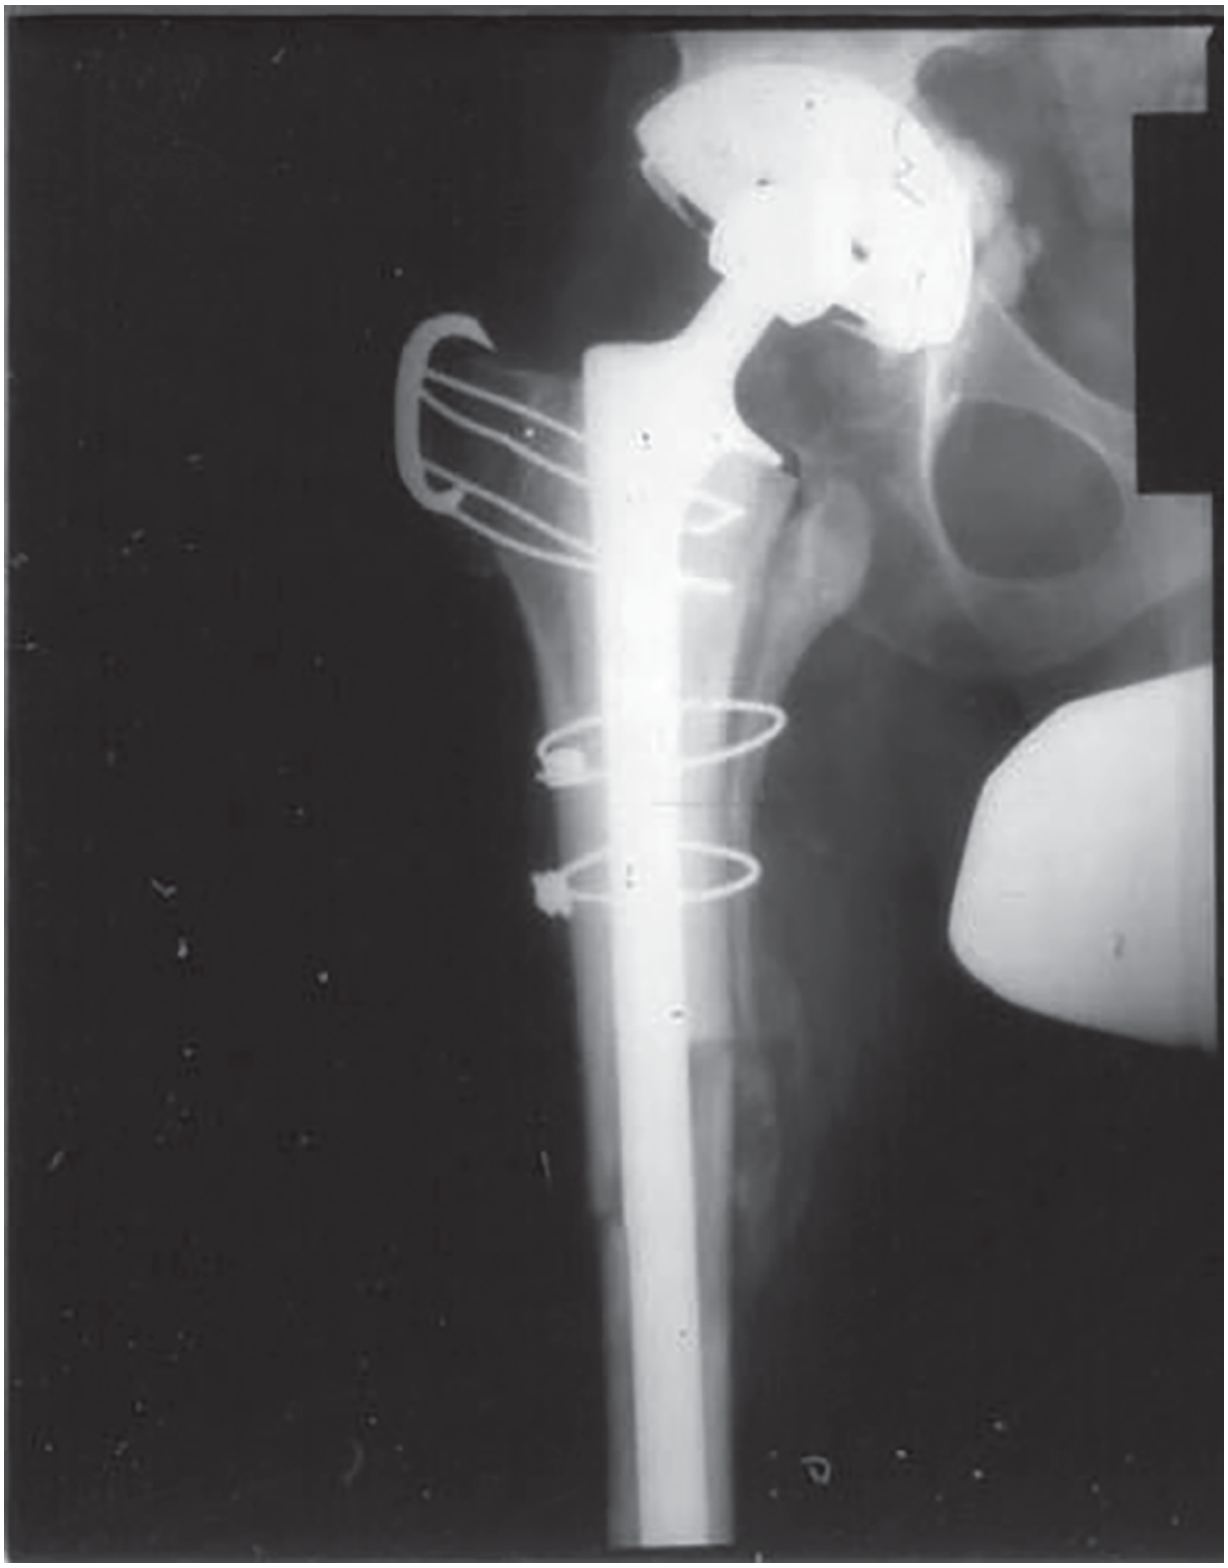

Figure 33.3 Postoperative AP radiograph of the proximal femur showing a long-stemmed implant cemented into a proximal femoral allograft. Note the step-cut junction to enhance junction stability.

Resolution of clinical scenario

- Impaction and proximal femoral bulk allografting are technically demanding techniques that should only be performed by experienced surgeons in experienced centers.
- Preoperative planning for both techniques is important.
- Proper allograft impaction and cement technique are critical for success in impaction allografting.
- All cement should be removed at the host–implant interface in proximal femoral allografting.
- Preservation of the soft tissues and stability of the construct for both techniques are important for long-term success.

Question 2: In patients who are undergoing revision THA, how does impaction allografting for femoral revision, compared to no impaction allografting, perform in terms of outcomes?

Rationale

Impaction allografting is a viable option in revision THA. Knowledge of the clinical outcomes of this technique is

important in deciding whether it is a suitable option for femoral revision.

Clinical comment

Impaction allografting is a technically demanding procedure that can be associated with several complications that may influence outcomes. As such, an evidence-based review of outcomes is important for patient-centered care.

Available literature and quality of the evidence

There are several level II[18–20] studies, while the majority is classified as level III/IV.[4,21–37]

Findings

The results of impaction allografting for femoral revision are generally encouraging. Gie et al. revised 58 hips with minimal bone loss and found that the average clinical scores for pain function, and mobility had improved at the final follow-up.[21] Patients reporting minimal to no pain in some studies is reported as >80%.[4,22,23] Other studies have used the Harris Hip Score and have reported an average value of 78 to 90 depending on the study.[4,23–26] Overall survivorship is reported between 77.4 and 100% up to 19 years,[1,18,19,25–30,37] while survivorship for aseptic loosening is reported as 98–99% up to 19 years.[1,28,30,37]

Subsidence and fracture are the two most commonly reported complications. Most studies show <5 mm subsidence in the majority of revisions; however, subsidence of >5 mm has been reported in as high as 38% in some studies.[4,23,31–34] It has been shown that greater preoperative bone loss corresponds with higher subsidence,[33,34] as does poor cementation and impaction.

Masterson compared noncemented versus cemented stems and found migration to be 4.4 and 1.85 mm, respectively, after the first year.[35] The current evidence, however, has failed to show the clinical significant of implant finish and subsidence.[1] Collared stem use has been described;[19],[25] however, it is suggested that highly polished, collarless double-tapered stems are the most appropriate implants to use given their propensity for controlled subsidence and physiological loading of the allograft envelope and surrounding host bone.[38] Reconstitution of the medial calcar with bone graft, mesh, or augmentation with cortical allograft appears to be important in reducing subsidence.[27],[30]

The prevalence of periprosthetic fractures ranges from 5 to 24% depending on the study source.[220_22],[25],[27],[29],[30],[36],[37] Intraoperative fractures tend to occur during impaction of the allograft which can be partially avoided by adequate exposure, prophylactic cerclage fixation and augmentation of the femoral shaft with cortical strut grafts.[22],[36] Removal of cement is also a risk for cortical perforation and is reported to occur in 10% of cases.[20] Furthermore, Ornstein et al. in their registry study reported that 6% of their patients sustained a postoperative diaphyseal fracture,[20] which is thought to be due to unrecognized intraoperative fractures or weakened areas of osteolysis. Infection rate was recorded as 2.7% in a prospective registry study,[20] while a large retrospective cohort study documented 3.9%.[37] Ornstein et al. in the largest retrospective cohort study documented a combined infection and periprosthetic fracture rate of 47% but did not report infection separately.[1]

Resolution of clinical scenario

- Outcomes for femoral impaction grafting are varying but satisfactory when the proper technique is utilized.
- Subsidence and periprosthetic fracture are common complications which negatively affect outcomes.
- Implant stability is important and adjuncts may be required.

Question 3: In patients who are undergoing revision THA, how does proximal femoral segmental allografting, compared to other treatments, perform in terms of clinical outcomes?

Rationale

Proximal femoral bulk allografting is also an option in revision THA with extensive meta-diaphyseal bone loss. Understanding the clinical outcomes is important to understanding its role in revision arthroplasty.

Clinical comment

Proximal femoral allografting is a viable option in cases of extensive bone loss, with an incompetent and nonsupporting diaphysis. It is technically demanding and associated with several complications of which surgeon should be aware. Decision-making for this technique using evidence-based outcomes is important for patient-centered care.

Available literature and quality of the evidence

The available literature consists of level III/IV[16,39–46] studies as well as a meta-analysis.[47]

Findings

Generally, the reports of success with proximal femoral replacement is considered satisfactory. Haddad et al. reported a Harris Hip Score of 79 and report a high level of satisfaction.[39,40] Rogers et al. in their meta-analysis of 16 studies and 498 patients quoted an overall success rate of 66–95% (average 80%) with no significant heterogeneity for the fixed and random effects model. Ilyas et al. reported on the use of freeze-dried allografts and reported the five-year survival at 87%.[41] Roos et al. reported 90% success in 20 patients in 4–20 years' follow-up.[42] Furthermore, Blackley et al. reported survivorship as 90% at five years and 86% at 10 years.[43] Survivorship is significantly affected by the degree of preoperative bone loss and length of graft used.[48]

The technique is not without its complications which commonly include infection, nonunion, dislocation, and fracture. As per Rogers et al., the pooled infection rate with the fixed and random effects model was 8% (95% confidence interval [CI]: 0.06–0.11).[47] Infection is thought to be a result of the length of procedure, soft tissue dissection, and contamination of the graft.[44,49,50] Failures due to fracture or aseptic loosening were pooled at 15%. However, there was some associated heterogeneity. They were not able to perform a meta-analysis of the nonunion rate due to a significant heterogeneity of data but provided a range of 1–25%.[47] Cementation into the distal portion has been suggested as a cause for nonunion.[51] Four of the studies included in the meta-analysis contained two of the highest nonunion values (18 and 25%) while one was not reported. Dislocation was reported as 12.8% (range 0–54%)

and again had significant data heterogeneity. Trochanteric nonunion or migration is reported as 7–77% with a mean of 25.25%. The lack of a strict definition of nonunion precluded a detailed analysis. Furthermore, the clinical implication of trochanteric nonunion is largely unknown.[45]

Graft resorption has also been a documented concern with incidences ranging from 3 to 58% in the reported literature.[43,46,49,51–54] The significance of this, however, is unclear. Several large-scale studies reported significant allograft resorption of 20 to 33%; however, none required revision.[39,40,43]

Resolution of clinical scenario

- Complications are common and generally include infection, nonunion, dislocation, and fracture.
- Length of graft and preoperative bone loss are predictive of outcome.
- The stem should be cemented into the allograft and construct stability at the allograft–host junction must be achieved to promote union.

Summary of answers

- Impaction grafting and allograft composite grafting are technically demanding procedures that should only be done by experienced surgeons. Proper preoperative planning is required.
- Due to the success of modular and nonmodular titanium diaphyseal fit stems, they are performed less frequently but still have a role in revisions with extensive bone loss that will not support a diaphyseal stem.

- Impaction grafting and proximal allograft grafting have encouraging results when done properly; however, they are subject to a wide variety of complications that can significantly affect outcome. Patient selection is important to optimize outcome.
- These techniques are now rarely used, and they are of historical interest. Nevertheless, on rare occasions, they may be useful and should remain as options for the rare case that cannot be addressed using modern fluted tapered stems.

34 Revision of the Acetabular Component

Nikolaos Davarinos MD MSc[1], Adam Hart MDCM MASc[2], and John Antoniou MD PhD[2]
[1] Orthopaedics, Bon Secours Hospital, Tralee, County Kerry, Ireland
[2] Division of Orthopaedic Surgery, Department of Surgery, McGill University, Montreal, QC, Canada

Clinical scenario

- A 41-year-old male presented with a two-year history of progressive left groin pain on weight bearing.
- He had a total hip arthroplasty (THA) performed 15 years ago for osteoarthritis of his left hip secondary to a displaced fracture of the acetabular dome.
- Clinical examination of the left hip showed restricted motion and antalgia, but good abductor muscle function.

An anteroposterior view of both hips of our patient (Figure 34.1) and a lateral view of the left hip (Figure 34.2) are shown after a first-stage revision THA performed elsewhere for infection. A second-stage procedure was planned after a period of appropriate antibiotic therapy and normalization of inflammatory markers.

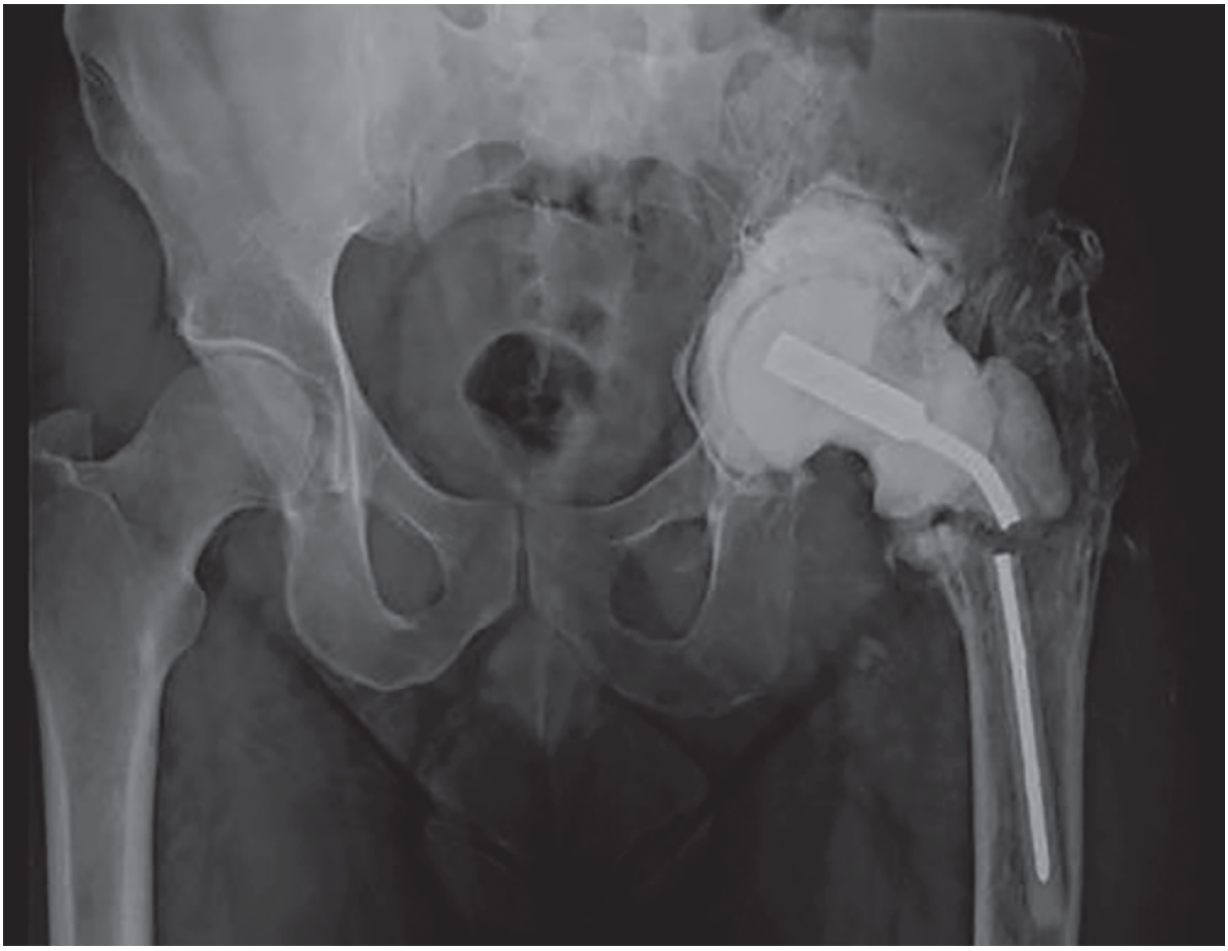

Figure 34.1 Anteroposterior radiograph of both hips of the clinical case showing a fractured cement spacer in situ after a first stage revision left total hip arthroplasty.

Top three questions

1. In patients with acetabular bone loss, which classification system, compared to others, is most useful?
2. In patients undergoing revision THA, which acetabular bone loss management techniques, compared to others, perform best in terms of outcomes?
3. In patients undergoing revision THA, does the use of porous tantalum, compared to other alternatives, result

in better outcomes?

Question 1: In patients with acetabular bone loss, which classification system, compared to others, is most useful?

Rationale

The goal of revising a loose acetabular component of a THA is to provide a stable construct that alleviates pain and restores lost function. Loosening of a primary acetabular component can be associated with significant periacetabular bone loss. Prior to revision, hip surgery it is of utmost importance to quantify the acetabular bone stock. Any deficiency needs to be addressed. Bone graft, reconstructive hardware, or a combination of both may be required. As such, a classification system for acetabular bone loss would facilitate preoperative planning.

Clinical comment

There is not a single accepted, standardized way to classify acetabular bone loss. The three classification systems most commonly used are: D'Antonio,[1] recommended by the American Academy of Orthopaedic Surgeons (AAOS), Paprosky et al.,[2] and Gross et al.[3]

Figure 34.2 Lateral radiograph of the left hip of the clinical case showing a fractured cement spacer in situ after a first stage revision left total hip arthroplasty.

Available literature and quality of the evidence

The overall quality in the literature is low. We identified one level II and three level V studies.

Findings

The AAOS classification (Table 34.1) of D'Antonio is a descriptive classification.[1]

Table 34.1 AAOS classification.

Type	Description of Deficiency
IA	Segmental (Peripheral)
IB	Segmental (Central)
II	Cavitary
III	Combined
IV	Pelvic Discontinuity
V	Arthrodesis

The Paprosky classification[2] uses anatomical landmarks to classify the extent of bony deficiency (Table 34.2) and guides reconstruction based on available techniques. Defects can be graded as completely (type 1), partially (type 2), or non- (type 3) supportive.

Table 34.2 Paprosky classification.

Type of Defect	Superior Migration of Hip Center*	Medial Migration of Hip Center**	Osteolysis of Teardrop***	Osteolysis of Ischium****
I	Minimum	None	None	None
2A	Minimum	Grade I	Mild	Mild
2B	Minimum to Marked	Grade II	Mild	Mild
2C	Minimum	Grade III	Moderate or Severe	Mild
3A	Marked	Grade II+ or III	Moderate	Moderate
3B	Marked	Grade III+	Severe	Severe

* Minimum is ≤3 cm proximal to the superior transverse obturator line, and marked is >3 cm proximal to the superior transverse obturator line.

** Grade I = lateral to Kohler's ilioischial line, grade II = to Kohler's line, grade II+ = medial expansion of Kohler's line into the pelvis, grade III = violation of Kohler's line with some migration into the pelvis, and grade III+ = marked migration into the pelvis.

*** Mild = minimum loss of the lateral border, moderate = complete loss of the lateral border, severe = loss of the lateral and medial borders.

**** Mild = 0–7 mm distal to the superior transverse obturator line, moderate = 8–14 mm distal to the obturator line and severe ≥15 mm distal to the obturator line.

Gross et al. devised a classification based on the type of bone graft required for revision (Table 34.3).[3] Campbell et al. critically evaluated the reliability of these three classification systems showing inconsistency in both interobserver and intraobserver reliability among all three.[4]

Table 34.3 Gross classification.

Type	Description of Deficiency
I	Contained defect with intact rim and columns
IIA	Noncontained defect – minor column (>50% of host acetabulum in contact with cup
IIB	Noncontained defect – major column (<50% of host acetabulum in contact with cup

Resolution of clinical scenario

These classifications show limited reliability and should be considered a general guide to discern between simple and complex reconstructive scenarios. There is no clear best option.

Question 2: In patients undergoing revision THA, which acetabular bone loss management techniques, compared to others, perform best in terms of outcomes?

Rationale

There is no consensus regarding the optimal method of reconstruction in cases of revision hip arthroplasty with severe bone loss. The major decisions regarding surgical technique for complex acetabular revision concerns the use of bone graft, cages, and cemented versus cementless components. The plethora of potential combinations of grafts and metallic devices has led to a huge diversity of reconstructive options in revision acetabular arthroplasty. This creates significant difficulty for systematic analysis of clinical literature incorporating a very heterogeneous mix of surgical techniques.

Clinical comment

Acetabular bone loss can be compensated by placing a high hip center or by using asymmetrical or bilobed acetabular components. Cementless hemispherical cups provide durable survivorship in the revision setting if initial stability and contact with sufficient host bone is possible. Cemented fixation of a polyethylene cup or liner into a supporting cage has often been the construct of choice where allograft is required to support more than 50% of the new acetabular component. Supplementary acetabular fixation may be necessary to stabilize pelvic discontinuity and protect or support bone graft and/or cups. Trabecular metal shells can be used for severe acetabular defects where bone grafting has traditionally performed poorly.

Available literature and quality of the evidence

The overall quality in the literature is low. Most of the evidence was level III–V with level IV being the most frequent.

Findings

Basically, smaller defects (contained or cavitary) can be treated with impacted morselized cancellous allograft bone chips. Satisfactory outcomes have been reported using cementless porous hemispherical acetabular components for these defects.[5–7]

Noncontained, segmental defects are subdivided into those where host bone support for the implant is >50% (Paprosky 3A, Gross 2A) or <50% (Paprosky 3B, Gross 2B). Radiologically, these defects produce significant superolateral and superomedial cup migration respectively. Sporer et al. achieved 78% 10-year survival with cementless acetabular components supported by distal femoral structural bulk allograft buttress for 3A defects.[8] Paprosky

et al. published a series in 2016 with a 21 year follow-up concluding that the use of distal femoral allograft can be considered in young patients with type IIIA acetabular defects that could benefit from restoration of bone stock.[9] Others have shown either good medium term survival with bulk grafts[10–12] or frequent loosening with graft resorption.[13,14]

Options for 3B defects include placing the component high on the remaining host bone, implanting a large cementless acetabular component, using structural bone graft, or replacing lost bone with massive partial or total acetabular allograft, protected with an antiprotrusio cage, containing a cemented liner. Reconstructing the acetabulum with a high hip center has been associated with early loosening,[15] although 94% survival at 10.4 years has been reported.[16] Treatment of type 3B defects with cemented polyethylene cups and large allografts alone has produced poor results.[17,18] The use of reconstruction cages improves their survival despite implantation difficulties and low potential for biological bone ingrowth.[19]

Use of porous tantalum acetabular shells, cups, and augments can address these difficulties.[20–35] Brubaker et al.[35] proposed specific interventions for different grades of acetabular defect based on a modification of the classification of Gross et al.,[3] validated by Saleh et al.[36] They calculated a prognosis for each intervention based on the available literature (Table 34.4). Kosashvili et al. reported good short-term outcomes with the “component-cage technique”, combining ilioischial cages with trabecular metal shells for pelvic discontinuity.[30] Sculco et al. reported the evolution of the cup-cage technique for major acetabular defects.[37] Hourscht et al. discussed the reconstruction of AAOS type III and IV defects with the Ganz reinforcement ring.[38] Abolghasemian et al. reported the reconstruction of

massive uncontained acetabular defects using allograft with cage or ring reinforcement.[39] Garcia-Rey et al. published THA revision series using impaction allografting with mesh.[40] Finally, Maruyama et al. published a new reconstruction method using a medial-reduced cemented socket and additional bulk bone in conjunction with impaction morselized bone grafting fixed by cement.[41] Conventional porous-coated acetabular implants have proven effective in revision THA where bone stock is sufficient for stability and ingrowth, and success with these implants occurs when contact with host bone is greater than 50%.[5–7] Antiprotrusio cages are recommended for host support of less than 50%, but implantation is problematic and biological bone ingrowth is not possible.[19,42]

Table 34.4 Modified gross classification.

Defect Type	Bone Loss	Treatment	Survival (Min 5 years)
I	None	Primary component	As for primary THA
II	Contained	Morselized allograft ± roof ring	84–95%
III	Segmental <50%	Minor column structural allograft + cage, or bilobed cup, or tantalum component	76–94%
IV	Segmental >50%	Major column or acetabular structural allograft with cage, or custom implant	77–100%
V	Discontinuity	As for type IV + fixation of discontinuity	As for type IV

Porous tantalum acetabular cups may provide a solution.[20–34] The porosity of materials commonly used to manufacture acetabular shells approximates 30–50% of their volume. Porous tantalum exhibits almost double this porosity (80%) for bone-metal interdigitation.[43] Porous tantalum implants display high surface frictional characteristics and good osseointegration properties.[43–45] Trabecular metal revision shells are made completely of porous tantalum and have perforations for screw fixation. These shells can be positioned for maximal bone contact using a polyethylene liner locked within or cemented at the required orientation.[22,33,46] When less than 50% host bone is available to support the shell, tantalum augments are used to help fill the defect. A thin layer of cement between the shell and each augment minimizes metal fretting.[46] For pelvic discontinuity, tantalum cup and reconstruction cage constructs can be used. The cage is positioned over the cup, bridging the acetabular defect, and a polyethylene liner is cemented into the cage.[20,46,47]

An alternative approach to pelvic discontinuity was first published by Paprosky et al. in 2014 describing the technique of pelvic distraction using porous tantalum.[48]

Resolution of clinical scenario

There are no trials in the clinical literature to differentiate between treatment modalities for each grade of acetabular bone loss in revision hip arthroplasty. Evidence for different surgical techniques is limited to comparison of case series and expert reviews. The up-to-date studies treating acetabular bone loss are presented in table format with their respective survivorships (Table 34.5).

Table 34.5 Sample summary of studies dealing with acetabular bone loss (in bold the ones using porous tantalum).

Year	Author	Number of cases	Mean follow-up (years)	Survival (%)

Question 3: In patients undergoing revision THA, does the use of porous tantalum, compared to other alternatives, result in better outcomes?

Rationale

The advent[61] and validation[62] of porous tantalum trabecular metal shells signaled a new era in the management of severe acetabular defects. Tantalum is more porous, less stiff, and creates more friction with bone than conventional porous-coated acetabular implants with better potential for biologic osteointegration. Since the trabecular metal has such biologically attractive properties, the expectation has been better survivorship of the implants and improved patient clinical outcomes such as Harris Hips Scores and overall survivorship. Yet, when compared with other cementless designs, porous tantalum does not reduce the risk of re-revision after revision THA in a study involving two national registries.[63]

Clinical comment

Despite its promising short- to medium term results and its sound biologic milieu, porous tantalum does not provide all the answers to the problem of acetabular bone loss when present in the face of revision THA. Custom triflange cups represent such a new direction with early success that complements the promising work of porous tantalum.[64]

Available literature and quality of the evidence

The overall quality in the literature is low. The evidence was level III for both the porous tantalum and the triflange cup studies.

Findings

A total of 2442 first-time THA revisions with porous tantalum cups and 4401 first-time revisions with other uncemented cups were included in this collaborative study between the Australian and Swedish national joint registries. The mean age of the patients was 69 years (range 19–97 years), 3754 (55%) of the patients were women, and the mean follow-up for the porous tantalum and uncemented

control groups was 3.0 years (standard deviation [SD]: ±2.1 years) and 3.4 years (SD: ±2.3 years), respectively. Concomitant stem revision was more common in the porous tantalum group (43% vs 36%). Kaplan–Meier survivorship with re-revision for any reason up to seven years was comparable between the porous tantalum cup group and the uncemented cup control group (86%; 95% confidence interval [CI]: 85–89%, and 87%; 95% CI: 85–89%, respectively; p = 0.85) and the overall survivorship up to seven years with a second revision for periprosthetic joint infection (PJI) as the endpoint (97%; 95% CI: 95–98%; and 97%; 95% CI: 96–98%, respectively; p = 0.64). Excluding procedures where augments had been used or studying primary osteoarthritis and first revision owing to aseptic loosening subgroups did not change this result. Implant survival for a porous tantalum cup in first-time THA revision was similar to the survival of the uncemented cup control group. With the numbers available, no benefit in survival with re-revision for infection as the endpoint could be ascribed to the porous tantalum cup group, as has been suggested by earlier work.[63]

The custom triflange is a patient-specific implant for the treatment of severe bone loss in revision THA. Through a process of three-dimensional modeling and prototyping, a hydroxyapatite-coated component is created for acetabular reconstruction. In their paper, the authors present a table/review of the case series with of custom triflanges. The most common complications include dislocation and infection, although the rates of implant removal are low. Clinical results are promising given the challenging problem.[64]

Resolution of clinical scenario

Porous tantalum trabecular metal shells have good survival statistics for reconstruction of severe acetabular defects in

case series with short- to medium term review. Yet, these promising results have not yet translated into long-term benefits as per the findings of the Swedish and Australian registries. The custom triflange cup is an alternative solution gaining popularity due to its affordability, relatively uncomplicated surgical technique and patient specific design.[64]

Summary of answers

- There is no single, standardized, readily reproducible classification system with prognostic ability regarding the treatment of acetabular defects in revision hip surgery.
- The main management options for the surgeon include bone graft, acetabular cups, rings or cages, and combinations of the above. The techniques have unique pros and cons, but the goals are to obtain stable and durable acetabular component fixation and a healed pelvis while minimizing complications leading to the highest possible functional patient outcome.
- Structural bulk allografts may be used to provide a mechanical environment that supports host bone ingrowth into an acetabular component. Alternatively, they may allow restoration of joint mechanics in situations where host bone loss precluded biologic fixation.
- Porous tantalum has provided a much-needed solution for large defects with good short- to medium term results. Indeed, the use of tantalum appears to answer many of the questions faced in these difficult cases.
- The custom triflange cup seems to complement the porous tantalum success well for larger defects

(Paprosky IIB) and offers a comparable alternative in terms of results and pricing.

- Revision hip surgery and in particular acetabular surgery addressing bone loss is complex. Its principles reflect a variety of choices with no direct comparisons of the surgical approaches and hardware options. Each patient's treatment is individualized based on their underlying disease process and previous surgical history. So, direct comparison with other techniques of revision THA can be misleading unless the studies are stratified for variables such as: type of study, sample size, the acetabular defect type, mean follow-up, indication for revision, patient outcomes, and study endpoints, patient's American Society of Anesthesiologists (ASA) class, and of course the surgeon's training and experience.

Acknowledgments

The authors wish to thank Dr. David Zukor for his contribution to the clinical case. This is a revision of a previously published work/chapter. So, most importantly the current authors would like to acknowledge the original authors of this chapter and their work: Mr. Alan J. Walsh FRCSI(Tr&Orth), Clinical Fellow, and Dr. Vassilios S. Nikolaou MD, Clinical Fellow.

35 Antibiotic Cement in Total Knee Arthroplasty

Stephen M. Petis MD MSc FRCSC[1] and Steven J. MacDonald MD FRCSC[2]

[1] Woodstock General Hospital, Woodstock, ON, Canada

[2] London Health Sciences Centre, University Hospital, London, ON, Canada

Clinical scenario

- A 65-year-old male with tricompartmental arthritis undergoes a primary total knee arthroplasty (TKA).
- His past medical history is remarkable for rheumatoid arthritis, type 2 diabetes mellitus, chronic diabetic nephropathy, and peripheral vascular disease.

Top three questions

1. For patients undergoing primary TKA, does the routine use of antibiotic-loaded bone cement (ALBC) reduce the rate of periprosthetic joint infection (PJI) compared to cement without antibiotics?
2. In patients undergoing TKA, does the routine use of ALBC lead to higher aseptic mechanical failure rates compared to cement without antibiotics?
3. In patients undergoing TKA, is the routine use of antibiotic-impregnated cement cost-effective compared to antibiotics without cement?

Question 1: For patients undergoing primary TKA, does the routine use of antibiotic-loaded bone cement (ALBC) reduce the rate of periprosthetic joint infection (PJI) compared to cement without antibiotics?

Rationale

By 2030, it is predicted that 3.48 million primary TKAs will be performed each year in the United States.[1] As the number of procedures performed continues to rise, the burden of PJI following TKA will rise concomitantly.

Clinical comment

PJIs are associated with patient morbidity and mortality, poor patient-reported outcomes, and tremendous costs to the healthcare system.[2–4] Any intervention that mitigates the risk of PJI following TKA would be worthwhile.

Available literature and quality of the evidence

The best available evidence includes three randomized, controlled trials.[5–7] One of these trials is a level I (therapeutic) trial. The other two trials are graded as level II (therapeutic) despite their randomized study design because of lack of blinding and poor randomization technique. Impactful data are also available from large registry-derived studies, graded as level IV (therapeutic) based on their retrospective design.[8,9] Finally, there is a meta-analysis of randomized controlled trials (RCTs; level I) that also seeks to answer this question.

Findings

There are three randomized trials examining the clinical effectiveness of ALBC on PJI following TKA. Chiu et al. randomized 78 patients undergoing TKA to receive cement with or without 2 g of cefuroxime added to each 40 g batch of cement.[5] The primary diagnosis was osteoarthritis in all cases, and every patient had been diagnosed with diabetes mellitus. At mean follow-up of 50 months, there was a significant reduction in deep PJI for patients with ALBC (relative risk [RR] = 0.865; 95% confidence interval [CI]: 0.77–0.97; p = 0.021). However, this study had methodological and practical limitations, including lack of blinding, small sample size, and hybrid fixation technique (cementless femur and cemented tibia). Chiu et al. later published a series of 340 primary TKAs randomized to receive ALBC (178 knees) and cement without antibiotics (162 knees).[6] The PJI rate was significantly lower in the group with ALBC (0% vs 3.1%, p = 0.024). Similarly, this study was limited by the lack of blinding, as well as generalizability, as the procedures were performed in an environment that was not optimized for sterility. In the largest trial to date on the topic, Hinarejos et al. randomized 3000 TKA patients to ALBC (n = 1483) versus plain cement (n = 1465).[7] They found no significant difference in the deep infection rate between the two groups (1.4% in both, p = 0.96). In their meta-analysis of RCTs, which included all of the above trials, Zhou et al. found no significant difference in deep or superficial infection rate.[10]

A large series from the Finnish Arthroplasty Register retrospectively examined 40 135 primary TKAs using a Cox regression analysis to determine risk factors for PJI.[8] The risk of PJI was higher for cases without ALBC (hazard ratio [HR] = 1.35; 95% CI: 1.01–1.18), as well as for cases with intravenous (IV) antibiotics alone compared to IV antibiotics with ALBC (HR = 1.42; 95% CI: 1.08–1.88).

Patients with secondary osteoarthritis (HR = 1.86; 95% CI: 1.12–3.11) and rheumatoid arthritis (HR = 1.86; 95% CI: 1.31–2.63) were identified as having a higher risk of PJI after primary TKA. A more recent registry review performed in Spain examined the effect of ALBC on infection rates in 1250 TKAs (555 with and 695 without ALBC).[9] They found a significant reduction in PJI rates (RR = 0.37; 95% CI: 0.16–0.87; p = 0.019) after the introduction of ALBC. Interestingly, two other registry studies, one from New Zealand (n = 64 566 joints) and another from the United States (n = 56 216 knees) both found increased infection rate in those undergoing surgery with ALBC.

Registry data should be interpreted cautiously, as the diagnosis of PJI cannot be confirmed, and the data output is limited by the initial accuracy of diagnostic coding at the time of treatment. In addition, registry data are naturally prone to selection bias.

Resolution of clinical scenario

- There is conflicting evidence as to whether ALBC reduces the rate of PJI following primary TKA.
- The risk of PJI after TKA is higher in certain patient populations, such as diabetes mellitus and inflammatory arthropathy, and ALBC should be used to reduce the risk of infection following TKA in these patients.
- A large level I, RCT would add to the literature, as current recommendations are based on studies with methodological shortcomings.

Question 2: In patients undergoing TKA, does the routine use of ALBC lead to higher aseptic mechanical failure rates compared to cement without antibiotics?

Rationale

One of the most commonly reported modes of failure requiring revision after TKA is aseptic loosening.[11],[12] Identifying a modifiable, surgeon-controlled risk factor that could reduce the rate of aseptic mechanical failure would improve long-term patient outcomes and reduce the burden of revision surgery.

Clinical comment

Basic science research suggests that the addition of antibiotics to polymethylmethacrylate may compromise the structural integrity of the cement in a dose-dependent fashion.[13] There is clinical concern that the addition of antibiotics to bone cement may lead to earlier mechanical loosening of TKA implants.

Available literature and quality of the evidence

The available literature on aseptic loosening rates and the use of ALBC is based on limited data where implant loosening is a secondary reported outcome after infection rates. There are two RCTs (level II, therapeutic) reporting aseptic loosening rates using ALBC following TKA. In addition, a large database study assessed the issue in total hip arthroplasty (THA).

Findings

The aforementioned study by Chiu et al. examined 340 primary TKAs randomized to either cement with or without antibiotics with a mean follow-up of 49 months.[6] There was one (0.6%) reported femoral component loosening at two years in the ALBC cohort and none in the plain cement cohort. Additionally, a randomized study using radiostereometric analysis (RSA) compared two different bone cements impregnated with gentamicin to determine differences in tibial component migration. At two-year follow-up, there were no differences identified, suggesting that early implant migration as a surrogate for loosening did not differ depending on the brand of ALBC selected.[14] Although there are no studies examining implant migration using RSA comparing plain cement and ALBC following TKA, Bohm et al. used similar RSA techniques to demonstrate that implant subsidence was no different using ALBC versus plain cement following cemented THA.[15] Finally, in a study of over 20 000 Norwegian THA patients, Engesaeter et al. found a significantly higher infection rate in the systemic-only antibiotic group compared to the combined systemic and bone cement group (odds ratio = 1.4; p = 0.001).[16]

Resolution of clinical scenario

- Based on limited data, it appears that using ALBC does not increase the risk of aseptic loosening following TKA.
- Further research is needed through either a prospective, comparative study or large-scale retrospective study to discern the long-term risk of ALBC on aseptic loosening rates following TKA.

Question 3: In patients undergoing TKA, is the routine use of antibiotic-impregnated cement cost-effective compared to antibiotics without cement?

Rationale

The addition of antibiotics to bone cement is costlier than cement prepared without antibiotics. The cost of antibiotics added to commercially available bone cement (typically 1 g of antibiotic per 40 g of cement) ranges from $210 to $500 per batch of cement.[17,18]

Clinical comment

The treatment of PJI following TKA ranges from $25 000 to over $100 000 depending on surgical technique, duration of parenteral antibiotic therapy, and complexity of reimplantation surgery.[3,19,20] If antibiotics added to cement could reduce the burden of PJI following TKA, it may be a cost-effective intervention in the long term.

Available literature and quality of the evidence

There are no cost-effectiveness studies modeling the economic impact of ALBC usage during TKA utilizing the landmark methodology outlined by Chang et al.[21] Two retrospective studies (level IV, economic and decision analysis) have examined the costs of ALBC in TKA; however, neither study performed a true cost-effectiveness analysis.

Findings

A retrospective study by Gutowski et al. modeled the cost-effectiveness of various preparations of antibiotic cement on PJI rates after TKA.[18] They determined that, depending on the preparation used (hand-mixed versus pre-mixed), a cost of $2112 to over $100 000 was necessary before one case of PJI was prevented. The hand-mixed preparations (1 g of either vancomycin or tobramycin added to each batch of cement) were less costly and as effective as the premixed varieties for PJI prophylaxis. Although hand-mixing antibiotics into the cement is off-label usage, the authors recommend that its usage should be considered in a cost-conscious environment.

A registry review by Sanz-Ruiz et al. also compared the cost savings of using ALBC routinely compared to plain cement in primary TKA.[9] It should be noted that the cost of ALBC was less expensive (€60) compared to the cost of commercially available cement in North America. The incidence of PJI dropped by 61% after the introduction of ALBC in this series, which amounted to $1295 cost savings per case based on the number of infections prevented with ALBC and the mean added cost to treat PJI in Spain (approximately $45 000).

Resolution of clinical scenario

- The routine use of ALBC should result in cost savings through a reduction in PJIs.
- Consideration should be given to hand-mixed antibiotic preparations, as these are far less costly than premixed variations, and seemingly as effective.
- A more robust cost-effectiveness analysis examining ALBC in TKA is required, as the current cost data are piggy-backed onto retrospective studies examining different outcomes.

Summary of answers

- ALBC reduces the rate of periprosthetic joint infection in RCTs and large registry database studies.
- The rate of aseptic loosening following TKA with the use ALBC does not differ compared to using plain bone cement.
- Although the use of ALBC may reduce costs by reducing the burden of periprosthetic joint infection, formal cost-effectiveness analysis studies are needed to affirm findings from limited existing literature.

36 Unicompartmental Knee Arthroplasty and Patellofemoral Resurfacing Arthroplasty

Waleed Albishi MBBS, Paul Jamieson MD, Ivan Kamikovski MD, and Geoffrey Dervin MD
Division of Orthopaedic Surgery, Department of Surgery, University of Ottawa, Ottawa, ON, Canada

Clinical scenario 1

- An active 58-year-old female has lateral knee pain that is disabling.
- She had lateral meniscectomy as a teenager.
- Her flexion is to 130° and there is no contracture, and ligaments are otherwise stable.

Clinical scenario 2

- A 46-year-old woman with a medical history of multiple patella dislocations with previous lateral release.
- Progressive worsening of anterior knee pain, aggravated by climbing and descending stairs and rising from sitting position. Injections and physical therapy ineffective.
- Left knee range of motion is from 0–20° flexion. Lateral patella tracking and stable knee ligaments. Her radiographs show a severe lateral patellofemoral osteoarthritis (PF OA).

Top three questions

1. Does unicompartmental knee arthroplasty (UKA) provide better patient-reported outcomes despite worse survivorship than total knee arthroplasty (TKA) in patients under age 60 with isolated medial compartment OA?
2. Is lateral UKA a better alternative to TKA for patients under age 60 with respect to functional outcome?
3. What are the patient-reported outcomes for patellofemoral arthroplasty (PFA) versus TKA for patients under age 55 with isolated PF OA ?

Question 1: Does unicompartmental knee arthroplasty (UKA) provide better patient-reported outcomes despite worse survivorship than total knee arthroplasty (TKA) in patients under age 60 with isolated medial compartment OA?

Rationale

UKA has been an accepted alternative to TKA since the 1970s. It is attractive because of its ligament and bone preserving surgery, shorter and simpler rehabilitation, and some findings suggesting improved function and satisfaction when compared to TKA. However, registry data have consistently shown nearly double the revision rate to that of TKA across all age categories, especially in those under the age of 60, fueling the debate as to the role for UKA in this age group.

Clinical comment

Many patients under the age of 60 with isolated medial compartment OA which has failed conservative management have the surgical option of either medial UKA or TKA. Although of limited strength, recent literature supports the notion that UKA produces as good and sometimes more favorable reported patient-reported outcome measures (PROMs) compared with TKA and yet reported survivorship is typically only half as good.

Available literature and quality of the evidence

The available literature to answer this question is limited to level III retrospective observational studies, level IV case series, and systematic reviews of the former.

Findings

Multiple level III and IV studies have been completed to ascertain the survivorship of UKA in young patients, and there are mixed results in the literature. The evidence is mixed between the designer center series, cohort groups, and national registries. In 2011, Pandit et al. published a retrospective review of their first 1000 phase three Oxford medial UKAs implanted at the designer center and subdivided the patients into those younger (245 patients) and older than 60 (755 patients) at age of implantation. They found no difference in 10-year survivorship between the two groups, 97.3% (91.3–100%) and 95.1% (90.8–99.3%), respectively, with functional scores equal or better in the under 60 years of age group.[1] Several other case series have been published with similar outcomes and survivorship beyond 10 years.[2–5] A 2018 systematic review by Kleeblad et al. aimed to compare outcomes and revision rates between UKA and TKA in patients under the age of 65.[6] To calculate revision rates, the authors identified 21 cohort studies reporting data on 2224 UKAs and 33 cohort

studies reporting data on 4737 TKAs. The overall UKA revision rate was 8.2% at a mean follow-up of 9.8 years and an annual revision rate (ARR) of 1.00 (95% confidence interval [CI]: 0.77–1.30). Alternatively, the overall TKA revision rate was 6.95% at a mean follow-up of 8.4 years and an ARR of 0.53 (95% CI: 0.36–0.78). Few studies have specifically assessed survivorship of UKA in very young patients. Parratte et al. performed a retrospective review of 25 patients under the age of 50 who underwent medial UKA, and although they found that the mean KSS score improved from 54 to 89 preoperatively, their 12-year survival rate was 80.6%.[7] The 2018 annual report of the Australian Orthopaedic Association National Joint Replacement Registry looking at 52 000 primary UKAs reported the cumulative percent revision of primary UKAs and found that patients aged between 55–64 had a 15.9% (range 15.3–16.6%) revision rate at 10 years and 30.4% (range 28.0–33.0%) at 17 years. Further, patients with UKA under the age of 55 had a cumulative percent revision of 22.8% (21.7–23.9%) at 10 years and 39.4% (36.6–41.4%) at 17 years.[8] Conversely, TKA patients between the ages of 55 and 64 had an 11.8% (11.1–12.5%) revision rate and patients less than 55 had a 17.8% (16.4–19.3%) revision rate at 17 years.

Regarding functional outcomes, in the Kleeblad et al. systematic review, significantly higher overall ROM (125° vs 114, $p = 0.004$) as well as higher Knee Society Scores at long-term follow-up were found in the UKA group compared to the TKA group (88.1 and 85.8, respectively, $p = 0.04$).[6] A retrospective case series by Walker et al. of 118 consecutive Oxford medial UKAs in patients aged 60 or younger found that 93% of patients returned to activity postoperatively at minimum two-year follow-up and 62% of patients were defined as “very active” based on the UCLA score of ≥7.[9] Von Keudell et al. performed a retrospective

age matched cohort analysis of 485 knee surgeries with a minimum three-year follow-up and found that in patients between the ages of 55 and 64 higher satisfaction was found in the UKA group with 93% of patients having excellent/good patient satisfaction compared to 89% in the TKA group.[10] In those under the age of 55, 96% of patients with UKA had excellent/good patient satisfaction compared to 81% in the TKA group. Goh et al. published a retrospective matched cohort analysis of 160 patients under the age of 55 who underwent TKA and found that at both six months and two years patients in the UKA group had significantly greater ROM than those who underwent a TKA (128° ± 11° vs 117° ± 15°, respectively, at two years, $p < 0.001$). They did not, however, identify any difference in functional outcomes or patient satisfaction scores.[11]

At this time, UKA in patients under the age of 60 requires careful patient selection, meticulous surgical technique, and adequate surgical experience and also benefits from a shared decision-making process between the patient and surgeon. To this end, several authors have developed surgical decision tools to provide support and information to patients deciding between undergoing TKA and UKA.[12–14] Prospective randomized studies, some of which are ongoing, are required to better answer this question.[15]

Question 2: Is lateral UKA a better alternative to TKA for this patient under age 60 with respect to functional outcome?

Rationale

Despite the potential benefits of UKA as a bone preservation technique with faster recovery and lower

morbidity, lateral UKA accounts for less than 1% of all knee replacement procedures.

Clinical comment

It is critical to appreciate whether the benefits to patients outweigh the concerns of technical complexity and survivorship.

Available literature and quality of the evidence

Multiple retrospective case series provide the only real evidence from which to answer the question.

Consistently good early results were obtained by Berend with contemporary metal backed tibia designs.[16] They reported on 93 patients who had 100 lateral UKA and average age 68 years done through a lateral parapatellar approach. Knee Society Scores averaged 46 for pain, 94 for clinical, and 89 for function, and ROM averaged 124° with only two related reoperations – one for open reduction and internal fixation for fracture and one revision for pain. Furthermore, implant survivorship studies have showed very encouraging results with a range of 95–99% survivorship at 10-year follow up.[17–19] Indications for lateral UKA have been extended to include young patients with higher levels of activity. More importantly, Walker et al. showed that 98% of their cohort returned to sports and recreational activities after a lateral UKA. Two-thirds of them achieved high activity levels as measured by the Short Form 36 Health Survey.[19] As in medial UKA, most of the outcome studies involve fixed-bearing constructs, but interest remains as to whether the low wear characteristics of a mobile-bearing insert may have long-term benefits. Early studies of mobile-bearing lateral UKA were plagued with high dislocation rates.[20] Design modifications were required to account for the laxity and increased femoral

roll-back unique to lateral joint kinematics, and improvements in technique and design have led to a dramatic reduction in dislocation rate from 10% to 1.7% in the designer series.[21] Independent studies have reported good early- and medium-term outcomes, though some did have a high dislocation rate of 6%.[22] Though bearing dislocation and revisions are a concern, other potential issues also exist with either technique, such as overcorrection into varus, which must be avoided to prevent early failures. A recent systematic review confirmed that progression of OA and aseptic loosening are the major overall failure modes in lateral UKA. Bearing dislocation was the main failure mode in early years and in mobile-bearing implants, whereas OA progression caused most failures in late years and in fixed-bearing implants.[23]

Resolution of clinical scenario

- Lateral UKA can provide clinical functional results as good as medial with a high level of activity permitted.
- Mobile-bearing lateral UKA can theoretically allow slightly more flexion than fixed-bearing design at risk of insert dislocation.
- Care must be taken not to overcorrect into varus position and best results are maintained with slight valgus postoperative alignment.

Question 3: What are the patient-reported outcomes for PF arthroplasty (PFA) versus TKA for patients under age 55 with isolated PF OA?

Rationale

PF malalignment resulting in lateral facet overload is a common precursor to articular wear.[24] PF OA affects approximately 10% of patients aged over 40 years, with a female preponderance.[25]

Clinical comment

Currently, conservative treatment of PF OA includes quadricep strengthening, bracing or taping, oral and topical NSAIDs, hyaluronic acid and/or corticosteroid injections, and activity modification. Critical evaluation of the location and extent of PF cartilage lesions is required to properly stratify patients for procedures after patients have completed a thorough rehabilitation regimen.

Findings

Nonarthroplasty options

There is little evidence to use a simple procedure such as lateral release. Shea et al. recommended lateral release be reserved for patients with anterior knee pain who had computed-tomography-proven patellar tilt with minimal facet changes and minimal or no subluxation and cautioned that it should not be offered in cases of normally aligned patella.[26] Patellectomy is no longer considered a mainstream option for PF OA as quadricep weakness will result and only half of patients can expect good to excellent results.[27]

The most commonly performed osteotomies are for isolated lateral facet disease with severe narrowing where a simple debridement and lateral release are ineffective. The anteromedialization tibial tubercle osteotomy popularized by Fulkerson is conceptually most appealing with reliable outcomes and is specifically suited for cases where

articular lesions are concentrated in the lateral and distal facet of the patella given that medialization and anteriorization will address each of these individually.[28] It is important to taper the osteotomy distally to avoid a stress riser as fractures have been reported, leading to a recommendation of six weeks of non-weight-bearing postoperatively.[29]

Patellofemoral arthroplasty (PFA)

Patients in their 40s and 50s who fail repeated surgical intervention need a practical alternative to TKA for the medium-term improvement that can be achieved with PFA. Results with contemporary PFA designs have a reduced incidence of the problems related to patellar maltracking that typically plagued earlier generation designs. Patients must be advised that progression of tibiofemoral OA will likely be the main reason for revision emphasizing good patient selection and preoperative discussion. As per the 2018 Australian registry annual report, the cumulative percent revision for primary PFA undertaken for OA was 14.3% at five years and 45.9% at 15 years.[8] Younger patients can be reassured that failed PFA can be readily and successfully converted to TKA, as Lonner et al. have shown.[30] Prosthetic design (be it onlay or inlay), the need of realignment procedures, and the etiology of PF arthritis (post-traumatic, dysplastic, or idiopathic) are important factors to consider when planning the surgery and prognosticating patient results.[31]

Total knee arthroplasty (TKA)

TKA can provide significant improvement in younger patients with isolated PF arthritis. Lonner et al. have shown 91% excellent objective outcome in 32 knees in patients 40 years or younger with a 7.9-year mean follow-up.[30] However, only 50% of patients had good to excellent

functional outcomes on the Knee Society Score. Additionally, limitations in functional activities (i.e. moving laterally, turning, carrying loads, playing tennis) have been reported in 52% of TKA patients, compared with 22% in age-matched patients without reported knee complaints.[32]

Few studies to date have compared the functional outcomes of TKA with those of PFA using modern implants in a younger patient cohort. Meding and colleagues compared the outcome of TKA versus PFA in younger patients.[33] The study consisted of a retrospective cohort of 27 patients (33 TKAs) with average follow-up of 6.2 years. The patients ranged in age from 38 to 60 years of age with a mean of 52 years. The investigators used comparative historical data on PFA outcomes in 10 studies. The investigators concluded that TKA was a superior procedure. However, of the 10 PFA papers reviewed six involved first-generation PF designs that have largely been abandoned or redesigned. On the other hand, Dahm et al. retrospectively compared the clinical and functional outcomes of patients from their institution who underwent either PFA or TKA for the treatment of isolated PF OA.[34] Twenty-three PFA and 22 TKA patients were included with a mean follow-up of 2.5 years. Mean age was 60 years and 69 years, respectively. Patients treated with PFA demonstrated similar results with respect to pain relief but showed improved function and return to activity when compared to TKA patients. PFA patients also experienced less intra-operative blood loss, fewer complications, and shorter hospital stays following surgery. These results allowed them to conclude that PFA is a less invasive treatment option for patients with isolated PF OA, with outcomes comparable with TKA.

Summary of answers

- At this time, UKA in patients under the age of 60 requires careful patient selection, meticulous surgical technique, and adequate surgical experience, and also benefits from a shared decision-making process between the patient and surgeon.
- Lateral UKA can provide clinical functional results as good as medial with a high level of activity permitted.
- Mobile-bearing lateral UKA can theoretically allow slightly more flexion than fixed-bearing design at risk of insert dislocation.
- Care must be taken not to overcorrect into varus position and best results are maintained with slight valgus postoperative alignment.
- PFA is a reasonable choice to extend function and reduce pain while avoiding a more complex TKA.
- Like UKA, it remains an intermediate solution for some patients and an important option.

37 Cemented versus Uncemented Fixation in Total Knee Arthroplasty

Thomas Turgeon MD FRCSC
Division of Orthopaedic Surgery, Department of Surgery, University of Manitoba, Winnipeg, MB, Canada

Clinical scenario

- A 57-year-old female office worker with two years of severe bilateral knee pain (body mass index [BMI]: 34).
- Walking tolerance is about one block, unable to participate in recreational activities, sleep is regularly disrupted by pain.
- Has failed nonoperative management, correctable varus deformity, range of motion (ROM) 10–120°, advanced radiographic osteoarthritis medially with lateral compartment changes.

Top three questions

1. In total knee arthroplasty (TKA) in younger patients, is the survival of the implant improved with uncemented components as compared to cemented fixation?
2. In patients undergoing TKA, are the clinical outcomes improved with cementless fixation versus those fixed with cement?
3. In patients undergoing TKA, is the bone quality adjacent to the TKA improved following uncemented TKA as opposed to cemented TKA with intended benefit for future TKA revision?

Question 1: In total knee arthroplasty (TKA) in younger patients, is the survival of the implant improved with uncemented components as compared to cemented fixation?

Rationale

The durability or survival of TKA is a key feature to consider, especially in younger patients undergoing TKA.

Clinical comment

There are numerous impacts when considering TKA surgery. For the patient, there is the pain and effort of rehabilitation associated with the initial procedure. The patient is also exposed to the risks of surgery, which in rare cases can be as severe as death.[1] There is lost income from work in addition to missed family and social opportunities.[2] To governments and payors, there is the financial cost of the implant and the procedure. If revision TKA is required, all of the above impacts tend to be greater than in the primary procedure.[3],[4] By maximizing the survival of the TKA implant and procedure, the risk of subsequent revision is reduced, thereby minimizing the impact to the patient's personal, financial, and social wellbeing and to the healthcare system.

Available literature and quality of the evidence

While there have been multiple randomized controlled trials (RCTs) assessing the survival of uncemented versus cemented TKA, most are too small to determine implant survival between groups. To address the limitations of these smaller studies, five meta-analyses have been

performed including a Cochrane review that provide some clarity, but each has limitations to answer the question of survival. Multiple national joint registries provide the clearest information on real-world use of cemented and uncemented TKA, but these are limited based on the granularity of the data within the registries.

Findings

When performed well and with consistent subject matter, meta-analyses can provide strong recommendations. The Cochrane review by Nakama et al. (level I) focused principally on the fixation and stability of cemented and uncemented tibial components as assessed by radiostereometric analysis (RSA) in three RCTs at two years.[5] RSA is a high-resolution radiographic technique that compares the position of radio-dense implants to small marker beads embedded in the bone to assess relative motion between implant and bone. Early continuous migration of the mean total point motion of the implant relative to bone of >0.2 mm at two years has been associated with a high risk of early loosening and implant failure.[6] The review found the overall movement of cemented tibial implants was less than uncemented, but that uncemented implants were at lower risk of future aseptic loosening with a risk ratio (RR) of implant instability to bone versus cement fixation (RR = 0.47; 95% confidence interval [CI]: 0.24–0.92; p = 0.03).[5] They found that the uncemented implants tended to move a small amount early and then stabilize. Most cemented tibial components were stable, but those that were not stable never stabilized and continued to migrate. In reviewing clinical outcomes, Gandhi et al. reviewed 15 studies that were a mix of RCTs and cohort studies (level II).[7] They found that the combined odds ratio (OR) for failure due to aseptic loosening for the uncemented group was 4.2 (95%

CI: 2.7–6.5; p <0.001). However, when they only assessed the five RCTs in the review, there was no statistical difference (level I) between fixation types. They concluded that there was improved survival of the cemented compared to uncemented implants. Mont et al. (level II) described a similar phenomenon in their 37 study review with uncemented implants with an OR 1.8 (95% CI: 1.1–3.1) of failure with all study types assessed, but with no survival difference found when only the five RCTS (level I) were assessed.[8] Wang et al. reviewed nine studies (level II) which were a mix of RCT and case series and reported ORs of 3.41 (95% CI: 1.83–6.35) at five years and 4.73 (95% CI: 2.07–10.79) in favor of cemented fixation over uncemented.[9] Voigt et al. reviewed 14 RCTs (level I) and used both survival and implant instability by RSA as a marker or failure and found no difference between fixation methods at either 5 or 8–10 years.[10] Survival with cement TKA fixation appears better, but despite the rigors of meta-analysis methods the results are not entirely conclusive.

National joint registry data are a powerful tool that can attest to real-world use of implants. While causality can be difficult to prove with registries, their massive scale can lead to strong conclusions. Unlike the meta-analyses, the registries have been consistent in their overall finding that uncemented TKAs have reduced survival as compared to cemented TKAs with relative risks ranging from 1.1 to 1.9.[11–15] All of the registries recognize that younger patients undergoing TKA have higher revision rates and that the trend in the use of uncemented TKA is in younger patients. As a result, age is a confounder in the assessment of uncemented TKA survival and is controlled for in the analysis by the different registries. While the overall survival is reduced, sub-analysis within the registries demonstrates some interesting findings. The New Zealand registry reported on only three uncemented knee designs

with one design accounting for 78% of the uncemented volume (level II).[13] While the survival of the predominant design was worse than the mean survival of cemented designs, the remaining two uncemented designs did not differ suggesting that the single poorly performing design skewed the results for the uncemented group as a whole. The Swedish Registry (level II) found that, after controlling for confounders, that the relative risk of failure for of a TKA with an uncemented tibial component was 1.6 (95% CI: 1.3–1.9) times higher than for cemented tibial components.[15] That said, it reported no difference for knees implanted within the last 10 years and indicated that the driving force for their finding was uncemented knees performed between 1985 and 1994. This raises the possibility that more modern implant designs and surgical techniques may have improved the survival of uncemented TKA to that of cemented TKA. The British National Joint Registry (level II) found that uncemented and hybrid fixation (typically cemented tibial fixation and uncemented femoral fixation) performed more poorly with posteriorly stabilized designs versus minimally constrained TKA.[12] The Australian Registry (level II) reported that hybrid fixation with posterior stabilized designs had increased failure rates (HR = 1.29 [1.18, 1.40]) with uncemented versus cement fixation, but no difference in minimally constrained designs.[11] Completely uncemented designs fared worse in both design styles (HR = 1.12 [1.00, 1.26] and HR = 1.25 [1.20, 1.31], respectively). The general conclusion of the registry data suggests that survival is not improved with uncemented fixation and is, in fact, worse than cemented fixation but that there may be design issues that cause some variation in the results.

Resolution of clinical scenario

- Survival of uncemented implants may be design-dependent.
- There is no substantial evidence that uncemented TKA improves the implant survival versus cemented TKA in any patient group, and survival appears to actually be greater with cemented fixation.

Question 2: In patients undergoing TKA, are the clinical outcomes improved with cementless fixation versus those fixed with cement?

Rationale

The underlying purpose of TKA is to relieve pain and restore function. Regardless of fixation type, knee replacements must be effective to be of value to both the patients and the healthcare system.

Clinical comment

The patient is undergoing surgery due to the pain that she is experiencing and the significant limitations on her activities and reduced quality of life. Regardless of implant survival, the success in pain relief and restoration of function will be her biggest immediate concern. She will not want to sacrifice her clinical outcome quality to potentially improve a subsequent surgical procedure.

Available literature and quality of the evidence

There have been a number of RCTs assessing the outcome of TKA using the two fixation types. The challenge is that most are inadequately powered to assess for clinical outcome metrics. Meta-analysis is ideal for merging these

types of data to help address this shortcoming; however, the variety of outcome metrics make pooling data from multiple studies challenging.

Findings

The power to pool clinical data using meta-analysis has been performed by a few studies. The Cochrane review by Nakama et al. (level I) found no difference in patient-reported outcome measures (PROMs) of the three RCTs reviewed.[5] The review of RCTs and cohort studies by Gandhi et al. (level II), assessed nine studies using the Knee Society Score (KSS) and also found no difference between groups, but found the results to vary from study to study.[6] One RCT of 81 subjects found that pain scores neared statistical and clinical significance with uncemented knee patients reporting more pain at six months from surgery, but that the finding dissipated by one year (level I).[16] Demey et al. (level I) assessed the KSS in an RCT powered to detect a difference of 15 points at a minimum of 24 months' follow-up and found no difference between fixation types.[17] The minimal clinically important difference (MCID) of the KSS has been identified as six points.[18] Fernandez et al. published their findings (level I) on 145 subjects in a blinded RCT and found that subjects with a porous tantalum uncemented tibial base plate had statistically improved KSS and Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC) scores at five years versus cemented tibial base plates (mean difference of 3.9 and 4.0 points [$p = 0.02$], respectively).[19] Given the MCID for the KSS is approximately six points and for the WOMAC has been reported as high as 15, these results do not appear to be clinically important.[18],[20] Powered to find a five-point difference in KSS at two years, Fricka et al. (level I) found

no difference between fixation types in their RCT.[21] Similarly, in an RCT powered to detect a three-point difference in KSS in patients younger than 55, Kim et al. (level I) found no difference between groups at a mean follow-up of 16.6 years.[22] There has been no clinically important difference demonstrated between uncemented and cemented fixation in TKA.

Significant complications can lead to negative impacts on quality of life. In reviewing their outcomes through their meta-analysis of 953 patients, Wang et al. (level II) found no difference in infection rates between the two fixation methods (OR = 0.96; 95% CI: 0.37–2.48).[9] Similarly, Voight et al. (level I) found no difference between the groups (RR = 1.20; 95% CI: 0.63–2.28) in the rate of *adverse events*.[7]

Resolution of clinical scenario

- There is no evidence of differences in clinical outcomes for patients undergoing either cemented or uncemented fixation of their TKA.
- Complication rates appear to be similar between fixation types.

Question 3: In patients undergoing TKA, is the bone quality adjacent to the TKA improved following uncemented TKA as opposed to cemented TKA with intended benefit for future TKA revision?

Rationale

Given her age, the patient wonders if using an uncemented TKA will help in the face of a future surgery by preserving bone for future use.

Clinical comment

For younger patients, the risk of future revision of their TKA is real.[11–15] A common argument for the use of uncemented TKA is to preserve bone for use in future revision surgery by avoiding the stress shielding and bone mineral density loss associated with cemented fixation.[23]

Available literature and quality of the evidence

The available literature assessing bone mineral density difference between uncemented and cemented fixation is of limited quality. There is a single, small RCT with no power calculations to justify the sample size. There are three cohort studies with only one providing a sample size justification.

Findings

While several cohort studies have reviewed specific implant designs, to date only one RCT has assessed the issue of bone mineral density comparing fixation types. In their small (38 knee) study (level II), they were unable to detect a difference in bone mineral density between fixation groups.[24] A cohort trial of the same size (38 knees) was powered to detect a bone density difference of approximately 28%.[25] They, too, found no difference between fixation types, but were unable to control for preoperative bone density due to the nonprospective design of the study (level III). Small et al. reviewed bone density based on radiographic assessment in matched cohorts of 67 knees.[26] They found no difference between fixation types more than 10 years from surgery (level III). A second

matched cohort study with prospective data collection included preoperative bone densitometry testing (level II). In their cohorts (28 knees in each), they found the bone mineral density declined by 37% (±24%) in the lateral tibia with cemented fixation versus only 7% (±23%) in the uncemented porous tantalum fixation group at two years from surgery ($p = 0.001$).[27] No difference was identified in the medial tibial bone density between groups.

Resolution of clinical scenario

- There is no consistent benefit in maintenance of bone mineral density of the tibia following uncemented TKA fixation.
- There is potential for different implant designs to have differing impacts on long-term bone mineral density of the tibia.
- No clear benefit has been shown to the preservation of bone density based on uncemented versus cemented fixation of TKA.

Summary of answers

- There is no consistent evidence that uncemented TKA improves the implant survival versus cemented TKA in any patient group.
- There is no evidence of differences in clinical outcomes for patients undergoing either cemented or uncemented fixation of their total knee replacement.
- There is no consistent benefit in maintenance of bone mineral density of the tibia following uncemented TKA fixation.

[2] Division of Orthopaedic Surgery, St Michael's Hospital, University of Toronto, Toronto, ON, Canada

Clinical scenario

- A 63-year-old woman who is otherwise independent presents with progressive, symptomatic end-stage tricompartmental osteoarthritis of the knee.
- She has exhausted nonoperative modalities and wishes to proceed with total knee arthroplasty (TKA).

Relevant background

Contemporary TKA designs vary in the degree to which the tibial and femoral articular surfaces are constrained to one another by patient soft tissues versus elements of the prosthesis itself. It is generally accepted that lower-constraint designs are preferable in the context of modest deformity and competent knee ligaments, allowing forces across the knee joint to be maximally absorbed by patients' own soft tissues. In contrast, greater amounts of implant constraint typically require more bone resection may constrain joint motion and result in greater forces on implant components as well as the bone–implant interface, increasing the risk of earlier failure.

The large majority of primary TKA procedures involve the implantation of lower-constraint implants that rely entirely on the medial and lateral collateral ligaments for varus/valgus stability, while sacrificing the anterior cruciate.

However, primary TKA implant designs differ in terms of treatment of the posterior cruciate ligament (PCL). Generally speaking these can be divided into two groups: those that retain the PCL (cruciate-retaining, or CR) and those that sacrifice it (PCL-sacrificing or posterior stabilized, or PS). CR designs have limited conformity between the tibial and femoral articulations, conceptually relying on the retained PCL to limit posterior tibial translation and facilitate femoral rollback in flexion. In contrast, PS designs rely on the tibiofemoral articulations for femoral rollback. Traditionally, this has been achieved through the use of a cam-and-post mechanism, whereby a post on the tibial polyethylene engages with the femoral component as the knee is flexed.

Advocates of CR implants have suggested advantages to their use, including less femoral bone resection, lower risk of iatrogenic fracture, more physiologic knee kinematics, superior function owing to retention of proprioceptive receptors within the PCL, and lower rates of polyethylene liner failure particularly as compared to the cam-and-post design. In contrast, advocates of PS implants suggest benefits, such as greater range of motion (ROM), more predictable outcomes, and lower risk of late instability attributable to PCL rupture.

Importance of the problem

TKA is among the most common contemporary surgical procedures. In 2012, 700 100 knee arthroplasty procedures were performed in the United States, making it the most

common operating room procedure with a population rate of over wo surgeries per 1000 people.[1] In addition to being common, surgical treatment of knee osteoarthritis represents a considerable healthcare cost burden. In 2013, osteoarthritis was the second-most-expensive condition billed to Medicare, and the most expensive condition billed to private insurance in the United States.[2] Although TKA has shown good results in decreasing pain and improving function in patients with symptomatic degenerative disease, up to 20% of patients remain dissatisfied with the results of their surgery.[3] Considering the marked health economic burden of TKA, and the notable patient dissatisfaction rate with this procedure, it is critical that evidence-based decisions be made around implant selection so as to maximize healthcare value.

Top three questions

1. In older active patients with osteoarthritis of the knee, is the use of CR TKA implants associated with differences in patient-reported clinical outcomes as compared to PS designs?
2. In older active patients with osteoarthritis of the knee, is the use of CR TKA implants associated with differences in implant survival as compared to PS designs?
3. In older active patients with osteoarthritis of the knee, is the use of CR TKA implants associated with differences in ROM as compared to PS designs?

Question 1: In older active patients with osteoarthritis of the knee, is the use of CR TKA implants associated with differences in patient-reported clinical outcomes as compared to PS designs?

Rationale and clinical comment

TKA is an elective procedure, with the primary therapeutic goals of improving patients' function and quality of life. Consequently, assessment of the outcomes of this procedure should be made from the patient's perspective. Thus, it is important to consider whether the choice of CR versus PS implants results in any difference in outcomes of the surgery from the patient perspective, as measured using validated patient-reported outcome measures.

Available literature and quality of the evidence

Multiple randomized controlled trials (RCTs) are available assessing this question. Four of these were summarized in a Cochrane review published in 2013.[4–8] A literature search of Embase and Medline databases identified an additional seven subsequently reported RCTs.[9–15] Thus, a total of 11 randomized trials were used to address this question, all with a level of evidence of I. Given this available evidence, no lower-quality studies were used to address this question.

Findings

A Cochrane review that included studies published up to December 2012 found no significant difference in patient-reported outcome scores between CR and PS TKA across

four studies that used the Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC).[13–16] One more recent study was identified that reported WOMAC scores, which found a mean difference in WOMAC scores of 3.8 points (significant difference [SD] 2.8 points; p <0.001) favoring an ultra-congruent PS liner over a CR implant in 210 knees. Pooled results from these studies encompassing 641 knees at follow-up times from 24 to 87 months found an absolute difference in scores of 2.11 points in favor of PS knees (95% confidence interval [CI]: −0.11–4.33 points),[12] which narrowly missed statistical significance and is unlikely to reach the threshold of a minimal clinically important difference (MCID). The overall quality of evidence was low, with a frequently unclear or high risk of bias.

Four studies were identified that reported Visual Analog Scale scores for knee pain,[13,14,17,18] with no significant differences identified. Pooled results encompassing 315 knees at follow-up times ranging from one to six years found no significant difference in outcomes (1.44 mm on a 100 mm scale in favor of PS; 95% CI: −1.8–4.68 mm).

Of the remaining four studies, three reported individual WOMAC domain scores only,[9,10,15] while one reported individual domain Knee Osteoarthritis Outcome Scores (KOOS) only.[11] Of these, one study identified worse WOMAC pain subdomain scores in those patients who received a PS design (mean 4.2 points vs 2.5 points; p = 0.043), but no difference in other domains.[15] The remaining studies did not identify any significant differences in any PROMs.

Overall, the presently available evidence is limited somewhat by relatively small individual studies and variability in both outcome measures and follow-up intervals. Nevertheless, it is possible to say with moderate

certainty that there is no clinically relevant difference in patient-reported outcomes of TKA associated with the use of CR as compared to PS designs.

Resolution of clinical scenario

In terms of patient-reported outcomes of TKA, the best available evidence suggests no difference in outcomes associated with the use of CR versus PS designs. In the absence of other factors, and assuming the surgeon is comfortable with both designs, either would be an excellent choice for this patient.

Question 2: In older active patients with osteoarthritis of the knee, is the use of CR TKA implants associated with differences in implant survival as compared to PS designs?

Rationale and clinical comment

Mean life expectancies in the developed world are continuing to increase, and are currently approaching or exceeding 80 years of age. In contrast, the prevalence of total knee replacement in younger patients, including those under 50 years of age, is rising. While total knee replacement in younger patients has been shown to be effective at improving quality of life, it is also associated with higher risks of revision.[19],[20] Given the considerable patient and health resource burden associated with revision surgery, as well as the more modest outcomes achieved as compared to primary surgery, both patients and surgeons should seek strategies to maximize the survival of a well-functioning primary TKA.

Available literature and quality of the evidence

Multiple RCTs are available to assess this question, although in all cases data were reported as incidental comments within the manuscript and were not included among the primary or secondary outcome measures. Seven of these studies were summarized in a Cochrane review published in 2013. A literature search of Embase and Medline databases identified an additional three subsequently reported RCTs that included survivorship data.[10],[12],[16] One of these is an update of the report from Chaudhary et al. included in the Cochrane review.[10] Thus, a total of nine randomized trials were used to address this question, all with level I evidence.

Given that none of the identified studies included implant survival among the reported primary or secondary outcome measures, an additional search was performed of the English-language reports of available national joint replacement registries. This search identified two joint registries that reported data relevant to the question.[20],[21] These reports could be considered level III evidence, although there is some debate regarding the appropriateness of applying the traditional hierarchy of clinical evidence to registry data.[22]

Findings

No single available study included implant survival as an outcome measure, and the Cochrane review did not report any pooled results across studies. Both aggregated data from the nine identified studies, as well as results of joint replacement registries, suggest a possible small survival advantage for CR knees, albeit with a high degree of uncertainty.

When aggregated, the nine identified studies included a total of 741 CR knees and 735 PS implants with follow-up times ranging from 2 to 10 years. Among these, six CR implants were reported to have been revised, as were eight PS implants. This represents revision rates of 0.8 and 1.1% for CR and PS knees, respectively. However, it must be recognized that the quality of this evidence is low, given that survival was not tracked as an outcome measure in any study, as well as heterogeneity in follow-up times and lack of available statistical analysis of pooled results.

Data from the United Kingdom and Australian joint replacement registries support a small survival advantage for CR knees at follow-up times over 10 years. The Australian Joint Replacement Registry reports significantly lower revision rates for CR knees at 10-year follow-up (5.0% [95% CI: 4.9–5.2%] vs 6.1% [95% CI: 5.9–6.3%]), a trend that persists at 15 years but narrowly misses significance (7.1% [95% CI: 6.8–7.3] vs 8.2% [95% CI: 7.2–9.2]). A similar survival advantage for CR knees is reported by the United Kingdom's registry at 13-year follow-up, with absolute difference in revision rates of 0.87% (3.82% [95% CI: 3.66–3.96] vs 4.69% [95% CI: 4.43–4.96]). Although the number of knee replacements tracked by each of these registries is in the hundreds of thousands, the quality of the evidence remains low as a result of the high risks of bias and confounding, and other weaknesses inherent in observational cohorts.

Resolution of clinical scenario

Although there may be a small survival advantage for CR implants, the absolute magnitude of this difference is small and the quality of evidence low. In the absence of other factors, the use of a CR design can be considered in this patient. However, this should only be done if the surgeon is comfortable using these implant designs.

Question 3: In older active patients with osteoarthritis of the knee, is the use of CR TKA implants associated with differences in ROM as compared to PS designs?

Rationale and Clinical Comment

As total knee replacement has become more reliable in providing relief from arthritis pain, there has been increasing emphasis on restoring patient function. Advanced knee arthritis is frequently characterized by restricted ROM, and both patients and surgeons may expect to see improvements in the arc of motion following arthroplasty surgery. Some authors have suggested that a minimum of 110° of flexion is required to successfully complete a range of activities of daily living,[23] with increasing motion being associated with improved postoperative function up to an optimal arc of approximately 130°.[24–26] In some patient populations and cultures, even greater postoperative flexion may be desirable to allow participation in social and religious activities that require kneeling.[27] Given this, any differences in postoperative ROM associated with CR versus PS designs may be relevant to both surgeons and patients in decision-making around knee replacement surgery.

Available literature and quality of the evidence

Multiple RCTs are available assessing this question. Eleven of these were summarized in a Cochrane review published in 2013.[4,5,7,17,18,28–34] A literature search of Embase and Medline databases identified an additional six subsequently

reported RCTs.[9,12–16] Thus, a total of 17 randomized trials were used to address this question, all with level I evidence. Given this available evidence, no lower-quality studies were used to address this question.

Findings

Pooled data from 11 studies as reported in the Cochrane review from 2013 demonstrated a statistically significant, albeit likely clinically insignificant, advantage for PS knees in terms of total ROM.[4,5,7,17,18,28–34] A small difference in flexion favoring PS knees narrowly failed to reach significance. Over a total of 1440 knees, PS implants demonstrated a mean of 2.4° greater ROM (95% CI: 0.13–4.61°) and 1.5° greater flexion (95% CI: −0.24–3.15°). In contrast, there was no significant observed difference in extension, with mean difference of 0.36° (95% CI: −0.63–1.36°). The authors of the review reported overall low quality of evidence, citing multiple studies with high of frequently unclear risk of bias.

The results of the six more recent trials are consistent with these findings, with five of these studies finding significant advantages in terms of ROM and/or flexion for PS knees,[12–16] and the sixth finding no difference between groups.[9] Rajgopal et al. evaluated total arc of motion, finding a mean difference of 4.6° (95% CI: 3.7–5.4°).[12] Of the five studies that evaluated flexion, four reported sufficient data for pooling.[13–16] Overall, the quality of evidence from these more recent studies is moderate, with some uncertainty around randomization methodology and follow-up intervals in isolated studies.

When pooled across all 12 available studies encompassing 1650 patients, the use of PS implants was associated with a 2.98° (95% CI: 2.03–3.92) greater arc of motion. Similarly, when pooled across all 13 studies encompassing 1165

patients, the use of PS implants was associated with a 3.59° (95% CI: 1.44–5.75) greater maximum flexion angle.

Overall, the available evidence consistently demonstrates an advantage in terms of both flexion and total ROM for PS TKA, with moderate certainty. However, in the absence of accepted MCIDs for these outcomes, the clinical relevance of these differences remains debatable.

Resolution of clinical scenario

Although PS implants appear to be associated with greater ROM and flexion, the clinical relevance of this difference remains uncertain, and this does not appear to consistently translate into improved patient-reported outcomes. Thus, in the general population, either a CR or PS implant remains and excellent choice. In patients whose specific postoperative activity goals include the need for deeper flexion (e.g. frequent kneeling), surgeons and patients may consider preferentially using a PS implant. However, any associated incremental ROM may not be clinically significant, and must be weighed against the surgeon's technical comfort and the potential for decreased survivorship.

Summary of answers

- The use of CR TKA implants is not associated with any differences in patient-reported clinical outcomes as compared to PS designs.
- The use of CR TKA implants may be associated with a small improvement in implant survival as compared to PS designs, although the quality of evidence supporting this is low.

- The use of CR TKA implants is associated with a lesser arc of motion (between 2–4°) and flexion (between 1 and 6°) as compared to PS designs as supported by moderate quality evidence, although the clinical significance of these differences remains unclear.

39 Patellar Resurfacing in Total Knee Arthroplasty

Michael G. Zywiel MD MSc FRCSC, Rajiv Gandhi MD MSc FRCSC, and Nizar N. Mahomed MD ScD FRCSC
Division of Orthopaedic Surgery, Toronto Western Hospital, University of Toronto, Toronto, ON, Canada

Clinical scenario

- A 67-year-old woman with end-stage tricompartmental osteoarthritis of the knee, and who is otherwise independent, undergoes elective total knee replacement.
- She asks her surgeon whether she will have the underside of her patella resurfaced as part of the procedure.

Introduction

Since the introduction of the total condylar knee prosthesis in the 1970s, virtually all total knee arthroplasty (TKA) surgery is characterized by complete resection of the distal femoral and proximal tibial articular surfaces, and replacement with synthetic materials. Consequently, all abnormal cartilage and subchondral bone associated with osteoarthritis is removed from the primary weight bearing surfaces of the knee joint. Although there is little controversy about the routine resection of the femoral and tibial articular surfaces in the setting of multicompartmental osteoarthritis of the knee, optimal management of the patellar articular surface is less clear. Some knee surgeons advocate leaving the native patellar surface intact, others recommend routine resurfacing with

a polyethylene component, while yet others recommend selective resurfacing based on one or more patient factors and/or intraoperative findings.[1]

Top four questions

1. In older active patients with osteoarthritis of the knee, is patellar resurfacing associated with differences in patient-reported clinical outcomes as compared to nonresurfacing?
2. In older active patients with osteoarthritis of the knee, is patellar resurfacing associated with differences in objective functional outcomes as compared to nonresurfacing?
3. In older active patients with osteoarthritis of the knee, is patellar resurfacing associated with differences in complications (anterior knee pain, and complications other than anterior knee pain) as compared to nonresurfacing?
4. In older active patients with osteoarthritis of the knee, is patellar resurfacing associated with differences in reoperation rates as compared to nonresurfacing?

Available literature and quality of the evidence

A considerable body of higher-quality evidence was identified to answer these questions. A search of Medline and EMBASE databases identified 11 English-language meta-analyses of randomized and/or quasi-randomized controlled trials that address one or more of these questions,[2–12] with publication dates spanning from 2005 until 2018. These meta-analyses aggregate data from between 8 and 28 individual level I and II studies published

between 1982 and 2015, with a total of 53 studies appearing in one or more meta-analyses.

Question 1: In older active patients with osteoarthritis of the knee, is patellar resurfacing associated with differences in patient-reported clinical outcomes as compared to nonresurfacing?

Rationale and clinical comment

The primary goals of total knee replacement surgery are to improve patients' quality of life on an elective basis, specifically in terms of reducing pain and functional limitations associated with degenerative disease of the *Knee* Consequently, any assessment of the relative outcomes of knee replacement surgery with or without patellar resurfacing should be made from the patients' perspective, using validated patient-reported outcome measures (PROMs). Patient-reported outcome measures reflect the results of surgery that matter most to patients. They have a high importance when determining the effectiveness of TKA in treating patient symptoms, as well as when comparing different surgery performed using different techniques or implants. Although TKA can affect general health, joint/disease-specific patient-reported outcomes are more sensitive in detecting differences in outcomes of this procedure.

Available literature and quality of the evidence

Of the 11 meta-analyses identified, four specifically assessed for differences in patient-reported outcomes

following TKA with or without patellar resurfacing.[2,7,9,12] These four meta-analyses synthesized data from between 5 and 9 individual controlled trials, encompassing between 456 and 1102 individual TKA procedures. Three of these meta-analyses assessed patient satisfaction,[7,9,12] while the fourth assessed patient-reported general knee pain using a Visual Analog Scale (VAS).[2]

None of the meta-analyses assessed outcomes in terms of validated joint-specific outcome measures. Consequently, Medline, Embase, and the reference lists of all 11 meta-analyses were searched to identify individual studies that assessed outcomes using joint-specific PROMs, with three level I studies identified.[13–15] Given this available evidence, no lower-quality studies were used to address this question.

Findings

Three meta-analyses synthesized data from between five and nine studies to assess in the impact of patellar resurfacing on patient satisfaction with surgery,[7,9,12] with all three finding no significant difference between groups. Two meta-analyses pooled data from five and nine trials respectively to determine aggregate satisfaction rates,[9,12] with both finding near-identical proportions of satisfied patients in both groups, ranging from 90.0 to 92.1% among patients who underwent patellar resurfacing, and between 89.1 and 89.3% in patients who did not. The relative risk for dissatisfaction after TKA failed to reach significance in all three meta-analyses, with a 95% confidence interval (CI) spanning one in all cases.

One network meta-analysis with inclusion criteria limited to level I trials compared 10-point VAS pain scores between three groups of patients across nine studies who underwent TKA: those with patellar resurfacing (n = 154), those with patellar denervation but no resurfacing (n = 135), and

those with no denervation or resurfacing (n = 167).[2] Analysis of pooled results failed to identify any significant unadjusted mean difference (UMD) in pain scores associated with patellar resurfacing, irrespective of whether unresurfaced patellae were (UMD 0.11 points [−0.21 to 0.43]) or were not (UMD 0.11 [−0.21 to 0.44]) denervated.

Three individual trials were identified that reported joint-specific patient reported outcomes, none of which identified any significant differences associated with patellar resurfacing.[13–15] Two trials reported components of the Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC) at follow-up times between 1 and 10 years,[14,15] while one reported the Knee Osteoarthritis Outcome Score (KOOS) at three months to six years.[13] All three studies were limited by small sample sizes (ranging from 16 to 54 per group) and notable loss to follow-up. Differences in reporting (absolute vs change scores, time intervals) precluded pooling of WOMAC scores across the two studies. While a number of meta-analyses reported outcomes measured using surgeon-reported outcome measures such as the Knee Society Score (KSS) or Hospital for Special Surgery (HSS) knee score, nonpooled PROM data.

Overall, while a number of studies have reported differences in patient satisfaction associated with patellar resurfacing in TKA, the presently available evidence is limited by infrequent reporting of validated joint-specific PROMs and variability in reporting. It is possible to say with moderate-to-high certainty that there is no clinically relevant difference in patient-reported satisfaction with TKA associated with patellar resurfacing versus nonresurfacing. While the available evidence suggests no difference in joint-specific PROMs associated with patellar

resurfacing, certainty in this finding is low owing to marked limitations with the available evidence.

Resolution of clinical scenario

In terms of patient-reported outcomes of TKA, the best available evidence suggests no difference in patient satisfaction with surgery irrespective of whether or not the patellar is resurfaced. However, insufficient evidence is available to guide decision-making around patellar resurfacing based on potential differences in joint-specific PROMs

Question 2: In older active patients with osteoarthritis of the knee, is patellar resurfacing associated with differences in objective functional outcomes as compared to nonresurfacing?

Rationale and clinical comment

Many patients with symptomatic osteoarthritis are otherwise healthy and independent in their community. However, many also complain of significant functional limitations secondary to the pain and stiffness of knee osteoarthritis, such as limited walking tolerance, difficulty with climbing and descending stairs, and need for a walking aid. Patients frequently cite these functional limitations as reasons to pursue knee replacement surgery, with an implicit or explicit desire to return to pre-disease function. Given these common expectations of TKA surgery, surgeons and patients may wish to know whether this

outcome might be affected by the decision of whether to resurface the patella at the time of surgery.

Available literature and quality of the evidence

Of the 11 meta-analyses identified, eight specifically assessed for differences in objective function scores following TKA.[2,3,5–9,11] However, one study did not pool results citing excessive heterogeneity.[11] As a result, seven meta-analyses reported sufficient data to address this question, pooling data from between 3 and 14 individual trials, encompassing between 507 and 2194 knees. All seven meta-analyses evaluated objective functional outcomes using the Knee Society Function Score (KSFS). Given this available evidence, no lower-quality studies were used to address this question.

Findings

All seven meta-analyses consistently found no significant difference in mean KSFS – a clinician-reported outcome score evaluating walking tolerance, stair climbing ability, and reliance on a walking aid – irrespective of whether the patella is resurfaced at the time of TKA.[16] Pooled results revealed mean differences in scores of between 0.16 and 2.58 points on a 100-point scale, with 95% CIs crossing 0 in all cases. One study performed subgroup analyses, finding no difference in functional outcomes even when pooled analysis was limited to follow-up intervals of more than five years; mean difference of 1.82 (−1.44 to 5.08) points.[3] No other measures of objective function were reported in the identified studies.

Resolution of clinical scenario

Based on the available evidence, it is possible to say with high certainty that patients and clinicians can expect to

achieve similar objective function following TKA in terms of walking tolerance, stair climbing ability, and need for a walking aid, irrespective of whether the patella is resurfaced. Consequently, the decision of whether to resurface should not be made based on expected differences in objective function following recovery.

Question 3: In older active patients with osteoarthritis of the knee, is patellar resurfacing associated with differences in complications (anterior knee pain, and complications other than anterior knee pain) as compared to nonresurfacing?

Rationale and clinical comment

With survival rates exceeding 90% at 15 years, total knee replacement is among the more successful modern surgical interventions. Nevertheless, studies have suggested that around 20% of patients may be dissatisfied with the results of TKA, with persistent pain among the more common reasons.[17] With around 700 000 primary TKA procedures performed annually in the United States alone,[18] significant numbers of otherwise well patients may be left dissatisfied with the results of their surgery.

Some authors have suggested that a failure to resurface the patella during TKA may result in higher rates of persistent pain, particularly in the anterior aspect of the knee.[1] However, others argue that the link between retention of the native patellar articular surface and persistent pain are unclear, and that resurfacing may in fact increase the risk of other patellar complications.[1]

Given the large number of TKAs performed in the developed world, the potential impact of patellar resurfacing on anterior knee pain and patellofemoral complications may be of interest to both surgeons and patients as part of surgical decision-making.

Available literature and quality of the evidence

Of the 11 meta-analyses identified, 10 specifically assessed for differences in anterior knee pain and/or other related complications associated with patellar resurfacing.[2,3,5–12] One study did not pool data as a result of excessive heterogeneity.[11] All of the remaining nine meta-analyses evaluated differences in knee pain, while three additionally evaluated the risk of other related complications including patella fracture, pain with climbing stairs, or a composite measure of patellofemoral complications.[2,9,12] The nine studies that reported sufficient data to address this question pooled data from between 7 and 13 individual trials, encompassing between 634 and 2453 knees. Given this available evidence, no lower-quality studies were used to address this question.

Findings

The nine studies evaluating the relationships between patellar resurfacing and postoperative anterior knee pain consistently identified considerably lower rates of anterior knee pain in patients who had undergone patellar resurfacing, but confidence in these findings was low as a result of high heterogeneity between studies.

Five studies reported aggregate rates of persistent anterior knee pain summed across individual trials, and all five found that rates were approximately twice as high in patients with unresurfaced patellae.[6–9,12] Pooled rates of anterior knee pain ranged from 7.6 to 16.2% in knees with

resurfaced patellae, compared to between 15.9 and 26.2% in unresurfaced knees. However, the results of meta-analyses were less consistent. Only three studies identified significant differences in anterior knee pain favoring patellar resurfacing: two found risk ratios of 0.39 (0.20–0.75) and 0.40 (0.19–0.85),[9,10] and one reporting an odds ratio of 0.58 (0.45–0.75).[8] The remaining six studies all reported risk ratios favoring patellar resurfacing between 0.63 and 0.97, but with CIs spanning one.[2,3,5–7,12] Three studies reported absolute risk reduction associated with resurfacing ranging from 13.8 to 0%,[3,5,10] with only one of the three observed differences reaching statistical significance.[10]

Meta-analyses of other patellar complications similarly appear to, on balance, favor resurfacing. One study that pooled data from 254 knees in two trials found significantly lower rates of stair climbing pain associated with patellar resurfacing (12.7% vs 26.4%; RR = 0.43 [0.22–0.83]),[9] while a second that pooled data from 3220 knees in 14 trials found significantly lower rates of any patellofemoral complications following resurfacing (5.9% vs 12.6%; RR = 0.55 [0.34–0.90]).[12] While some authors have suggested that patellar resurfacing may be associated with an increased risk of patellar fracture,[19,20] a recent meta-analysis that pooled data from 2791 knees in 11 trials found no differences in patellar fracture rates irrespective of whether or not resurfacing was performed (RR = 1.12 [0.49–2.52]).[2,14,21–30]

Resolution of clinical scenario

On balance, it appears that patellar resurfacing is associated with considerably lower rates of postoperative anterior knee pain, as well as with lower rates of pain associated with stair climbing and overall patellofemoral

complication rates. These differences may very well be clinically significant, with absolute risk differences potentially exceeding 10%. However, certainty in these findings, particularly the magnitude of difference, is hampered by considerable heterogeneity between studies. Nevertheless, patients and clinicians can have moderate certainty that routinely resurfacing the patella at the time of TKA will result in clinically meaningful reduction in anterior knee pain and overall patella-related complications following surgery.

Question 4: In older active patients with osteoarthritis of the knee, is patellar resurfacing associated with differences in reoperation rates as compared to nonresurfacing?

Rationale and clinical comment

The need to undergo reoperation following primary knee replacement surgery is an undesirable outcome for all involved. It is necessarily associated with additional costs for the healthcare payor, and frequently places incremental financial and psychosocial burden on the patient. It also exposes the patient to additional perioperative risks that can have devastating consequences. While patients and surgeons are rarely keen to pursue additional surgery, both may be more willing to consider this when the outcome of index surgery is unsatisfactory. Some authors have suggested that patients with unresurfaced patellae may be more likely to undergo a second operation in an attempt to address persistent postoperative knee pain or otherwise attempt to improve on an unsatisfactory outcome.[1] However, some surgeons may worry that patellar

resurfacing may increase the risk of patellar fracture or other challenging complications that would require reoperation.[1] Given these competing interests, surgeons and patients are likely to want to know whether patellar resurfacing may influence subsequent reoperation rates.

Available literature and quality of the evidence

Ten of the 11 meta-analyses assessed for differences in reoperation rates associated with patellar resurfacing, pooling data from between 10 and 22 individual trials, encompassing between 1003 and 3335 knees.[2,3,5–12] Given this available evidence, no lower-quality studies were used to address this question.

Findings

All 10 meta-analyses found significantly lower reoperation rates in patients who had undergone patellar resurfacing at the time of index TKA. These findings were consistent irrespective of whether the indications were specifically limited to patellofemoral problems (n = 6 studies).[2,5,6,8,9,12] While four studies did not explicitly state any inclusion/exclusion criteria based on reason for reoperation,[3,7,10,11] it is also not clear that all reoperations for any reason were included.

Five studies aggregated reoperation rates across the included trials, consistently finding an absolute difference in reoperation rates of between 3 and 4%.[6–9,12] The reported aggregated reoperation rates with resurfacing ranged from 1 to 4.95%, while those without resurfacing ranged from 4 to 7.8%. Two meta-analyses that assessed absolute risk reduction both reported rates of 4%.[3,5]

Of the nine meta-analyses that reported relative risk, findings ranged from 0.46 to 0.68 in favor of patellar

resurfacing, with 95% CIs remaining below one in all nine.[2,3,5–7,9–12]

Resolution of clinical scenario

The available evidence suggests with high confidence that routine patellar resurfacing is associated with statistically significant and clinically meaningful reductions in reoperation rates for patellofemoral problems following TKA. However, it is less certain from the available evidence whether this holds true for reoperations for any reason. Regardless, surgeons might consider routinely resurfacing the patella at the time of index TKA to decrease the likelihood of subsequent reoperation for patellofemoral pain.

Summary of answers

- Patellar resurfacing in TKA does not appear to be associated with differences in patient-reported outcomes, albeit based on very limited available evidence.
- Patellar resurfacing is not associated with any difference in objective functional outcomes in terms of walking distance, stair climbing ability, and use of a walking aid.
- Patellar resurfacing is associated with meaningfully lower rates of anterior knee pain as supported by moderate quality evidence, and appears to also be associated with lower overall rates of patella-related complications.
- Patellar resurfacing is associated with lower reoperation rates following TKA, particularly for patella-related indications.

40 Mechanical versus Kinematic Alignment in Total Knee Arthroplasty

Pascal-André Vendittoli MD MSc[1], William Blakeney MBBS MSc MS FRACS[2], Charles Rivière[3], and Gene Dossett[4]

[1] Surgery Department, Université de Montréal, Hôpital Maisonneuve Rosemont, Montreal, QC, Canada

[2] Albany Health Campus, Department of Surgery, Albany, Australia

[3] The MSK Lab, Charing Cross Campus, Imperial College London, UK

[4] Phoenix VA Health Care System, Phoenix, AZ, USA

Clinical scenario

- A 65-year-old man with end-stage degenerative knee disease scheduled for total knee arthroplasty (TKA).
- He has slightly bowed lower limbs (varus) and is asking if this will be modified by the surgery.
- He is wondering if there is a TKA technique that could restore his knee anatomy and function.

Top three questions

1. In patients undergoing TKA, does kinematic alignment provide better functional outcomes than mechanical alignment?
2. In patients undergoing TKA, does kinematic alignment (KA) result in different complications compared to mechanical alignment (MA)?

3. In patients with knee degeneration, is KA TKA suitable for all patients' anatomies treated with MA TKA?

Question 1: In patients undergoing TKA, does kinematic alignment provide better functional outcomes than mechanical alignment?

Rationale

A stable knee with a neutral mechanically aligned lower limb MA has been one of the primary surgical aims of TKA,[1] as it provides good long-term implant survivorship.[2] Despite the many improvements in implant design and in the precision of surgery (computer navigation, patient-specific instrumentation and robotics), MA TKA functional outcomes are disappointing (high rates of dissatisfaction and residual symptoms).[3],[4]

Clinical comment

Interest in alternative, more anatomical, surgical techniques like the kinematic alignment (KA) TKA has recently re-emerged,[5] with the hope they would provide better knee kinematics and functional outcomes than MA TKA.

Available literature and quality of the evidence

- Level I: 2 meta-analyses and 4 randomized trials.
- Level II: 1 randomized trial with methodologic limitations.
- Level III: 3 case-control studies.

Findings

At one or two years' follow-up, three randomized controlled trials (RCTs)[6–8] found better clinical scores (Knee Society Score [KSS] and Western Ontario and McMaster Universities Osteoarthritis Index [WOMAC]) with KA TKA, while two others found no significant difference.[9,10] The KA technique demonstrated quicker recovery (measured by the KSS and WOMAC scores), higher rates of forgotten knee, and lower rates of residual pain.[6–8] Five meta-analyses including the above RCTs have also demonstrated improved functional outcomes according to WOMAC, Oxford Knee Score (OKS), and KSS scales, and increased knee flexion with KA compared to MA.[11–15] Another meta-analysis limiting the analysis to studies including patient-specific instruments did not find a difference.[16] None have found improved outcomes for MA.

Mechanical alignment is known to modify knee kinematics and gait.[17] A case-control study demonstrated that MA TKAs displayed several significant knee kinematic differences to a healthy group: less sagittal plane range of motion, decreased maximum flexion, increased adduction angle, and increased external tibial rotation. Conversely, there was no significant knee kinematic differences between KA and healthy knees. The postoperative Knee injury and Osteoarthritis Outcome Score (KOOS) was significantly higher in the KA group compared to the MA group. Similarly, Niki et al. in a matched study of KA and MA TKAs found an increased knee adduction moment in the MA group.[18] Another gait study by McNair et al., however, found little difference between KA and MA.[19]

Resolution of clinical scenario

- With the studies available, KA demonstrates improved clinical outcomes scores at 1–2 years postoperatively compared to MA.
- MA does not replicate normal knee kinematics and gait.
- There is level III evidence that found KA to better replicate healthy knee kinematics.

Question 2: In patients undergoing TKA, does kinematic alignment (KA) result in different complications compared to mechanical alignment (MA)

Rationale

One of the concerns about performing KA TKA is that it might be associated with an increased risk of early failure and other complications. It is therefore important to assess the evidence regarding complications in KA versus MA TKA.

Clinical comment

When considering a new technique for surgery, it is important to compare its clinical performance with the current standard of practice.

Available literature and quality of the evidence

- Level I: 2 meta-analyses and 5 randomized trials.
- Level II: 1 randomized trial with methodologic limitations.
- Level III: 2 case control studies.

Findings

A meta-analysis of an aggregated 877 kinematic TKAs reported a cumulative survivorship of 97.4% at a weighted mean follow-up of 37.9 months.[12] The most common reasons for revision were patellofemoral problems in eight patients (1.2%). There was no difference reported in the complication rate between 229 KA and 229 MA TKA patients (3.9% vs 4.4%, p = 0.83). A second meta-analysis had the same findings.[11]

There were no significant differences in the complications rates seen between the MA and KA groups in all five RCTs at a follow-up of 1–2 years, although all these trials were underpowered to assess the early complication rate.[6–10]

To estimate tibial component long-term survivorship with KA TKA, Laende et al. used radiostereometric analysis in an RCT comparing tibial component migration of TKAs implanted with patient-specific instrumentation targeting kinematic alignment (n = 24) versus components placed using computer-assisted surgery targeting neutral mechanical alignment (n = 23).[20] They found no difference over two years in longitudinal migration of the tibial component between the two groups (reaching median maximum total point motion migration at two years of 0.40 mm for the KA group and 0.37 mm for the MA group, p = 0.82; p = 0.68 adjusted for age, sex, and body mass index [BMI] for all follow-ups). Both groups had mean migrations below acceptable thresholds. There was no difference in inducible displacement (p = 0.34) or patient-reported outcome measures (PROMS) (p = 0.61 for the OKS). Their findings support that KA is a viable option with no evidence that it compromises fixation.

A retrospective review of a single surgeon's database of 2725 TKAs with a minimum follow-up of two years

contained eight patients (0.3%) that presented with tibial component failure.[21] These patients were compared to 24 matched cohort patients to determine the cause of failure. Patients with tibial component failure had a significantly greater BMI (6 kg/m^2; p = 0.034) and greater posterior slope of the tibia component than controls (11° ± 3.1 vs 6° ± 2.7, p = 0.002). There was an increase in the varus position of the tibial base plate in the group with component failure, but this was not statistically significant (4° ± 2.7 vs 2° ± 2.3, p = 0.07).

Resolution of clinical scenario

- Although all RCTs are underpowered to assess with confidence the early complication rate, no obvious increase is seen with KA TKA.
- No RCT has long enough follow-up to evaluate implant survivorship.
- Further long-term follow-up studies are required.

Question 3: In patients with knee degeneration, is KA TKA suitable for all patients' anatomies treated with MA TKA?

Rationale

There are concerns that KA alignment techniques may not be appropriate for extreme patient anatomies. In particular, whether restoring severe constitutional limb valgus or varus, femorotibial joint line obliquity or varus obliquity of the tibial plateau might affect clinical outcomes and/or implant survivorship.

Clinical comment

It is important to know if KA is safe to use for all patients and define those, if any, for which the technique should be modified or avoided.

Available literature and quality of the evidence

- Level I: 4 randomized trials.
- Level II: 2 randomized trial with methodologic limitations.
- Level IV: 5 case series.

Findings

There is currently little clinical evidence about which particular knee anatomies might not be suitable for KA technique. The fundamental premise of KA TKA is to restore the pre-arthritic knee alignment and kinematics. Patients in which disease has modified the knee or lower limb anatomy to such an extent that it cannot be restored by TKA would therefore not be appropriate candidates for KA TKA. Authors have suggested extra-articular deformity, post-traumatic joint modifications, collateral ligament insufficiency, patellar instability, and severe fixed contracture may be contraindications to KA TKA.[22–24] We found no evidence that severe constitutional limb valgus or varus, femorotibial joint line obliquity, or varus obliquity of the tibial plateau might affect clinical outcomes (functional score and implants survivorship) in KA TKA.

Howell et al. looked at 222 KA TKAs at 10 years post-surgery.[25] Implant survivorship was 97.4% for any reason and 98.4% for revisions exclusively for aseptic failure at 10 years. They found no correlation of survival with postoperative limb alignment classified as varus outlier,

valgus outlier, or in-range. There were also no clinical differences seen with tibial components placed in varus alignment.

In their RCT, Calliess et al. found no correlation between preoperative deformities and postoperative outcomes; however, the authors only included mild to moderate deformities (<10° frontal limb deformity and <4° tibial implant obliquity relative to the tibial mechanical axis).[7]

Young et al. reported that 31% of tibias were in >5° varus alignment compared with 4% in the MA group, yet they detected no increase in complications at two-year follow-up.[9] They, however, excluded patients with >15° of varus or valgus deformity preoperatively. Waterson et al. similarly excluded patients with a varus or valgus deformity >10° in their trial.[10] In the RCT by Dossett et al. the range of deformities was only from 11.4° valgus to 9.3° varus.[6] Therefore, most of the trials assessing kinematic alignment do not include extreme anatomies. Almaawi et al. analyzed preoperative CT scans of 4884 patients undergoing TKA and demonstrated the hip–knee–ankle angle (HKA) was >5° in 19% and >10° in 3% of them.[23] It is in these 3% of patients with extreme anatomy that strict kinematic alignment may not be appropriate.

A number of recent case series looking at outcomes from MA TKA have reported no significant difference in long-term survivorship when the postoperative HKA is within ±3° of neutral compared to malaligned knees.[26–28]

Restricted KA protocols have been suggested for patients with extreme anatomies.[20] There is currently little evidence to support their use.

Resolution of clinical scenario

- RCTs of KA to date have not displayed correlation between preoperative deformities and postoperative outcomes at short-term follow-up.
- Many of the trials, however, excluded patients with extreme anatomies.

Summary of answers

- The KA technique generally results in higher functional scores in comparison to the MA technique.
- Early complication rates are comparable to the MA technique.
- There is minimal evidence to support KA use in all patient anatomies.
- Longer follow-up is needed to assess survivorship and define the correct indications for KA techniques in TKA.

Top three questions

1. In subjects without knee pathology, what are the normal collateral ligaments' tensions/laxities during range of motion?
2. In patients with knee degeneration treated with a total knee arthroplasty (TKA), do those with greater ligament stability, compared to those with laxer ligaments, have better clinical results?
3. In patients with knee degeneration treated with a TKA, do some surgical techniques, compared to others, achieve better ligament balance and knee stability?

Question 1: In subjects without knee pathology, what are the normal collateral ligaments' tensions/laxities during range of motion?

Rationale

Understanding the laxity of the collateral ligaments of the native knee, in extension and flexion, may help surgeons to avoid undesirable outcomes following TKA. It may allow for the improvement of implant designs and for the modification of surgical techniques to better restore or preserve the tension of native ligaments.

Clinical comment

With the traditional use of nonanatomical alignment methods and implants in TKA, it is unknown whether the ligament laxities following TKA should replicate the values observed in native knees in order to provide improved knee function, patient satisfaction, and implant survivorship.

Available literature and quality of the evidence

Nine studies that evaluated laxities of the collateral ligaments in the arc of motion of normal knees were identified. These studies are descriptive in nature, using a limited number of living subjects, cadaveric specimens, or reconstructed three-dimensional (3D) models. Quality of evidence: level IV. Moreover, protocols and methods to assess the ligaments' behavior were very different from one study to the next.

Findings

Both collateral ligaments were found to be tighter in extension than in flexion. Comparing both collaterals in extension, a looser lateral collateral ligament (LCL) was reported. This difference in side-to-side LCL laxity increased with greater flexion.[1–9] During knee flexion, a tighter medial collateral ligament (MCL) with a laxer LCL results in posterior translation of the lateral condyle over the lateral tibial plateau, creating internal rotation of the tibia with a medial pivot center of rotation.[4,7,10–12] This internal tibial rotation allows higher postoperative knee flexion[13] and reduces pressure on the patella.[14,15] In papers comparing males and females, females tend to have laxer ligaments than males.[1–8,10,16]

Many authors evaluating collateral ligament laxities identify that MCL tightness plays a major role in native knee function and stability.[4,7,10–12] In addition to its function as the major valgus stabilizer, the deep MCL has a significant role in knee rotational stability, especially with a ruptured or sacrificed anterior cruciate ligament (ACL).[14,16–18] The knee's collateral ligaments laxities are rarely modified in knees with less than 15° of deformity.[19] The biomechanics of a knee that has undergone TKA are different from those of a normal knee. It is therefore unknown if ligament tension values aimed for during TKA should be the same values that are measured in normal knees. Some authors suggest that medial soft tissue releases or femoral component external rotation may loosen the MCL and affect TKA outcomes.[9,14]

Resolution of clinical scenario

- In normal knees, both collateral ligaments are tighter in extension than in flexion, with the LCL laxer than the MCL with increased flexion.

- The MCL plays a major role in valgus and rotational knee stability, especially in the presence of a deficient or sacrificed ACL.
- Medial soft tissue releases when performing a TKA, which leads to increased MCL laxity, which may have a significant impact on postoperative knee function.

Question 2: In patients with knee degeneration treated with a total knee arthroplasty (TKA), do those with greater ligament stability, compared to those with laxer ligaments, have better clinical results?

Rationale

TKA with mechanical alignment (MA) may not replicate collateral ligament laxity/tensions observed in the native knee. Often, surgeons must perform collateral ligament release to adjust the mediolateral (M/L) and flexion/extension balance. Is there clinical evidence that a certain level of collateral ligament laxity and M/L or flexion/extension imbalance would impact patients' function and satisfaction?

Clinical comment

Understanding the postoperative correlation between ligament balance and clinical results may help surgeons to improve their surgical technique, thereby improving their patients' results.

Available literature and quality of the evidence

- 1 level III and 4 level IV studies that evaluated the correlation between ligamentous laxity and clinical and functional outcome were identified in the literature.
- 2 level IV studies that evaluated the extent of acceptable ligamentous laxity were also identified.

Findings

Knee instability after TKA is considered the second most common cause of revision surgeries, with rates varying from 21 to 35%.[20,21] An unbalanced knee is defined as failure to balance the soft tissue envelope to obtain a rectangular flexion and extension gap. Residual imbalance was associated with loosening, polyethylene wear, and failure.[22,23]

Looking at the relation between patient outcomes measured by clinical scores and ligament balance, an M/L gap difference of <3 mm, using an intraoperative tensor and navigation, provided better Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC) scores than larger gaps (84.9 ± 18 vs 74.8 ± 20.8, p = 0.017) in 108 TKA patients.[24] Using a knee balancer in 526 TKAs and defining the unbalanced knee with an M/L difference of more than 3°, a significant difference was found between balanced and unbalanced knees regarding the change in the clinical rating knee score for the extension and flexion balance (t-test, p = 0.046; and ANOVA, p = 0.001, respectively). On the other hand, the authors did not find a significant difference in the change in the Oxford Knee Score.[25]

In a multicenter study involving 176 TKAs, the use of intraoperative pressure sensors helped distinguish balanced from unbalanced knees. Balanced knees were defined as having M/L intercompartmental loading difference ≤15 lb through a range of motion. At six months

postoperatively, balanced patients showed significantly better WOMAC (14.5 vs 23.8, p = 0.0001) and Knee Society Score (KSS) scores (172.4 vs 145.3, p = 0.0001) compared to unbalanced knees.[20] Conversely, a study comparing medial/lateral compartmental force ratio and total contact force found no correlation with functional scores at one year in a cohort of 101 TKAs.[26]

Regarding range of motion and ligament laxity, in a study of 63 TKAs, 78% of slightly loose knees reached more than 100° of flexion compared to 62.5% of tighter knees.[27] Evaluating bilateral TKA patients with different postoperative contralateral laxities (evaluated with stress radiographs, >3° opening was considered loose), 10/11 patients preferred the loose side compared with 11/22 who preferred the other side ($p < 0.05$).[28] Evaluating anteroposterior laxity at 75° of flexion in 93 TKAs, patients with knee laxity >10 mm had significantly inferior KSS (77.0 vs 55.3, p = 0.05) and knee flexion (99° vs 112°, p = 0.01).[29]

Computer navigation may be predictive of the need for ligament release and may reduce systematic over-release.[30] On the other hand, surgeons' appreciation of ligament balance by feeling was shown to be very limited. Without special instruments, the surgeon's perception of balance depends on surgical training, operative experience, and overall skill, but it may be influenced by different patient factors, such as body mass index, gender, and comorbidities.[31],[32]

Resolution of clinical scenario

- It is still not clear what maximal M/L gap difference is acceptable/desirable.

- An unstable TKA is linked with increased complication and revision rates.
- Better M/L balanced TKAs seem to provide higher clinical scores.
- A looser well-balanced TKA seems to be better tolerated by patients than a tighter TKA.

Question 3: In patients with knee degeneration treated with a TKA, do some surgical techniques, compared to others, achieve better ligament balance and knee stability?

Rationale

Numerous TKA surgical techniques have been described to adjust implant position and help balance collateral ligaments in flexion and extension. Determining if one technique is more efficient and/or provides better clinical results would help surgeons performing TKA to obtain better outcomes for their patients.

Clinical comment

Normal knees do not have symmetric M/L collateral ligament balance. Most techniques have been developed for the MA method and aim at creating rectangular extension and flexion gaps.

Available literature and quality of the evidence

- 3 level I and 1 level IV articles compared the difference between measured resection (MR) and gap balancing (GB) techniques.

- 1 level III article on pressure sensors.
- 1 level II article on navigation.
- 4 level I randomized controlled trials (RCTs) and 1 level II RCT with methodologic limitations were found comparing the kinematic alignment (KA) technique and MA method.

Findings

With MA, two main techniques have been used: GB and MR.[33] GB relies on soft tissue release followed by appropriate femoral bone cuts to obtain balanced rectangular gaps in flexion and extension, whilst MR uses anatomical landmarks (the anteroposterior axis, the transepicondylar axis, and the posterior femoral condylar surfaces) to guide bone resection, followed by soft tissue releases to balance the flexion/extension spaces.[29,32]

Comparing implant position and orientation between the two techniques, a meta-analysis found that GB gives significantly better femoral axial ($p < 0.0001$) and rotational alignments ($p = 0.007$) but was associated with more the joint line elevation ($p < 0.00001$).[34] Evaluating ligament balance obtained with GB or MR, a meta-analysis found similar results for both techniques, except for the mean extension gap M/L difference, which was greater in patients undergoing MR technique (0.58 mm; $p = 0.008$). With GB technique, the femoral component was more externally rotated by less than 1° and the joint line was higher by 1 mm. Authors concluded that both methods were equally efficient to balance collateral ligaments.[35] Precise estimation of the ligament balance is difficult to perform during surgery.[31] Different tools, such as balancers, computer navigation, or pressure sensors, have been tested to improve the accuracy of GB and MR techniques. Using

computer navigation on 225 knees, Fickert et al. obtained rectangular gaps with ±3 mm M/L difference in 98% of the cases for the extension gap and 93% of the cases for the flexion gap.[36] Using intraoperative pressure sensors during TKA, M/L pressures within 15 lb of intercompartmental force were obtained in 15% (n = 29); 57% (n = 107) were balanced between 15–75 lb, and 28% (n = 53) with >75 lb of force difference. In this study, greater improvement in the University of California Los Angeles activity level was associated with a M/L force difference <60 lb (p = 0.006), but no correlation was found with KSS objective, function, and satisfaction scores. With a specific knee gap balancer, TKAs were balanced within a M/L difference of 3° or less in 175/218 (80%) knees for the flexion space and 214/218 (98%) knees for the extension space.[25]

Comparing patient outcomes between the MR and GB techniques, a randomized study of 24 single radius posterior-stabilized TKAs found no differences for the WOMAC (p = 0.15) or KSS (p = 0.06), and no difference regarding the frequency of liftoff, were observed.[37] A meta-analysis found that GB gives statistically significant higher KSS (p = 0.04) and KSS Function Score (p <0.0001).[34] A systematic review and meta-analysis of 2259 TKAs concluded that total outliers were lower with GB (risk ratio = 1.72; p = 0.0004) but the two techniques were comparable in range of motion, WOMAC, complications, and revision rate.[38]

Evaluating 1000 lower limb CT scans of patients scheduled for TKA, Blakeney et al. found MA bone resections created significant gap imbalances.[39] Extension space imbalances (≥3 mm) occurred in 25% of varus and 54% of valgus knees and severe imbalances (≥5 mm) were present in up to 8% of varus and 19% of valgus knees. Only 49% of varus and 18% of valgus knees had <3 mm of imbalance throughout

the extension and flexion spaces and medial and lateral compartments. MA techniques such as MR or GB, aimed at rectangular and equal extension and flexion gaps, do not consider the natural higher laxity of the LCL and the increased laxity of the collaterals in flexion.[3,40] Only KA technique aims to maintain/restore the native ligament laxities and joint orientation.[41] Three RCTs found better clinical scores (KSS and WOMAC) with KA,[42–44] while two others found no significant difference.[45,46] Three meta-analyses demonstrated better WOMAC and KSS scores, and increased knee flexion with KA compared to MA,[47–49] while one which limited their analysis to RCTs using patient-specific instruments did not find a difference.[50]

Resolution of clinical scenario

- It is still not clear from the literature what the ideal collateral ligament laxities and joint spaces should be during TKA, especially with current TKA implant designs and MA.
- M/L ligament balance is difficult to estimate during surgery; different tools like knee balancers, computer navigation, or pressure sensors can be used to improve accuracy of GB and MR techniques.
- Comparing GB and MR efficacy to balance joint spaces, no conclusion can be drawn regarding the superiority of one technique over the other.
- KA aims at preserving/restoring native knee collateral ligament laxities and was found to improve clinical scores in comparison to MA.

Summary of answers

- The collateral ligaments play a significant role in knee balance post TKA and should be carefully considered intraoperatively.
- No conclusions can be drawn about gap balancing versus measured resection for achieving mediolateral balance.
- Mediolateral balance is important, but it is unclear what the optimal parameters are.

42 Robotics in Total Knee Arthroplasty

Seper Ekhtiari MD MSc, Vickas Khanna MD, and Anthony Adili MD
Division of Orthopaedic Surgery, Department of Surgery, McMaster University, Hamilton, ON, Canada

Clinical scenario

- You see a 59-year-old female patient in your office who has advanced knee osteoarthritis, primarily in the medial compartment. Her symptoms are limited to the medial compartment and no longer respond to conservative treatment. Her quality of life is also compromised as a result of her symptoms.
- She is interested in her surgical options, and has heard about “robotic surgery” in the news. She asks you about arthroplasty options, including replacing “just the arthritic compartment.”
- As the chief executive officer (CEO) of a different hospital, she is also curious about the impacts of robotic-assisted surgery at a hospital level.

Top three questions

1. In patients undergoing knee arthroplasty, does robotic-assisted surgery result in more accurate component positioning compared to conventional knee arthroplasty?
2. In patients undergoing knee arthroplasty, does robotic-assisted surgery result in improved patient-centered

outcomes compared to conventional knee arthroplasty?

3. In patients undergoing knee arthroplasty, is robotic-assisted surgery cost-effective compared to conventional knee arthroplasty?

Question 1: In patients undergoing knee arthroplasty, does robotic-assisted surgery result in more accurate component positioning compared to conventional knee arthroplasty?

Rationale

One of the most promising aspects of robotic-assisted knee arthroplasty is the achievement of more accurate component positioning by eliminating human error and variability. Thus, it is important to understand if, and by how much, robotic-assisted surgery improves accuracy.

Clinical comment

Despite improvements in technology and technique,[1] about one in five patients undergoing total knee arthroplasty (TKA) are unsatisfied, usually due to persistent postsurgical pain and stiffness.[2] The knee is a complex joint, with simultaneous rotation, pivot, and translation in multiple planes throughout its range of motion.[3] As well, proprioception in the knee is an important aspect of balance, gait, and overall lower limb function.[4] The ability to precisely determine patient-specific bone cuts and implant positioning, while preserving native anatomy may help to create a knee that feels and behaves more like the patient's native knee, thereby resulting in improved

satisfaction. Robotic-assisted surgery has the potential to achieve this level of accuracy.

Available literature and quality of the evidence

Multiple randomized controlled trials (RCTs) have investigated the impact of robotic-assisted surgery on the accuracy of final component position. In 2007, Park et al. reported the results of the one of the earliest studies on robotic knee arthroplasty (level I).[5] They randomized 72 patients to robotic or conventional TKA. They found no difference in the overall mechanical axis alignment between the two groups, but did find that components placed using the robotic-assisted technique were significantly more accurate in terms of component axis and alignment. Similarly, Song et al. (level I) randomized 100 patients to robotic-assisted versus conventional TKA.[6] They found no significant difference between the two groups in terms of overall mechanical axis alignment or tibial component positioning between the two groups. Femoral prosthesis alignment in the coronal plane was significantly more accurate in the robotic-assisted group compared to the conventional group. In addition, there were significantly fewer outliers in terms of mechanical axis alignment in the robotic-assisted group compared to the conventional group (0% vs 24%, $p < 0.001$).[6] Liow et al. randomized 60 patients to robotic or conventional TKA (level I).[7] Once again, they reported no significant difference in terms of mechanical axis alignment, but did find significantly higher rates of coronal plane outliers and femoral notching in the conventional group. In addition, the robotic-assisted group had significantly more accurate restoration of the joint line compared to the conventional group (3.2% shift vs 20.6% shift, $p = 0.001$).[7]

The same appears to be true for unicompartmental knee arthroplasty (UKA). Bell et al. (level I) randomized 139 patients to conventional or robotic UKA. They found that there were significantly fewer errors in component positioning for all components and in all planes.[8]

Findings

Overall, level I evidence suggests that robotic-assisted knee arthroplasty is significantly more accurate than conventional surgery in terms of component positioning, but it does not affect overall mechanical axis alignment.[5–8] There are limitations in postoperative alignment assessment using only plain radiographs, as these measurements are affected by lower limb loading, rotation, and flexion angles. Importantly, most studies report significantly fewer outliers in terms of component positioning with robotic surgery compared to conventional surgery.[6,7] Further, most clinicians' assessments of TKA alignment are based primarily on the coronal plane with less attention given to sagittal plain alignment. Robotic-assisted surgery may be particularly important in patients with significant deformity or bone loss. While conventional surgery may still allow the achievement of an acceptable mechanical axis, accurate component positioning is significantly more difficult in these patients due to the loss of normal anatomical landmarks.

Resolution of clinical scenario

- Level I evidence suggests that robotic-assisted knee arthroplasty *does* result in significantly more accurate component positioning, joint line restoration, and fewer outliers; this is true for both UKA and TKA.
- Level I evidence suggests that robotic-assisted TKA *does not* result in significantly different mechanical axis

alignment.

Question 2: In patients undergoing knee arthroplasty, does robotic-assisted surgery result in improved patient-centered outcomes compared to conventional knee arthroplasty?

Rationale

With robotic-assisted surgery, there is the potential for less invasive, more tissue-friendly, and more patient-specific surgical techniques. Do these technical improvements then translate into the potential for patients to experience faster postoperative recovery and better functional outcomes? It is important to understand if this potential is borne out in clinical practice.

Clinical comment

As with any new healthcare intervention, it is crucial to understand the impact on patient outcomes. Robotic-assisted prostatectomy is one of the first widely used robotic surgical procedures, and has shown promise for improving patient-important outcomes. A recent meta-analysis found that robotic-assisted prostatectomy was associated with better outcomes in terms of blood loss, nerve injury, urinary incontinence, and erectile dysfunction compared to open or laparoscopic surgery.[9] As well, studies of minimally invasive surgery across different surgical specialties have consistently demonstrated lower levels of postoperative pain and faster recovery with less invasive techniques.[10–12] It is important to understand which, if any, of these potential benefits can be expected with current robotic-assisted knee arthroplasty technology.

Available literature and quality of the evidence

A prospective cohort study (level II) by Kayani et al. compared 20 patients undergoing robotic-assisted TKA with 20 patients undergoing conventional TKA.[13] They reported that patients undergoing robotic surgery had significantly lower pain scores and opioid requirements on each of the first three days after surgery. As well, patients in the conventional group had a significantly greater drop in postoperative hemoglobin values compared to the robotic-assisted group. In addition, patients in the robotic-assisted group were discharged over a full day earlier on average compared to the conventional group (delta 28 hours, $p < 0.001$). Finally, at time of discharge, patients in the robotic-assisted group had significantly faster attainment of physiotherapy targets, specifically straight leg raise and maximal knee flexion ($p < 0.001$).

Multiple RCTs have assessed the impact of robotic-assisted TKA on patient-reported outcomes during outpatient follow-up. In their RCT of 72 patients (level I), Park et al. followed patients for approximately four years after surgery. They found no difference between robotic-assisted TKA patients and conventional TKA patients in terms of Knee Society Score (KSS) or range of motion at final follow-up.[5] Song et al. randomized 100 patients to robotic versus conventional TKA (level I), and found that at a final follow-up of 3.5 years, there were no significant differences between the two groups in terms of Hospital for Special Surgery Knee score, Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC) score, or range of motion.[6] Similarly, in their RCT of 60 patients (level I), Liow et al. found no significant differences between robotic-assisted and conventional group patients in terms of KSS, Oxford Knee Score (OKS), or overall patient satisfaction. Interestingly, they did find significantly higher scores on

the SF-36 vitality and role emotional subscales for patients in the robotic-assisted group.[14]

Evidence from an RCT has reported similar findings for robotic-assisted UKA. Gilmour et al., in their RCT of 139 patients (level I), found no significant differences in KSS or OKS scores at two-year follow-up.[15] Data from the same RCT, however, found that patients in the robotic-assisted group had significantly lower pain scores in the first eight postoperative weeks compared to patients in the conventional group ($p = 0.04$).[16] Evidence from a recent RCT of 120 patients (level I) found that patients undergoing robotic-assisted UKA had greater knee excursion between foot-strike and mid-stance (18.0° vs 15.7°, $p = 0.04$) compared to conventional UKA. There were no significant differences in terms of total knee excursion, or excursion from midstance to terminal stance.[17] It is unclear if this small magnitude change in one specific phase of the gait cycle has any patient-important benefits.

Findings

Overall, weak level II evidence, based on a study with a small sample size demonstrates that in the acute and subacute postoperative period, patients undergoing robotic-assisted TKA experience a smaller drop in hemoglobin, lower pain scores and analgesic needs, faster functional recovery, and are discharged earlier compared to those undergoing conventional TKA surgery.[13] Similarly, a single level I study with fewer than 100 patients per arm, suggests that patients undergoing robotic-assisted UKA surgery had significantly lower pain scores in the subacute postoperative period compared to patients undergoing conventional UKA surgery.[16] These conclusions should be

viewed with much caution given the limited sample sizes and quantity of studies.

In contrast, multiple level I studies demonstrate that at two to five years after surgery, there are no significant differences in patient-reported outcomes for those undergoing conventional TKA or UKA compared to those undergoing robotic-assisted surgery, with the exception of some subscales of the SF-36.[5,6,14,18]

Resolution of clinical scenario

- A single, small, level II evidence study suggests that robotic-assisted TKA *may* result in less pain, faster functional recovery, and shorter inpatient stay compared to conventional TKA surgery.
- Based on a single level I evidence study, patients undergoing robotic-assisted UKA *may* have lower pain scores in the subacute postoperative period compared to conventional UKA.
- Multiple level I studies suggest that robotic-assisted TKA *does not* result in significantly different patient-reported outcomes at two to five years postoperatively.

Question 3: In patients undergoing knee arthroplasty, is robotic-assisted surgery cost-effective compared to conventional knee arthroplasty?

Rationale

As with any new healthcare technology, there are concerns regarding the impact of incorporating robotic-assisted surgery, particularly with regards to the cost of new

devices and additional preoperative investigations. It is important to understand the short- and long-term cost implications of any proposed healthcare technology.

Clinical comment

In order to deliver healthcare effectively, it is important to consider the impact of any new intervention at both the patient level and the systems level. In an era of rising healthcare costs,[19] the micro- and macrolevels of healthcare are more intimately linked than ever. In addition to understanding the discrete cost of incorporating a new technology, it is important to consider complications, learning curves, and impact on operative resources in an effort to gauge the overall cost-effectiveness of the intervention.

Available literature and quality of the evidence

Evidence from RCTs has produced mixed results in terms of differences in operative time for robotic versus conventional TKA. Liow et al. found no difference in operative time between the two groups in their RCT of 60 patients (level I).[14] In contrast, Song et al. (level I) found significantly longer operative times by 25 minutes in the robotic-assisted group compared to the conventional group ($p < 0.001$).[6]

Evidence from a case series (level IV) demonstrates that the learning curve required for robotic-assisted TKA is about 20–40 cases for each surgeon, after which time there are no significant differences in operative time between robotic-assisted and conventional surgery. The authors suggested that early in the learning curve there was likely to be increased cost due to longer operative times and less expertise, though this was not assessed empirically.[20] For UKA, level II evidence demonstrates a learning curve of

only six cases to reach the same operative time as conventional surgery.[13]

Based on a Markov decision analysis (level II), robotic-assisted UKA was determined to be cost-effective in high-volume UKA centers (>94 cases/year), but not in lower volume centres.[21] No peer-reviewed, evidence-based economic analysis is available for robotic-assisted TKA. There is, however, a registered prospective cohort study that is underway with the specific goal of answering this question.[22]

Evidence from RCTs (level I) has demonstrated no difference in complication rates between robotic-assisted versus conventional knee arthroplasty; this is true for both TKA[6],[7] and UKA.[18] Finally, as mentioned above, level II evidence has found that patients undergoing robotic-assisted surgery are discharged over a full day earlier than those undergoing conventional surgery.

Findings

Overall, there is a lack of direct, evidence-based economic analysis to help determine whether robotic-assisted TKA is cost-effective. There is, however, level I–IV evidence that, when considered together, suggests that cost-effective robotic-assisted TKA is an attainable goal. Specifically, limited level I and II evidence has thus far shown a short learning curve for robotic UKA,[13] and has found that robotic UKA may have the potential to be cost-effective in high-volume centres.[21] Furthermore, complication rates and operative times are not significantly different between robotic and conventional knee arthroplasty, particularly once the learning curve has passed.[6],[7],[14],[18] Finally, robotic-assisted surgery may lead to shorter inpatient stays following knee arthroplasty. Taking into consideration this body of evidence, it is hypothesized that robotic-assisted

TKA can be cost-effective in high-volume TKA centers, though empirical economic analysis is needed to confirm this.

Resolution of clinical scenario

- A single study (level II evidence) demonstrated that robotic-assisted UKA *may* be cost-effective in high-volume centers (>94 cases/year).
- Level I evidence demonstrated *no difference* in complication rates for robotic versus conventional TKA or UKA.
- Level I evidence demonstrated *mixed evidence* regarding operative times for robotic versus conventional TKA, with some studies reporting longer times for robotic surgery, while others report no significant difference between the two.

Summary of answers

- Robotic-assisted knee arthroplasty results in more accurate component placement compared to conventional surgery, but it does not impact overall mechanical axis alignment.
- Based on very few, small studies, patients undergoing robotic-assisted knee arthroplasty may experience faster functional recovery, shorter inpatient stays, and lower pain levels in the acute and subacute postoperative periods, though larger studies are needed to truly assess this issue.
- There is no significant difference on the majority of patient-reported outcome measures at medium-term follow-up.

- Complication rates and operative times are similar between robotic-assisted and conventional knee arthroplasty after a brief learning curve.
- Based on a recent economic analysis, robotic-assisted UKA is cost-effective in large-volume UKA centers.

43 Patient-Specific Instrumentation in Total Knee Arthroplasty

Seper Ekhtiari MD MSc, Luc Rubinger MD, Vickas Khanna MD, and Anthony Adili MD
Division of Orthopaedic Surgery, Department of Surgery, McMaster University, Hamilton, ON, Canada

Clinical scenario

- You see a 65-year-old male patient in your office with tricompartmental knee osteoarthritis. He is quite symptomatic and is no longer responsive to nonoperative management.
- He is interested in total knee arthroplasty (TKA), and has heard about “personalized” implants on social media. He would like to know if such implants are better than standard implants.
- When you ask your company representative about patient-specific instrumentation (PSI) options, she tells you that some systems use computed tomography (CT), while others use magnetic resonance imaging (MRI). You wonder if there is a difference between the two.

Top three questions

1. In patients undergoing TKA, does PSI result in better radiographic outcomes compared to standard instrumentation?
2. In patients undergoing TKA, does PSI result in better functional outcomes compared to standard instrumentation?

3. In patients undergoing TKA with PSI, are CT-based PSI systems more accurate than MRI- based PSI systems?

Rationale

PSI has increased in popularity in recent years as orthopedic surgery responds to the growing trend of *personalized medicine*. This technology utilizes the patient's own anatomy, as visualized on advanced imaging, to create anatomically matched instruments, such as cutting jigs, to be used in that patient's operation. The hypothesized advantages of PSI are preoperative planning to minimize bony resection thus resulting and more accurate component positioning compared to standard instrumentation.[1]

Clinical comment

Overall, TKA is quite successful. A recent systematic review of 208 studies found that the majority of studies reported a patient satisfaction rate of 81–90% as measured by a response of “satisfied” or “very satisfied” on a five-point Likert scale. The median rate of satisfied patients was 88.9%.[2] Nonetheless, this leaves 10–20% of patients who undergo a major elective operation that are not satisfied with their outcome. It has been hypothesized that this may be due, at least in part, to component malpositioning, which occurs in up to 40% of cases.[3] PSI has the theoretical benefit of making accurate alignment technically easier, but it is important to understand whether this benefit is supported by evidence.

Available literature and quality of the evidence

Multiple randomized controlled trials (RCTs) have compared PSI to standard instrumentation in terms of radiographic outcomes. A recent meta-analysis of RCTs

(level I) analyzed 23 RCTs published before March 2018, involving a total of 2058 knees, with all patients randomized to either PSI or standard instrumentation.[1] A number of radiographic measures were used to judge component position accuracy, and most commonly included: hip–knee–ankle axis (HKA), coronal, sagittal, and axial alignment of the femoral component, and coronal and sagittal alignment of the tibial component. No new RCTs have been published since the aforementioned meta-analysis was performed and this publication was produced.

Findings

Based on the pooled estimate from trials assessing HKA as an outcome, there was no significant difference between PSI and standard instrumentation in terms of >3° deviation from target alignment (180°) or number of outliers. In fact, only 1 out of 14 trials found a significant difference in number of HKA outliers, favoring PSI.[1]

Coronal alignment of the femoral component was assessed in 13 RCTs. Meta-analysis revealed no significant difference between PSI and standard instrumentation patients with regards to absolute deviation from target alignment (90°) or number of outliers. Similarly, the sagittal alignment of the femoral component, from eight RCTs, was not found to be significantly different between the two groups in terms of absolute deviation or outliers. When assessing axial alignment of the femoral component, there was no significant difference between the two groups in terms of number of outliers. There was, however, a significant difference in terms of absolute deviation from target alignment (mean difference: −0.46, $p = 0.0004$, $I^2 = 48\%$). In the context of moderate heterogeneity ($I^2 = 48\%$, $p = 0.05$), this finding should be interpreted with caution.[1]

Tibial component alignment was also assessed in the sagittal (nine RCTs) and coronal (14 RCTs) planes. There was no significant difference either in terms of absolute deviation from the desired target (90°) or in terms of outliers.[1]

Overall, there are a large number of RCTs which have assessed whether PSI improves component positioning accuracy. Though each RCT in isolation must be interpreted with caution (no study randomized 100 or more patients per arm), a recent meta-analysis of these RCTs (level I) provides fairly robust data overall. There are clearly limitations in the postoperative measurement of component alignment. This produces a static image which does not account for changes during weightbearing or range of motion. Nonetheless, the best available evidence suggests that the use of PSI does not result in significantly more accurate tibial component positioning. For the femoral component, PSI may have a small effect (~0.5°) on axial alignment, but not sagittal or coronal alignment.

Interestingly, computer-assisted navigation and robotic-assisted total joint replacement surgery do appear to result in more accurate component positioning. Refer to the following chapters in this book for further details: “The Role of Computer Navigation in Total Hip Arthroplasty” (Chapter 21), “Mechanical versus Kinematic Alignment in Total Knee Arthroplasty” (Chapter 40), and “Robotics in Total Knee Arthroplasty” (Chapter 42).

Resolution of clinical scenario

- Level I evidence suggests that PSI *does not* result in significantly more accurate component positioning compared to standard instrumentation for most parameters.

- The only radiographic benefit of PSI *may* be in terms of the axial alignment of the femoral component, though the effect size is small and associated with moderate heterogeneity.

Question 2: In patients undergoing TKA, does PSI result in better functional outcomes compared to standard instrumentation?

Rationale

Underpinning all efforts to improve TKA is the ultimate goal of improving patient outcomes and satisfaction rates. Though there is a theoretical reason to believe that more accurate component positioning is possible with PSI, further evidence is required to assert that PSI improves outcomes. Thus, it is critical to understand whether PSI confers any clinical benefit in terms of patient-important outcomes.

Clinical comment

Evaluating and understanding the clinical benefits (if any) of any new intervention or technology is important in understanding its utility and communicating this information to patients. A number of potential explanations for patient dissatisfaction following TKA surgery have been proposed; these include stiffness, component malpositioning or malrotation, midflexion instability, subclinical infection, extensor mechanism deficiency, and neuropathic pain.[4] Patient-specific instrumentation has a theoretical potential to alleviate at least some of these concerns, such as component position, unnecessary bony resection, and soft tissue dissection.

Available literature and quality of the evidence

Woon et al. performed a meta-analysis of RCTs (level I) in 2018 (search date May 2016) to assess patient-reported outcomes following PSI TKA versus standard TKA. The study included four RCTs with a total of 458 patients.[5] Due to quite restrictive inclusion criteria, they included significantly fewer RCTs than another meta-analysis of RCTs (level I) published in 2016 by Huijbregts (search date May 2015). Huijbregts et al. included 21 RCTs, involving 1587 patients having undergone TKA.[6]

Findings

In their meta-analysis of four RCTs (level I), Woon et al. assessed four different patient-reported outcome measures. All four outcome measures were reported in all four included RCTs, which were the Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC), and the Knee Society Score (KSS) pain, function scores, and combined scores. Follow-up was between one and two years in all studies and only included cruciate-retaining knees. The meta-analysis found no significant difference between PSI and standard instrumentation on any of the clinical outcomes except for the KSS pain score, which showed an effect size of 3.6 in favor of PSI (95% confidence interval [CI]: 0.18–0.71; $I^2 = 0$).[5]

Huijbregts et al. also looked only at RCTs, but included 21 studies with over 1500 patients. Once again, no individual study randomized 100 or more patients per arm. Patient-reported outcome measures that were analyzed included the KSS, the Short Form 12 (SF-12), Oxford Knee Score (OKS), the Knee injury and Osteoarthritis Outcome Score (KOOS), and the Knee and Function Score. Pooled analysis revealed no significant difference for KSS, KOOS, Oxford or SF-12 scores three months postoperatively.[6] A single study with outcomes at one year found no difference in SF-12

scores, but did find a difference of two points in median OKS in favor of PSI at one year (p = 0.49).

Resolution of clinical scenario

- Level I evidence suggests that PSI *does not* result in improved patient outcomes at up to two years' follow-up.
- There is very little evidence to assess outcomes beyond the short to medium term.

Question 3: In patients undergoing TKA with PSI, are CT-based PSI systems more accurate than MRI-based PSI systems?

Rationale

PSI is available in one of two main ways: (i) through the company providing the TKA implants or (ii) through the hospital, in the form of three-dimensional (3D) planning and printing of instruments, followed by on-site sterilization and packaging.[7] The imaging modalities used to assess patient anatomy and create this instrumentation are also variable, and can be accomplished using CT or MRI.

Clinical comment

New technologies often have ancillary costs that must be considered when assessing their feasibility for introduction into a healthcare system or hospital. The vast majority of PSI systems require either CT or MRI to accurately determine patient anatomy prior to designing and producing the instrumentation. Intuitively, CT scan would be expected to provide a better view of bony anatomy,

whereas MRI is more useful for assessing soft tissue. From a cost perspective, CT is generally cheaper and more available than MRI in most centers. On the other hand, MRI has a more favorable safety profile compared to CT, given that no exposure to radiation is required.

Available literature and quality of the evidence

A meta-analysis of prospective comparative studies (level II) was published in 2017 by Wu et al.[8] Their search was inclusive up to and including June 2016, and their final analysis included six studies and a total of 336 patients. They assessed the proportion of outliers for the following alignment parameters: coronal overall limb alignment, and coronal and sagittal alignment of each component. More recently, Thijs et al. (level I) randomized 124 patients to either CT or MRI for PSI planning and reported implant survival and patient-reported outcomes at two years postoperatively.[9]

Findings

In their meta-analysis of prospective comparative studies, (three RCTs, one nonrandomized study, level II), with a total of 282 patients, Wu et al. found no significant difference between MRI and CT with regards to outliers for femoral or tibial component positioning in sagittal or coronal planes.[8] There was a significant difference in favor of MRI when assessing outliers for overall coronal limb alignment (risk ratio = 1.67; p = 0.04; 95% CI: 1.03, 2.72; I^2 = 0%).

Thijs et al. performed a RCT (level I) and at one-year follow-up had found no difference in hip–knee–ankle axis when using CT or MRI-based cutting guides; however, there were significantly more outliers for posterior tibial slope when using CT guides compared to MRI guides.[10]

Interestingly, at two years' follow-up, there was no difference between the two groups in terms of implant survival or revision surgery. Furthermore, there were no significant differences between the two groups with regards to any of the following patient-reported outcome measures: OKS, WOMAC, Visual Anal Scale (VAS) pain score, EQ-5D (a health-related quality of life measure).

Resolution of clinical scenario

- Level I and II evidence suggests that there *is no* significant difference in accuracy between CT and MRI on most radiographic parameters. There may be some isolated and small advantages in favor of MRI, though further, well-powered studies would be needed to confirm this.
- Level I evidence suggests that there *is not* a significant difference in implant survival or patient-reported outcomes with PSI regardless of the imaging modality used for planning.

Summary of answers

- Based on meta-analysis of many RCTs, patient-specific instrumentation does not result in more accurate component positioning, except perhaps in the case of axial alignment of the femoral component.
- Patient-specific instrumentation does not result in improved outcomes compared to standard instrumentation in TKA.
- There does not appear to be a major difference between CT and MRI for the planning and production of PSI. Thus, if PSI is employed, issues of cost and

safety can be considered on a case-by-case basis without concern regarding accuracy.

- Overall, based on a sizeable body of RCT evidence, there is little justification to recommend PSI in routine primary TKA.

44 Metal Allergy in Total Knee Arthroplasty

Amit Atrey MD MSc FRCSC
Division of Orthopaedic Surgery, Department of Surgery, University of Toronto, Toronto, ON, Canada

Clinical scenario

- A 65-year-old female, otherwise healthy, with end-stage osteoarthritis of her knee, undergoes an uncomplicated total knee arthroplasty (TKA) with a cobalt-chrome (Co-Cr) cemented prosthesis. The patella is resurfaced as well. The patient is discharged home after two days and within a few days postoperatively her range of motion (ROM) is 0–130°. At the six-week follow-up, ROM is the same with no effusions; the scar has healed properly and the patient is satisfied with the results. However, at the six-month follow-up, she presents with a painful knee, reduced ROM, mild effusion, and localized erythema.
- X-rays show no obvious loosening. Computed tomography (CT) reveals correct alignment of the components and infectious workup is negative including erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), white blood cell (WBC) count, and cultures. Arthroscopic arthrolysis is performed, revealing adhesions and synovitis. At the end of the operation the ROM is restored. All samples are negative for infection. Passive and active physiotherapy is initiated and pain is controlled.
- The patient's overall condition improves, but at the 12-month follow-up (six months post arthroscopy) she

returns with a similar picture: effusion, localized erythema, reduced ROM, and pain. Once more infection is ruled out, and no evidence of implant loosening is detected.

Introduction

The number of TKAs is increasing annually worldwide as a consequence of aging and higher rates of secondary osteoarthritis in the younger population.[1] Despite the technological advancement, as well as the expertise of the surgeons, some reports state that almost 20% of patients with well-fixed, properly aligned knee implants are not satisfied for various reasons.[2] Additionally, some experience pain and stiffness for which no readily available explanation exists.[3]

Type IV hypersensitivity reaction, on the other hand, is mediated by T-cell lymphocytes, taking days to occur in patients previously sensitized to the allergen. This is the classic contact dermatitis that appears in 10–48% of the general population. Metal particles cross-link with proteins and act as antigens initiating an immune response.[4]

Reports of unexplained persistent pain and loosening after joint replacement caused by hypersensitivity to metal implants were initially published in the mid-1970s and concerned mostly metal-on-metal hip prostheses.[5–8]

As in our clinical scenario, if all other common reasons of postoperative complications are excluded, metal hypersensitivity may be a possible predisposing factor that leads to this unexplained clinical picture and possibly to implant failure.

Top three questions

1. Among patients awaiting TKA, does routine allergy screening, compared to no screening, affect management and/or outcomes?
2. Among patients with suspected hypersensitivity reaction, does any diagnostic method perform better than others?
3. Among patients with a confirmed hypersensitivity reaction, which treatment options, compared to others, result in the best outcomes?

Question 1: Among patients awaiting TKA, does routine allergy screening, compared to no screening, affect management and/or outcomes?

Rationale/clinical comment

If routine screening for metal allergy of TKA candidates can identify those at higher risk of developing such hypersensitivity reactions then unwanted reactions leading to socioeconomic burden (prolonged hospitalization, revision surgeries, reduced quality of life, etc.), for an otherwise highly successful intervention, may be prevented.

Findings

The only published randomized controlled trial involved 120 patients that were randomized to receive either a seven layer-coated or noncoated total knee implant and had their plasma ion levels and patch test (PT) assessed preoperatively and at 12 months. This showed that sensitization (positive PT postoperatively) was rare (only 3/120 pts). There was a functional improvement and better

quality of life in both groups for all patients. However, those with known metal allergies were excluded from the study since according to local guidelines they could not be randomized.[9]

Some studies give emphasis to the preoperative history-taking which, in addition to laboratory testing, can potentially identify patients at risk of metal sensitivity.[10–13]

Niki et al., in their prospective study, suggested that routine prescreening is clinically useful, especially related to Cr sensitivity. In a total of 92 patients, 26% (24 patients) tested positive with lymphocyte transformation test (LTT) preoperatively. An additional five patients developed metal-related eczema that was relieved fully only in those who had subsequent revision surgery with nonchromium-containing implants.[14]

Granchi et al., in two publications, supported that medical history or symptoms of metal allergy prior to implantation seem to be a risk factor for failure. TKA failure was four times more likely in such patients and this was reaffirmed after the systematic review of literature.[15,16] Given that many patients with a documented metal allergy on history actually have negative allergy testing, the relationship between the two is somewhat unclear.

Additionally, authors in recently published articles recorded that patient reported allergies (metal and/or environmental exposure, foods, medications, etc.) are associated with significantly decreased functional outcomes and mental health scores after TKA and total hip arthroplasties (THAs) with a follow-up from one to five years.[17–19]

Conversely, Zeng et al. found no relationship between pain and metal allergy in TKAs or THAs in their study of 87

patients that were pre- and postoperatively tested for metal allergy.[20]

The counterargument is supported by a cohort study of 127 patients, 56 of whom tested positive for metal allergy with the skin PT. This cohort was matched to 161 control TKAs without history or positive laboratory findings. A follow-up at five years showed no difference in complications, reoperation, or pain.[21]

Münch et al. from Denmark reported that metal allergy diagnosed preoperatively did not increase the revision surgery in TKAs, after they matched their national knee arthroplasty registry and the national allergy database.[22] Additionally, recent reviews have not supported routine testing, and diagnosis should be made when all other possibilities are excluded.[4],[23]

Resolution of clinical scenario

Routine preoperative screening or testing is not clearly supported and opinions vary regarding the appropriate patients to test prior to surgery.

Question 2: Among patients with suspected hypersensitivity reaction, does any diagnostic method perform better than others?

Rationale/clinical importance

As in our previous question, if screening methods can identify potential metal hypersensitive patients awaiting TKA, this will aid toward the best possible and long lasting outcome. On the other hand, postoperative screening may

help in the differential diagnosis and provide information valuable toward the next intervention.

Findings

Skin PT is an in vivo method that is most frequently used for detecting type IV hypersensitivity reactions. Other options include the in vitro LTT and its modifications: biopsies, cytokine production analysis, and confocal microscopy.

Patch testing is widely available and easy to apply, while also providing results within a few days. However, questions have arisen to the sensitivity of the PT with differences reported in the number of antigen presenting cells in the skin and those in the periprosthetic tissues. This questions whether PT is the most appropriate test.[24,25]

Of the total of 25 studies reviewed, 22 use the PT alone or in conjunction with other tests to detect metal hypersensitivity reactions in pre- or postoperative screening.

The concept of postoperative sensitization is supported by some authors given the fact that in their studies some patients who were patch tested negative before surgery were patch tested positive at last follow-up. None of these patients required revision surgery, although some received hypoallergenic implants.[9–11,15]

Conversely, Thyssen et al. found that the prevalence of patients testing positive to metal allergy PT after operation was lower (6%) than in those who had tested positively before surgery (16%).[26] In addition, two studies recommend against patch testing since it was of no clinical value in predicting clinical outcome and the probability of revision surgery.[21,22]

The LTT is a laboratory measure of the level of lymphocyte proliferation in response to an allergen. The availability of LTT is limited, the number of allergens to be tested is small, and, once taken, blood samples need to be transported to the lab rapidly to avoid T-cell decay.[25]

The LTT is reported in 10 studies and three case reports. Specificity and sensitivity of such tests has not been defined yet with many false positives and negatives.[13,23] The number of LTTs performed was too low and provided only additional support in some reports.[10,12,24]

In one study, lymphocytic infiltration was found in 81% of PT-positive patients, although the number of cases was small.[24] A systematic review supports the concomitant use of both tests despite the fact that they could not differentiate between stable and unstable implants.[16]

The LTT was used as a single method of diagnosis in two studies and in three case reports.[14,27–30] Niki et al. reported a significant relationship between Cr sensitivity, the development of eczema in TKA patients, and testing positive to LTT. After revision surgery, symptoms resolved and the LTT turned negative.[14] Hallab et al. indicated elevated metal-specific lymphocyte reactivity in THA patients, especially in those with moderate radiographic osteolysis.[27]

Other laboratory methods have been described. Three reports concluded that the LTT, combined with PT, histopathology, and cytokine detection could be useful tools for the prevention and monitoring of possible metal sensitization.[24,31,32] Knee arthroscopy is recommended to obtain tissue for microbiological and histopathological examination, before revision surgery, by one author.[12]

Resolution of clinical scenario

Patch testing is the most readily available test to detect metal sensitivity, although its validity has to be verified. Lymphocyte transformation testing may be more useful; however, it is not widely available and must be standardized. False-negative results are common with both tests. Combining those tests may provide better diagnosis and monitoring of suspicious cases. Other interventions are rarely described and therefore further research is required.

Question 3: Among patients with a confirmed hypersensitivity reaction, which treatment options, compared to others, result in the best outcomes?

Rationale/clinical importance

Our patient is still in pain and distress; all common possible causes have been excluded and our data suggest that the patient may have developed sensitization to the implant. What would be our treatment plan?

Findings

Only anecdotal information exists regarding the mode of treatment in such cases. Complete resolution of symptoms, after revision surgery with a nonallergic prosthesis, has been described in several case reports.[28–30,33–36]

Contradictory to those reports, Verma et al. reported that 15 patients with dermatologic manifestations over the knee resolved with local corticosteroid treatment.[37]

In one case a large intra-articular pseudotumor was resected 13 years post TKA; no signs of implant loosening were observed and the prosthesis was not revised.

However, the patient did not fully recover. Her contralateral knee was also replaced with a press-fit implant and no complications. History was positive for sensitivity to cement but not on metals.[38]

In another prospective study, 5 out of 92 patients presented with eczematous manifestations. One showed spontaneous resolution, two underwent revision (one ceramic, one standard) with complete recovery in both, and two followed clinical observation with mild, but persistent, features.[14]

Innocenti used a hypoallergic implant in 25 metal-sensitive patients with no adverse effects at six-year follow-up.[13]

Similarly, in three studies, patients characterized as metal sensitive (PT and/or LTT) received hypoallergenic implants at revision and reported symptoms relief.[12],[24],[32]

Resolution of clinical scenario

After exclusion of all other causes of failure, patients with persistent symptoms of dermatitis and/or persistent pain, reduced ROM, and pain of unknown origin, the patient could be offered a revision surgery to a nonallergic prosthesis if conservative methods fail to improve symptoms. Several types of such prostheses exist, some of them providing the same designs and surgical techniques as standard ones, making them easy to use.[39] Caution should be used if the nonallergic prosthetic system is not one that the surgeon is familiar with, as this may in and of itself result in suboptimal outcomes.

Summary of answers

- Routine preoperative screening or testing is not clearly supported and opinions vary regarding the appropriate

patients to test prior to surgery.

- Patch testing is the most readily available test to detect metal sensitivity, although its validity has to be verified. Lymphocyte transformation testing may be more useful; however, it is not widely available and must be standardized.
- Several types of hypoallergenic prostheses exist, and if revision is indicated, these may be considered.

45 Perioperative Management in Total Knee Arthroplasty

Sebastian M. Klim MD and Mathias Glehr MD
Department of Orthopaedics and Traumatology, Medical University of Graz, Graz, Austria

Clinical scenario

- A 63-year-old patient is awaiting his total knee arthroplasty (TKA), which is scheduled for the next day. As you search his medical records you find that the patient has had a surgical site infection (SSI) after being treated with open reduction internal plate fixation for a broken clavicle in the past. Therefore, you are thinking about taking additional prevention measures.
- Your patient is an active person in good physical condition with no significant co-morbidities. Since he wants to exercise with his new joint like he did prior to surgery, he asks you if there are any perioperative therapy plans that could improve the surgical result regarding knee function and shorten the hospitalization time.
- The patient is concerned about postoperative pain. He wants to take as few pain pills as necessary and knows the pain reduction potential of cryotherapy from his sports activities. He therefore asks you if cryotherapy could help to reduce the required pain medication, and if a postoperative outcome improvement can be expected.

Top three questions

1. In patients scheduled for primary TKA, does preoperative bathing/showering or wiping with antiseptics result in fewer SSIs compared to nonantiseptic preparations?
2. In patients after primary TKA, does a fast-track (FT) early-mobilization schedule lead to an improved outcome in functional scores and hospitalization time compared to a regular joint care protocol?
3. In patients after primary TKA, does local cryotherapy have a positive effect on early postoperative parameters compared to protocols without cryotherapy application?

Question 1: In patients scheduled for primary TKA, does preoperative bathing/showering or wiping with antiseptics result in fewer SSIs compared to nonantiseptic preparations?

Rationale

Prosthetic joint infection (PJI) after TKA is among the most frequent indications for revision TKA.[1–4] A huge economic burden is associated with the increasing number of (septic) revision TKA.[5]

Clinical comment

One of the most frequent causes for wound contamination is skin microflora. With the incision made during surgery,

micro-organisms may be able to infect tissue, joint, and/or implant. It is a widely accepted fact that the use of an antiseptic skin wash product can reduce skin microflora. However, there is no consensus whether this leads to a reduced incidence of SSI/PJI.[6,7] Knowing the history of the patient, you want to know if bathing/showering with antiseptic skin wash products prior to surgery can help prevent an SSI/PJI.

Available literature and quality of the evidence

- Level III: our literature search showed 1 meta-analysis (including 4 retrospective comparative studies with 8787 patients) investigating exclusively TKA patients.[8]
- Level III: 1 retrospective comparative study including 2055 TKA patients.[9]
- Level I: 1 Cochrane systematic review (including 7 randomized controlled trials [RCTs] with 10 157 patients) investigating SSI of all localizations.[10]

Findings

The level III meta-analysis results (total study population) indicate a reduced incidence of SSI when chlorhexidine (the active substance in all investigations) was used in preoperative washing/wiping (risk ratio [RR] = 0.22; 95% confidence interval [CI]: 0.12–0.40; p = 0.000). Furthermore, a reduction of SSI rates in moderate and high risk patients according to the National Healthcare Safety Network (NHSN) risk classification is shown (RR = 0.18; 95% CI: 0.05–0.63; p = 0.007 and RR = 0.13; 95% CI: 0.03–0.67; p = 0.014.[8,11]

In contrast, the level I systematic review as well as the retrospective comparative study found no benefits in the chlorhexidine groups regarding SSI incidences. A

discrimination by risk classification has not been performed in these studies. Insignificant differences in SSI rates are reported in the chlorhexidine and in the placebo groups (RR = 0.60; 95% CI: 0.22–1.60; p = 0.330.[8–10]

Resolution of clinical scenario

- Routine use of preoperative chlorhexidine baths/showers or wipes is not recommended for daily clinical practice as it shows no SSI rate reduction in TKA.[9,10]
- The SSI risk should be calculated if deemed necessary.[11]
- In TKA patients with moderate to high SSI risk profiles chlorhexidine baths/showers or wipes should be considered, especially regarding the low cost and the very rare unwanted side effects. However, the available data do not support a final recommendation.[8]

Question 2: In patients after primary TKA, does a fast-track (FT) early-mobilization schedule lead to an improved outcome in functional scores and hospitalization time compared to a regular joint care protocol?

Rationale

Multidisciplinary perioperative treatment protocols for TKA have been presented and further advanced in recent years, aiming to provide standardized treatment leading to a

reduced length of stay, improved clinical outcome, and patient satisfaction.[12–14] To achieve this, physicians, anesthesiologists, physiotherapists, and nurses must closely work together and adhere to evidence-based protocols, known as *fast track* (or *FT*).

Clinical comment

Perioperative management plays a very important role regarding the outcome of a surgical procedure and overall patient satisfaction. FT protocols take an evidence-based approach to optimizing the clinical and organizational aspects aiming to reduce morbidity and mortality and speed up functional convalescence with a subsequently shortened length of hospitalization. You want to know if these protocols can help you and your patient to achieve a short hospital stay and a better functional outcome.

Available literature and quality of the evidence

- Level I: the literature search showed 2 meta-analysis including 16 studies on this topic.[15,16] In addition, there is 1 RCT focusing on early outcome in FT TKA.[17]

Findings

Both the meta-analysis and the RCT showed significantly reduced length of stay times in acute healthcare facilities when comparing the FT mobilization group to the control group. Guerra et al. found a reduction by 1.8 days (95% CI: 1.1–2.6; 6.9 vs 5.1 days). All studies report this without an increase in adverse events.[15–17]

Advantages regarding early functional outcomes (first 1–2 weeks) after surgery were reported by the analyzed studies, showing improved Knee Society and Western Ontario and McMaster Universities Osteoarthritis Index

(WOMAC) scores, and earlier sit-out-of-bed (SOOB) and walking. However, no differences could be shown regarding medium- and long-term functional outcomes when comparing FT protocols to standard mobilization schedules.[15–17]

Resolution of clinical scenario

- FT protocols significantly reduce the length of stay times in acute healthcare facilities without an increase in adverse events.[15–17]
- FT protocols show advantages regarding early functional outcomes; however, improved medium- and long-term outcomes are not apparent.[15–17]

Question 3: In patients after primary TKA, does local cryotherapy have a positive effect on early postoperative parameters compared to protocols without cryotherapy application?

Rationale

Basic cryotherapy via cool packs or ice is a relatively safe and cost-effective intervention. More sophisticated cryotherapy techniques include computer-assisted continuous cold flow devices which should provide a more even distribution of cooling fluid or gas but are substantially more expensive. While cryotherapy is the standard care in some countries, differing results in literature and few available level I studies might be the reason for its rare use in other countries.[18,19]

Clinical comment

Cryotherapy, the application of low temperatures to the skin surrounding a wound, works via reduction of inflammation enzyme activity, slowing of nerve signal conduction and a subsequent decrease of local swelling and perceived pain.[20–22] The further induced vasoconstriction should theoretically reduce blood loss following a surgical procedure or injury.[23]

Available literature and quality of the evidence

- Level I: the literature search showed one meta-analysis and 1 Cochrane review including a total of 14 different RCTs on this topic.[24,25]
- Level I: 5 RCTs were identified examining outcomes of continuous cold flow devices including 381 patients.[26–30]

Findings

Minor improvements of low quality regarding standard cryotherapy were reported by the meta-analysis, with a reduction in opioid consumption (mean difference, −0.13; 95% CI: −0.26 to −0.01 morphine equivalents in milligrams per kilogram per 48 hours; p = 0.03) and in pain improvement (mean difference, −0.51; 95% CI: −1.00 to −0.02 on the Visual Analog Scale [VAS]; p <0.05).[25]

The Cochrane review found very low-grade evidence favoring cryotherapy regarding blood loss (mean 225 mL, 95% CI: 39–410 mL less blood loss), pain at the second postoperative day (1.3 VAS, 95% CI: 2.37–0.27 VAS points lower), and range of motion (ROM) at discharge (11.39 [18%] more degrees of flexion, 95% CI: 4.13–18.66).[24]

The results of five RCTs investigating cryotherapy via continuous cold flow devices versus standard cryotherapy techniques showed an improved ROM (86 vs 80° of flexion,

p = 0.021). Further, one study found pain reduction on the second postoperative day similar to the Cochrane review.[30] No further improvements were found in these investigations.[26–30]

Resolution of clinical scenario

- No postoperative outcome improvement has been reported[25–29] except a minor improvement of ROM at time of discharge.[24,30]
- The evidence shows a minor improvement in opioid consumption and pain on the second postoperative day.[24,25,30]
- It seems that cryotherapy has minor benefits, but the routine use of standard and/or continuous flow cryotherapy cannot be recommended based on the present data.

Summary of answers

- The preoperative use of chlorhexidine baths/showers or wipes in primary TKA is not recommended for daily clinical practice.
- Although a final recommendation cannot be given with the present data, it should be considered to use chlorhexidine baths/showers or wipes in TKA patients with moderate to high SSI/PJI risk profiles.
- FT protocols can reduce the length of stay in acute healthcare facilities and lead to improved early functional outcomes.
- FT protocols do not lead to improved medium- and long-term outcomes.

- Due to minor benefits, the routine use of standard and/or continuous flow cryotherapy cannot be recommended based on the present data.

Top three questions

1. In patients undergoing total knee arthroplasty (TKA), does continuous passive motion (CPM), compared to standard postoperative care, help prevent arthrofibrosis?
2. In patients undergoing manipulation under anesthesia (MUA) for stiffness after TKA, is early manipulation better than late manipulation at restoring range of motion (ROM)?
3. In patients with arthrofibrosis following TKA, does open arthrolysis provide superior outcomes compared to arthroscopic arthrolysis?

Question 1: In patients undergoing total knee arthroplasty (TKA), does continuous passive motion (CPM), compared to standard postoperative care, help prevent arthrofibrosis?

Clinical scenario

A 65-year-old male has just undergone primary TKA under your care, and is now back on the ward. He is keen to start mobilizing as soon as possible and would like to have CPM as he has heard that this may reduce his risk of developing stiffness in the joint.

Rationale

CPM forms part of many postoperative protocols for the treatment of arthrofibrosis once it has occurred. Its value in preventing arthrofibrosis after primary TKA is unclear.

Clinical comment

A stiff knee following arthroplasty is one of the most dreaded complications and its treatment a challenge for surgeons. Arthrofibrosis is one of the most common causes of this stiffness.[1] It is a condition characterized by deposition of fibrous scar tissue within and around a joint, in response to an inflammatory process.

Available literature and quality of the evidence

- Level I: 1 meta-analysis of randomized trials.
- Level III: 3 case-control studies.

Findings

A meta-analysis by Brosseau et al. (level I) included 14 studies (952 patients), after excluding many other studies on the topic which lacked sufficient quality of evidence.[2] The included studies used CPM from 5 to 20 hours per day, for a duration of 18 hours to 2 weeks postoperatively after primary TKA. They performed a pooled analysis comparing patients receiving postoperative physiotherapy combined with CPM, against those receiving physiotherapy only (nine studies included). Eight of the studies initiated CPM on the first postoperative day, and the other study started it on the second day.

Active knee flexion at two weeks following surgery (pooled results from four studies, 286 patients) was compared, and showed that CPM was associated with a weighted mean difference (increase) of 4.30° (95% confidence interval [CI]: 1.96–6.63). They also reported a clinically important benefit in association with CPM, with a relative difference in active knee flexion of 22–25% over the period from 3 to 14 days postoperatively. One of the included studies reported postoperative time to achieve 90° of knee flexion, and found that the CPM group achieved this an average of 4.7 days earlier than the control group (9.1 days vs 13.8 days).[3] Active knee extension was also compared, but no statistically significant difference was found. Similarly, no significant differences were found between the groups for passive flexion or extension at follow-up to six months. The requirement for MUA was used as a marker for knee stiffness, and this was also compared in this study (pooled results from three studies, all began CPM within 24 hours). CPM was associated with a significant reduction in MUA (risk ratio [RR] = 0.12; 95% CI: 0.03–0.53); however, they questioned the clinical importance (5–18% relative difference).[2]

Another case-control study by Trzeciak et al. (level III) evaluated 101 TKAs in 93 patients, and assigned them into two groups.[4] The study group received CPM and active exercises, whereas the control group had only conventional physiotherapy. CPM was started on day one postoperatively, for two hours per day, with an initial ROM of 0–40°. ROM was increased as tolerated, by a mean of 10° per day, until discharge. On day 10 postoperatively, the patients were assessed, demonstrating no significant difference in mean ROM between the two groups: CPM group: 83° ±14°; control group: 77° ±21°. They reported that there may be some subjective improvement in pain level, joint stiffness, and function associated with CPM, but were not able to demonstrate any statistically significant differences. This study focused on the early postoperative outcomes, as it only showed follow-up at 10 days postoperatively, which may be too early to make a diagnosis of arthrofibrosis. Nonetheless, early progression in ROM and function is important in its prevention, and therefore these early outcomes may be related to arthrofibrosis risk.

There is debate about when CPM should be initiated to provide most benefit. A level III study by Daluga et al. evaluated the outcome of requirement for MUA after TKA over a three-year period, with a change in the CPM protocol halfway through.[5] The requirement for MUA was based on failure to meet flexion goals (70° before discharge – early MUA, failure to surpass 65–75° at early follow-up – intermediate MUA, failure to achieve 80–85° at three-month follow-up – late MUA). During the first half, CPM was commenced on day 3 postoperatively, and during the second half of the study, CPM was commenced on day one, and continued until discharge (length of stay not reported). The MUA rate remained constant at 12% throughout the

period despite the change in CPM protocol, suggesting no difference between starting CPM at day one or day three.

Additionally, there is no consensus about duration and method of CPM, and most studies do not evaluate this. The aforementioned meta-analysis stated that a comparison was made between short and long duration of CPM, and also between small and large range CPM, but that no statistically significant differences were found in relation to any outcome measures and the results were not shown.[2]

Many other studies included CPM as part of their postoperative rehabilitation protocol for all patients. At the time of writing, there are no other available studies that compare CPM against a control group, reporting arthrofibrosis as an outcome. Further work is needed to reinforce the evidence of the benefit of CPM in prevention of arthrofibrosis, but the limited evidence currently available suggests that CPM may lead to early improvements in ROM, and therefore may have a preventative effect.[2]

Resolution of clinical scenario

This patient should be assessed by the physiotherapists and early movement encouraged. CPM may be included as part of this protocol if appropriate.

Question 2: In patients undergoing manipulation under anesthesia (MUA) for stiffness after TKA, is early manipulation better than late manipulation at restoring range of motion (ROM)?

Clinical scenario

The gentleman returns to clinic two months after TKA with marked pain and stiffness in his knee. His knee flexion is limited to 60°.

Rationale

There are a range of treatment modalities available for arthrofibrosis following TKA. There are conservative options such as analgesia and physiotherapy, and more invasive interventions ranging from MUA to arthroscopic arthrolysis, open arthrolysis, and revision surgery. A key question that has been raised on this topic is that of the optimal timing for the procedure. If done too early (a level V narrative review by Schiavone Panni et al. suggested three weeks), this can cause wound breakdown.[6] However, if done too late, fibrous bands may have solidified and will not be amenable to breakdown via this method, and there may be a higher rate of complications, such as femoral fracture.

Clinical comment

This is a common scenario, which has been subject to various opinions on methods and timings of treatment. In reality, it may be reasonable to adopt a stepwise approach with many of these options. The first treatment modalities to be considered in the early stages should be conservative measures such as improved analgesia, physiotherapy, and exercises aimed at gradually improving ROM. Once these have been exhausted, some surgeons consider MUA as the next step. This section will explore the existing evidence for MUA as a treatment for arthrofibrosis.

Available literature and quality of the evidence

- Level III: 2 case-control studies.
- Level IV: 3 case series.

Findings

Manipulation under anesthesia (MUA)

A retrospective case-control series (level III) by Daluga et al. reviewed 94 TKAs that required MUA postoperatively, separating these into early (0–21 days), intermediate (22–90 days), and late (after 90 days), and compared them against a control group of 41 TKAs during the same period that had not required MUA.[5] The indications for MUA were flexion <70° or insufficient progress for the early group, flexion <65–75° at discharge or insufficient progress for the intermediate group, and flexion <80–85° at three months for the late group. They reported that MUA provided an overall mean increase in flexion ROM of 42°, and there was a significantly better result for the early group when compared with the late group in terms of mean flexion achieved (104° vs 97°). Unfortunately, there was no further analysis involving the intermediate group, which is the group representing the time period in which the majority of MUA procedures are undertaken. However, they did report that there was no significant difference in final flexion between the early and intermediate groups. No complications as a result of MUA were reported in any of the groups.

Similarly, in a retrospective case series (level IV) by Yercan et al., a series of 1188 TKAs over an 18-year period were reviewed, with 46 patients requiring MUA.[7] This study considered two different indications for MUA, which were flexion less than 75° after 10 days (early MUA), or flexion less than 95° within three months (late MUA). They showed a significant improvement in mean ROM for patients

undergoing MUA from 67° to 117°, with a mean increase in ROM of 47° at 31 months ($p < 0.015$), and that this benefit was largely maintained at final follow-up (mean ROM 114°). They also showed that there was greater long-term benefit for those having early MUA (10 days to 3 weeks), compared with those having late MUA (three weeks to three months), with final follow-up mean ROMs of 121° and 112°, respectively ($p = 0.021$). There were no complications following MUA for any of their patients.

A retrospective case series (level IV) by Bawa et al. reported 3244 TKAs over an eight-year period, of which 140 (4.3%) underwent MUA for stiffness, as indicated by failure to reach 90° of flexion by six weeks.[8] They demonstrated a mean increase in ROM of 34° after MUA ($p < 0.001$). Comparing MUAs done before and after 75 days, they showed a significant benefit in the group having early MUA (final ROM 103° vs 92°, $p = 0.001$). Additionally, they showed a negative correlation between time from TKA to MUA, and final ROM ($r = -0.20$, $p = 0.04$).

In a retrospective case-control study (level III), Keating et al. evaluated a series of 6297 TKAs over a 14-year period, and found that 113 (1.8%) of these developed early stiffness requiring MUA.[9] They defined their indication for MUA as flexion restriction to 90° or less after 2–3 months, after a supervised physiotherapy program had failed. In this cohort, MUA significantly improved ROM, with a mean flexion range of 70° before manipulation, increasing to 94.0° at six months, and 105° at five years ($p < 0.0001$). In response to previous work discussing a cut-off of 12 weeks for MUA, they compared their results of those undergoing MUA before and after 12 weeks, and found no significant difference ($p = 0.3597$).

A retrospective series (level IV) by Ipach et al. evaluated 858 TKAs over a five-year period, and showed that 39 of

them required MUA for stiffness, indicated by flexion <90° after two weeks.[10] The mean flexion ROM improved following MUA by 26.5°, but no statistical analysis was undertaken. They separated the MUAs by early (before 30 days) and late (after 30 days), and reported that there was no statistical significance between the absolute flexion ($p = 0.655$) or the gain in flexion ($p = 0.328$) between these groups.

Summary

Whilst there is contradictory evidence, most sources seem to suggest that MUA is best carried out in the early postoperative period. The evidence presented here suggests that while early MUA is indeed preferable low-level evidence suggests that benefits are still possible after three months.

Resolution of clinical scenario

As the patient is two months following surgery, it would be reasonable to offer an MUA in the first instance.

Question 3: In patients with arthrofibrosis following TKA, does open arthrolysis provide superior outcomes compared to arthroscopic arthrolysis?

Clinical scenario

A colleague refers you a 70-year-old gentleman who had a TKA nine months previously. He now has marked pain and stiffness in his knee, despite previous attempts at MUA.

Rationale

If symptoms of arthrofibrosis remain troublesome after several months, and more conservative measures have failed, the next consideration is arthrolysis. This section will focus on a comparison between the two different methods of arthrolysis (arthroscopic vs open).

Clinical comment

Arthroscopic procedures are generally less invasive, and involve smaller wounds and less disruption to surrounding tissues. It is important to understand if satisfactory results can be achieved arthroscopically.

Available literature and quality of the evidence

- Level III: 2 systematic reviews including level III evidence.
- Level III: 1 cohort study.
- Level V: 1 narrative review.

Findings

A systematic review by Ghani et al. (level III) included data from 25 studies (level III–IV) to evaluate the efficacy of different treatment modalities for arthrofibrosis including arthroscopic arthrolysis and open arthrolysis.[1] The increase in ROM was pooled and compared, showing reported ROM increases of 36.2° for arthroscopic arthrolysis and 43.4° for open arthrolysis, suggesting better results for open arthrolysis.

A systematic review (level III) by Fitzsimmons et al. included 20 articles in total (level II–IV), and evaluated MUA, arthroscopic arthrolysis and open arthrolysis, in the context of motion restriction after TKA, although not all

treatment modalities were represented in each study.[11] Arthroscopic arthrolysis resulted in a mean increase in ROM of 18.5–60° (12 studies), and in nine of these studies the arthroscopic procedure was combined with MUA. Open arthrolysis gave a mean increase in ROM of 19–31° (three studies). These findings suggest that greater ROM benefits can be achieved with arthroscopic arthrolysis combined with MUA, in contrast to the previously mentioned study. However, simply comparing ROM outcomes for each approach may be an oversimplification, as they have different roles and indications.

The aforementioned paper by Schiavone Panni et al. suggested that arthroscopic arthrolysis should only be performed in stiff painless knees, and much like MUA its role is predominantly in relieving flexion deficits as these are associated with fibrosis of the anterior structures.[6] The arthroscopic approach allows good access to the suprapatellar pouch, the intercondylar notch, and the medial and lateral gutters. Posterior capsule adhesions are difficult to address with this approach, but the posterior cruciate ligament can be accessed if necessary.[12]

Open arthrolysis may be considered in severe arthrofibrosis, at a later stage once conservative management has failed, and if the components are correctly placed. This procedure can be combined with exchange of polyethylene inserts or patellar components, and with additional procedures such as patellar tendon lengthening or tibial tuberosity transfer.[6]

A retrospective cohort study (level III) by Keeney et al. evaluated a series of 23 stiff TKAs, and drew comparison between revision TKA (n = 11) and a limited approach open arthrolysis procedure with exchange of the polyethylene insert component only (n = 12).[13] Both groups demonstrated significant improvements, with the limited

approach group producing a mean increase in ROM of 25.7° (70.6° to 96.3°, p <0.0001), and a reduction in mean extension deficit of 6.63° (7.45° to 0.82°, p = 0.002). In the limited approach group, there were also significant improvements in mean patient-reported measures of Knee Society Score – Knee (KSS; 36.9–74.7, p <0.0001), KSS – Function (41.7–62.5, p = 0.03), and pain score (7.9–1.5, p = 0.002).

Summary

Direct comparison between arthroscopic and open arthrolysis procedures may not always possible, as their indications and timings are different, but studies directly comparing them directly report equivocal findings.[1,11] In reality, the main advantage of performing open arthrolysis is that it can be combined with other procedures that are not possible arthroscopically. Given the evidence available, it seems reasonable to preferentially perform arthrolysis via an arthroscopic approach, unless there is felt to be a need for an additional procedure at the same time (e.g. downsizing of polyethylene insert).

Resolution of clinical scenario

Given that there is no evidence of any mechanical issues, and the implants appear to be well sized, the patient may be offered arthroscopic arthrolysis

Summary of answers

- CPM is often incorporated into early rehabilitation protocols after TKA. The limited evidence available suggests that it can improve early gains in ROM and may lead to a reduction in the risk of developing arthrofibrosis.

- MUA should be performed if arthrofibrosis is present within three months postoperatively, and the earlier the better once the diagnosis is made.
- After more than three months, arthroscopic arthrolysis (usually combined with MUA) can be considered, as this may prevent the need for more extensive revision procedures, and could be effective as late as two years postoperatively. For persistently stiff knees with late arthrofibrosis and severe restriction, open arthrolysis or revision procedures may be considered.

47 High-Flexion Implants in Total Knee Arthroplasty

Thomas J. Wood MD FRCSC[1], and Douglas D. R. Naudie MD FRCSC[2]

[1] Division of Orthopaedic Surgery, Department of Surgery, McMaster University, Hamilton, ON, Canada

[2] Division of Orthopaedic Surgery, Department of Surgery, Western University, London, ON, Canada

Clinical scenario

- A 55-year-old Muslim woman presents with end-stage degenerative joint disease of her knee. She has marked varus angular deformity with limited knee flexion to 100°.
- Radiographic evaluation demonstrates severe varus osteoarthritis. She explains how it is very important for her to properly position herself into prayer position.
- She has read about high-flexion (HF) total knee replacement prostheses and insists it is the only route for her.

Top three questions

1. In a patient who is considering a total knee arthroplasty (TKA), what design rationale can be provided for HF implants and are patients more satisfied with such designs compared to a conventional knee prosthesis?
2. Are functional outcomes superior in a patient who has undergone a TKA with a HF prosthesis compared to a

conventional total knee prosthesis?

3. In a patient who has undergone TKA with a HF TKA, what unique complications are encountered as compared to a conventional TKA?

Question 1: In a patient who is considering a total knee arthroplasty (TKA), what design rationale can be provided for HR implants and are patients more satisfied with such designs compared to a conventional knee prosthesis?

Rationale

HF TKA implants were designed and marketed for patients who desire to continue leisure and sporting activities or to return to cultural norms such as prayer. Moreover, these design changes were undertaken to see if patient satisfaction and overall function could be improved.

Findings

An easily measured shortfall of contemporary TKA is the range of motion (ROM) routinely obtained after surgical intervention and its comparison to the amounts required to perform routine activities of daily living (ADLs). This is supported by postoperative outcome studies that reveal stiffness as a cause of dissatisfaction amongst some patients.[1,2] HF total knee systems were designed to imitate the natural function of the knee more closely allowing for greater contact area and knee flexion.[3] Modifications in the HF design include the femoral condylar component

geometry and offset, curvature of radius, geometry and cutouts of the polyethylene insert, and height and position of the cam/post engagement.[4,5] The changes to the femoral component aim to make the most posterior lip of the posterior femoral condyles more rounded in order to increase the weight bearing area of this edge while the prosthesis is in deep flexion. These changes are also necessary to avoid impingement or edge loading of the component into the polyethylene insert, thus preventing fractures and/or delamination of the insert. These design changes require resection of extra host bone, which is replaced by the more rounded edge of the implant. Changes to the polyethylene insert have consisted of decreasing the congruency of the posterior portion to avoid impingement on the femur[6,7] and creating a recess in the polyethylene anteriorly to accept the patellar tendon as it "leans back" in deep flexion. Additionally, increasing the height of the posterior cam[6,7] has been addressed in some posterior stabilized designs to decrease the chance of "jumping the post" with increased flexion. These design changes would theoretically allow for greater ROM and better patient satisfaction.

In a level I meta-analysis of randomized controlled trials (RCTs), Li et al. evaluated 18 studies with 2069 knees. There was no difference in patient satisfaction scores with those who received HF total knees as compared to conventional knees.[4] There were no differences in Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC) or Short Form 36 (SF-36) scores.[4] Fu et al. evaluated 10 studies and 1230 knees in a level I meta-analysis of RCTs.[8] Similarly, they found no differences in WOMAC and SF-36 scores (weighted mean difference [WMD] = −0.03; 95% confidence interval [CI]: −4.11 to 4.06; p = 0.99; I^2 = 62%).[8] Both studies concluded that HF

prostheses did not appear to confer any superiority over standard prostheses.

Several RCTs have evaluated patient satisfaction following HF TKAs as compared to standard TKAs. Van der Ven et al. in an RCT of 56 patients comparing press-fit condylar (PFC) sigma fixed bearing cruciate retaining knee to PFC sigma rotating platform HF posterior stabilized knee showed no differences in patient reported outcome measures (WOMAC and Visual Analog Scale [VAS]).[9] Springorum et al. in a prospective RCT of 69 consecutive knees compared a PFC cruciate-retaining (CR) HF knee to a standard PFC total knee and found no differences in WOMAC scores.[10] McCalden et al. showed in an RCT of 100 patients comparing Genesis II standard posterior-stabilized (PS) inserts to HF inserts with no differences in WOMAC or SF-12 scores.[5] Finally, Lutzner et al. in an RCT of 122 patients compared Scorpio NRG HF implants to a standard Scorpio prosthesis and showed no differences in SF-36 scores.[11]

Similarly, in a prospective study comparing 100 patients who underwent bilateral total knees, one with a NexGen Legacy PS knee and the other with a NexGen PS-Flex knee, Kim et al. 2012 showed that 87% of patients had no preference as to which knee was better or were more satisfied with.[12] Lastly, in a large prospective level III study of 960 patients with a mean of 13.2 year follow-up, Kim et al. showed no differences in patient satisfaction at final follow-up when comparing NexGen Legacy PS total knee to the NexGen PS HF total knee.[13]

Resolution of clinical scenario

- HF total knee implants have different design modifications in posterior femoral condylar offset and

geometry, in polyethylene insert geometry including anterior cutouts and cam/post height and position to allow for more optimal contact area and knee flexion.

- There are no differences in patient satisfaction when comparing HF total knee implants to conventional implants.

Question 2: Are functional outcomes superior in a patient who has undergone a TKA with a HF prosthesis compared to a conventional total knee prosthesis?

Rationale

Although the theoretical advantage of HF TKAs is to obtain greater flexion and improve clinical outcomes, controversy exists whether such designs truly change functional outcomes. It is therefore important to critically examine outcomes when using HF designs and compare them to conventional total knee replacements.

Findings

In a level I meta-analysis of RCTs, Li et al. evaluated 18 studies with 2069 knees. When comparing postoperative ROM there was no difference between HF and standard knees (WMD = 0.78; 95% CI: −0.19 to 1.74; WMD = 0.41; 95% CI: −2.01 to 2.83).[4] There was also no difference found in Knee Society Score (KSS) and Harris Hip Score (HSS).[4] Furthermore, in a level I meta-analysis of RCTs, Jiang et al. evaluated 17 studies with 1778 patients.[4] Subgroup analysis showed there was no difference between PS flexion and PS knees (mean difference [MD] = 0.96;

95% CI: −0.23 to 2.15; p = 0.11) as well as CR flexion and CR knees (MD = 1.18; 95% CI: −0.55 to 2.91; p = 0.18) in terms of ROM. There was no difference in these subgroups in terms of KSS (MD = −0.67; 95% CI: −3.05 to 1.71; p = 0.16); (MD = 1.87; 95% CI: −1.49 to 5.23; p = 0.45) or HSS (MD = −0.13; 95%: CI −1.15 to 0.90; p = 0.81); (MD = 2.10; 95% CI: −0.39 to 4.59; p = 0.10).[14] Finally, Fu et al. evaluated 10 studies and 1230 knees in a level I meta-analysis of RCTs. There were no differences between HF and conventional components in terms of range of flexion (WMD = 1.14°; 95% CI: −0.11–2.39°; p = 0.07; I^2 = 39%).[8] There were also no differences observed in KSS (WMD = −0.03; 95% CI: −4.11 to 4.06; p = 0.99; I^2 = 62%).[8]

In the last decade several RCTs have been identified evaluating functional outcomes following HF TKAs. Guild and Labib evaluated the NexGen LPS standard and NexGen HF total knees in 278 knees. At two-yar follow -up there were no differences in ROM, clinical outcome, or radiographic evaluation.[3] At two-year follow-up the standard prosthesis group had a mean flexion of 121° and the HF group had a mean flexion of 120°.[3] Van der Ven et al. in an RCT evaluated 56 patients comparing PFC sigma fixed bearing cruciate retaining knee to the PFC sigma rotating platform HF posterior stabilized knee. Maximum knee flexion during kneeling was higher for the HF group although there were no differences seen in KSS.[9] Furthermore, in a prospective randomized study of 69 consecutive patients, Springorum et al. compared a PFC CR HF knee to a standard PFC knee. Knee flexion was 112.6° in the standard group and 117.3° in the HF group (p >0.05; 95 % CI: −11.5–1.9°).[10] There were no differences between groups at any time point in terms of KSS.[10] Lutzner et al. in an RCT of 122 patients compared Scorpio NRG HF implants to a standard Scorpio prosthesis and

showed no differences in postoperative ROM and KSS.[11] McCalden et al. in an RCT of 100 patients comparing Genesis II standard PS inserts to HF inserts showed no differences in knee flexion at two years ($p = 0.811$).[5] There were no differences in Knee Society clinical rating scores.[5] Finally, Hamilton et al. in a prospective RCT studied 142 patients comparing a HF and standard rotating platform knee showing no differences at one year in terms of clinical outcomes ($p = 0.949$), as well as radiographic flexion between groups ($p = 0.985$).[15]

Similarly, in a large prospective level III study of 960 patients, Kim et al. showed no differences in ROM ($p = 0.305$) or KSS scores ($p = 0.921$) when comparing NexGen Legacy PS knee and NexGen PS HF total knees.[13]

Resolution of clinical scenario

- There are no differences in ROM or functional scores when comparing HF total knees to conventional total knees.

Question 3: In a patient who has undergone TKA with a HF TKA, what unique complications are encountered as compared to a conventional TKA?

Rationale

It is important to investigate whether there are any potential complications with HF implants that need to be disclosed to patients prior to surgery. In particular, any TKA that undergoes deep flexion is subject to high shear

forces between the tibia and femur, which may result in early loosening.

Findings

In a level I meta-analysis of RCTs, Li et al. evaluated seven studies comparing complications with HF total knees compared to conventional knees. Overall, the odds ratio (OR) was 1.50 (95% CI: 0.95–2.39), suggesting that the risk of complications between HF and conventional knees is not different.[4] Another level I meta-analysis of RCTs by Jiang et al. showed no difference in revision rates between HF and conventional total knees (OR = 2.95; 95% CI: 0.70–12.45; p = 0.18).[14] There was no difference seen in component loosening rate (OR = 2.37; 95% CI: 0.35–16.26; p = 0.38), deep infection (OR = 1.93; 95% CI: 0.54–6.94; p = 0.31), anterior knee pain (OR 1.17; 95% CI: 0.52–2.61; p = 0.71), fracture (OR = 0.24; 95% CI: 0.47–19.35; p = 0.24), or patellar clunk (OR = 1.42; 95% CI: 0.05–40.47; p = 0.84).[14] Finally, Fu et al. did not show any differences in number of complications between HF and conventional implants when evaluating seven RCTs in a level I meta-analysis.[8]

Several RCTs have evaluated differences in complication rate when using HF total knee implants as compared to conventional implants. Guild and Labib showed in an RCT of 278 knees similar complication rate in NexGen LPS standard and NexGen HF knees.[3] Five knees in the NexGen HF group required manipulation under anesthesia for stiffness in addition to one case of patella fracture and superficial infection.[3] There were no cases of aseptic loosening, infection, or osteolysis.[3] Springorum et al. in an RCT compared a PFC CR HF knee to a standard PFC knee and showed no differences in complications (aseptic loosening, infection, reoperation).[10] Furthermore, Hamilton et al. in a prospective RCT studied 142 patients comparing

a HF and standard rotating platform knee. There were no differences in requirement for manipulation under anesthesia.[15] However, there was a significant increase in patellar crepitus in the HF group ($p = 0.017$). Finally, McCalden et al. in an RCT of 100 patients comparing Genesis II standard PS inserts to HF inserts showed no differences in anterior knee pain, reoperation, and infection at two years.[5] There were two cases requiring manipulation under anesthesia both of which were in the standard PS group.[5] Similarly, in a prospective study comparing 960 patients with mean follow-up of 13.2 years who underwent total knees with either a NexGen Legacy PS knee or a NexGen PS-Flex knee, Kim et al. showed no differences in implant survivorship at 14 years which was 99.8% in both groups (95% CI: 95–100).[3] There were no differences in complications and aseptic loosening was 0.2% in both groups.[13]

Lastly, in a retrieval study, Schnaser et al. compared 20 HF inserts to 20 PS standard inserts across three manufacturers in 120 patients. Ranges of motion between matched patients were not different.[6] There were no differences between mean overall damage scores, post damage, or posterior articular surface damage between groups ($p = 0.25$, $p = 0.11$, $p = 0.6$). This is in contrast to the award-winning paper from Paterson et al. which matched 20 retrieved HF inserts to 20 retrieved PS inserts from the same implant system. These authors found greater backside and post damage in the HF group but no difference in the articular surface or overall damage scores. These authors concluded that HF inserts are more susceptible to post damage, possibly as a result of higher contact stresses from greater flexion.

Resolution of clinical scenario

- There are no differences in complication profiles when comparing HF TKAs to conventional TKAs, with the exception of one retrieval study identifying greater post damage in HF polyethylene inserts.

Summary of answers

- HF total knee implants have alterations in posterior femoral condylar offset and geometry, polyethylene insert geometry including anterior cutouts, and cam/post height and position to optimize contact area and knee flexion.
- There are no differences in patient satisfaction when comparing HF total knees to conventional total knees.
- There are no differences in ROM or functional scores when comparing HF implants to conventional total knee implants.
- In clinical studies, there are no differences in complication rates when comparing HF total knees to conventional total knees.
- Retrieval studies suggest that HF inserts may be more susceptible to post damage.
- The introduction of a highly cross-linked HF inserts will require close clinical follow-up.

48 Venous Thromboembolism in Total Knee Arthroplasty

Harman Chaudhry MD MSc[1], and Mitch Winemaker MD FRCSC[2]

[1] Division of Orthopaedic Surgery, Department of Surgery, University of Toronto, Toronto, ON, Canada

[2] Division of Orthopaedic Surgery, Department of Surgery, McMaster University, Hamilton, ON, Canada

Clinical scenario

- A 70-year-old gentleman presents to your clinic for a preoperative appointment. He is scheduled to undergo a total knee arthroplasty (TKA) for debilitating multicompartmental osteoarthritis.
- He presents to you concerned about “blood clots” after surgery, as his wife suffered from a pulmonary embolism (PE) after her recent total knee replacement surgery.
- Specifically, he would like to know your regimen for screening and preventing venous thromboembolism after surgery.

Top three questions

1. In patients undergoing TKA, are newer-generation anticoagulants superior to older agents for venous thromboembolism prophylaxis?
2. In patients undergoing TKA, is routine postoperative screening, compared to no screening, for venous

thromboembolic disease effective in preventing morbidity and mortality?

3. In patients undergoing TKA, is extended duration venous thromboembolism prophylaxis more effective than short duration prophylaxis?

Question 1: In patients undergoing TKA, are newer generation anticoagulants superior to older agents for venous thromboembolism prophylaxis?

Rationale

Thromboembolic disease – specifically PE and deep vein thrombosis (DVT) – was once a common and morbid complication following TKA. The combination of iatrogenic surgical trauma, immobilization, and venous stasis (the so-called Virchow's triad) result in the formation of clots in the deep veins of the lower extremity, some of which migrate to the pulmonary circulation, potentially leading to fatal pulmonary disease. The introduction of prophylactic anticoagulation following TKA substantially reduced the incidence of thromboembolic disease in the lower extremities.[1] However, PE remains a dreaded, albeit infrequent, postoperative complication. Ongoing research has endeavored to determine the optimal prophylactic regimen to prevent thromboembolism following TKA.

Clinical comment

There are several available options for the prophylaxis of thromboembolic disease following TKA. Mechanical prophylaxis includes the use of lower extremity pneumatic

compression devices or continuous passive motion (CPM) to prevent venous stasis and the subsequent development of DVT. Chemoprophylaxis has traditionally involved the use of warfarin (i.e. a vitamin K antagonist), acetylsalicylic acid (ASA), heparin, or low-molecular-weight heparin (LMWH). Newer pharmacologic agents, referred to as *direct oral anticoagulants* or *DOACs*, are gaining widespread acceptance due to their perceived efficacy and convenience (i.e. oral administration, no requirement for weekly monitoring, etc.). DOACs include agents which directly inhibit thrombin or clotting factors (e.g. factor Xa inhibitors). The optimal choice has remained elusive.

Two competing issues have led to substantial controversy over the years. The need to prevent thromboembolism, including *asymptomatic* DVT, figured prominently in the first set of clinical guidelines on thromboembolism prophylaxis developed by the American College of Chest Physicians (ACCP).[2] On the contrary, concerns regarding clinically important bleeding complications (e.g. hematoma, wound healing complications, etc.) in addition to the prevention of PE (but not necessarily asymptomatic DVT) were important considerations in the initial guidelines developed by the American Academy of Orthopaedic Surgeons (AAOS).[2] Owing to these differences, some of the recommendations issued by each association, particularly pertaining to the use of ASA and other pharmacologic prophylactic agents, were in direct conflict with one another.[3] The most recent guidelines, however, are more concordant and have resolved major conflicts.[4,5]

Available literature and quality of the evidence

There are multiple randomized controlled trials (RCTs) addressing the topic of older (or traditional) prophylactic options (i.e. mechanical prophylaxis, warfarin, heparin, and

LMWHs), as well as several methodologically robust systematic reviews and meta-analyses.[6,7] Similar quality evidence exists comparing newer-generation anticoagulants to other newer-generation anticoagulants.[8,9] The most thorough quantitative summary of the latter is provided by a network meta-analysis comparing venous thromboembolism and major bleeding amongst six common prophylactic anticoagulants: fondaparinux, dabigatran, rivaroxaban, apixaban, edoxaban, and enoxaparin.[8]

The use of ASA for thromboembolism prophylaxis instead of anticoagulants has been the subject of controversy,[10] but it has also been the explored in several RCTs and a meta-analysis.[11] The meta-analysis evaluated eight RCTs comparing ASA versus anticoagulants in 1408 patients undergoing surgery for hip fracture, hip arthroplasty, or knee arthroplasty along with subgroup analyses conducted in each subcategory.

Collectively, the available literature on these comparisons represents level I evidence.

Findings

Mechanical prophylaxis

The use of a mechanical prophylaxis devices alone (i.e. intermitted pneumatic leg compression) does not prevent the risk of DVT as effectively as if an anticoagulant is added to this regimen (risk ratio [RR] = 0.52; 95% confidence interval [CI]: 0.33–0.82).[6] The risk of PE, or major or minor bleeding, is no different between regimens. The use of CPM devices after TKA has also been investigated in terms of preventing venous thromboembolism. A Cochrane review found that there was no advantage to the use of CPM in preventing venous thromboembolism after TKA (RR = 1.22; 95% CI: 0.85–1.79).[7]

DOACs

In a network meta-analysis, LMWH was compared to DOACs (and various DOACs were compared to one another).[8] The following DOACs were found to decrease the odds of venous thromboembolism as compared to enoxaparin (i.e. LMWH): apixaban (odds ratio [OR] = 0.59; 95% CI: 0.42–0.84), fondaparinux (OR = 0.47; 95% CI: 0.33–0.65), rivaroxaban (OR = 0.41; 95% CI: 0.30–0.58), and edoxaban (OR = 0.45; 95% CI: 0.24–0.84). Fondaparinux and rivaroxaban were found to increase the odds of major bleeding in comparison to LMWH (OR = 1.46; 95% CI: 1.05–2.03 and OR = 1.28; 95% CI: 1.04–1.57, respectively), whereas apixaban appeared to decrease the odds of major bleeding (OR = 0.82; 95% CI: 0.69–0.98). Importantly, the authors noted that all trials informing these conclusions were vulnerable to unclear or high risk of bias, and all were industry-sponsored trials.[8] In a separate meta-analysis, most newer-generation anticoagulants (with the exception of apixaban) were also found to increase bleeding risk compared to a LMWH.[9]

Acetylsalicylic acid (ASA)

Based on a meta-analysis of current level I evidence, ASA does not differ from anticoagulants in terms of incidence of proximal DVT in patients undergoing elective hip or knee arthroplasty (RR = 1.00; 95% CI: 0.49–2.05).[11] Rates of PE were too low to make meaningful comparative estimates. The risk of bleeding complications was also no different between groups following elective arthroplasty (RR = 0.63; 95% CI: 0.33–1.21). Of note, the anticoagulants used in the trials included in this estimate were all traditional anticoagulants (i.e. heparins or warfarin). An RCT comparison to between ASA and existing DOACs was not found. Further, in the hip fracture subgroup within the meta-analysis, it was noted that risk of bleeding was lower

with the use of ASA as compared to anticoagulants (RR = 0.32; 95% CI: 0.13–0.77).

Resolution of clinical scenario

There is currently no single gold standard regimen for thromboembolism prophylaxis. Guidelines remain broad, and more recent evidence has failed to resolve the issue. Some form of chemoprophylaxis is recommended, with or without the use of supplemental mechanical prophylaxis. Acceptable pharmacologic agents include ASA, warfarin, and newer-generation anticoagulants. There is a theoretical advantage of DOACs over ASA in terms of preventing thromboembolism; however, these agents have been associated with a higher risk of clinically important bleeding.

In this context, DOACs may represent the optimal choice in patients at high risk of thromboembolism, such as those requiring prolonged immobilization or with a previous history of DVT or PE. ASA may be the more appropriate option in patients at higher risk of bleeding or wound complications. These relative advantages have not been proven in high-quality RCTs of lower-extremity joint arthroplasty patients and therefore clinical equipoise remains.

Question 2: In patients undergoing TKA, is routine postoperative screening, compared to no screening, for venous thromboembolic disease effective in preventing morbidity and mortality?

Rationale

The use of investigations to routinely screen patients for asymptomatic DVTs is not currently the standard of care following TKA. Such screening may be advisable if it leads to a reduction in morbidity and mortality associated with thromboembolic disease.

Clinical comment

Color doppler-compression ultrasound has emerged as the most sensitive and specific diagnostic modality to detect DVT, particularly after orthopedic surgery.[12] A further advantage of this diagnostic test over traditional venography is that it is fast, convenient, and noninvasive. As such, it has excellent potential as a routine DVT screening tool as well. However, given the number of TKAs that are performed each year (i.e. over 600 000 annually in the United States alone), the use of a screening investigation for asymptomatic patients would add millions of dollars to costs every year.[13] These costs may be considered justifiable if such screening could help identify patients at risk for PE. Whether routine screening and detection of clinically asymptomatic DVTs (many of which will never become clinically important DVTs or PEs) leads to a clinical reduction in morbidity and mortality is debatable, however, and has been the subject of investigation.

Available literature and quality of the evidence

There are two high-quality RCTs, representing level I evidence, assessing the effectiveness of routine ultrasonographic screening following hip or knee arthroplasty in detecting clinically important venous thromboembolic events (i.e. PE or symptomatic DVT).[14],[15] Robinson and colleagues randomized 1024 patients

undergoing hip or knee arthroplasty to either bilateral lower extremity ultrasound screening or a sham screening procedure.[14] For both groups, pharmacologic prophylaxis was discontinued after hospital discharge in patients who did not have any evidence of thromboembolism. Schmidt and colleagues randomized 346 elective lower-extremity arthroplasty patients stratified by type of arthroplasty (i.e. hip or knee) to either prolonged prophylaxis (i.e. five weeks of LMWH) or both short duration prophylaxis (i.e. 10 days maximum of LMWH) and postoperative ultrasound screening.[15] In the latter group, anticoagulation was only continued beyond the tenth day if there was evidence of venous thromboembolism.

Findings

Robinson and colleagues found no benefit in preventing symptomatic PE or symptomatic proximal DVT between the two groups within the 90-day follow-up window (0% difference; 95% CI: −1.2% to 1.2%).[14] Schmidt and colleagues also found no differences in a composite endpoint of venous thromboembolism and mortality (8.7% with screening vs 4.3%, p = 0.12) or venous thromboembolism alone (1.2% with screening vs 0.6%, p = 0.34) at 35-day follow-up.[15] This study also evaluated for asymptomatic DVT – the clinical importance of which is less clear – and found no difference between groups at day 35.

Resolution of clinical scenario

The routine use of ultrasonographic DVT screening for patients following TKA is not recommended, as it does not lead to a reduction in clinically important venous thromboembolic events.

Question 3: In patients undergoing TKA, is extended duration venous thromboembolism prophylaxis more effective than short duration prophylaxis?

Rationale

The duration of required prophylaxis is a common inquiry posed by both patients and orthopedic surgeons. There are risks to lengthier regimens of thromboembolism prophylaxis, and identifying the optimal duration is therefore important.

Clinical comment

The delicate balance between avoidance of bleeding complications and prevention of venous thromboembolism and PE is a recurrent theme in decision-making around venous thromboembolism prophylaxis in arthroplasty surgery.[3,10] In terms of length of prophylaxis, there are two schools of thoughts. One school believes that thromboembolism prophylaxis should occur for a period of 1–2 weeks (or occasionally only until discharge from hospital), while the other argues for a more prolonged regimen of 5–7 weeks.

It is in the immediate postoperative period that patients are most pro-inflammatory and most immobile, and therefore likely at highest risk for developing venous thromboembolism. Once discharged, ongoing mobilization and physiotherapy is encouraged, theoretically decreasing the risk of thromboembolism. This would favor limiting the length that patients are exposed to anticoagulants to limit bleeding complications. On the contrary, once the

immediate postoperative inflammation settles and the wound heals, the bleeding risk of prophylactic anticoagulation is arguably lower as well. Indeed, there are certainly physiologic reasons for and against extended duration prophylaxis. Ideally, clinical outcomes – and more specifically, evidence of clinical benefit associated with acceptable rates of adverse bleeding events – would guide this decision.

Available literature and quality of the evidence

There is a high-quality level I systematic review and meta-analysis of RCTs available to answer this question published by the Cochrane group.[16] The most recent iteration of this review was published in 2016. This review evaluated trials which compared anticoagulants including LMWH, UFH (unfractionated heparin), vitamin K antagonists, and/or DOACs administered for an extended duration (5–7 weeks) with similar anticoagulants administered for only 1–2 weeks. Importantly, trials of ASA were not included in this review.

Findings

Sixteen RCTs comprising a total of 24930 patients were included in this systematic review.[16] Only three of the 16 trials included TKA, with the remaining focused on total hip arthroplasty. The comparisons were further subdivided for meta-analysis based on the pharmacologic agents included in the RCTs. A total of six different pharmacologic treatment combinations were identified. The only positive finding was a reduction in all symptomatic venous thromboembolic events (OR = 0.20; 95% CI: 0.06–0.68; moderate confidence) and symptomatic DVT alone (OR = 0.18; 95% CI: 0.04–0.81) with an extended duration of DOAC prophylaxis in patients following total hip arthroplasty. A difference in PE alone was not detected,

although this outcome suffered from low numbers and therefore low confidence. Other anticoagulants (i.e. heparins and vitamin K antagonists) failed to demonstrate a difference between short and extended duration prophylactic regimens.

Resolution of clinical scenario

In the setting of TKA, the evidence to guide decision-making is lacking. Although more extensive evidence is available for total hip arthroplasty, even these data do not conclusively support one regimen over the other. Evidence from two RCTs demonstrates that an extended duration DOAC regimen reduces symptomatic DVT (with high GRADE confidence), but not necessarily PE, without increasing bleeding complications (with moderate GRADE confidence). These findings, however, were not consistent across all types of anticoagulants. Further, whether these findings can be reproduced in TKA remains to be demonstrated.

Summary of answers

- There is no single gold standard pharmacologic agent for venous thromboembolism prophylaxis after TKA. The evidence is not conclusive, and orthopedic surgeons must weigh the need for potent prophylaxis and the need to prevent bleeding.
- Newer-generation anticoagulants (i.e. DOACs) may represent the optimal thromboembolism prophylaxis choice in patients at high risk of thromboembolism, whereas ASA may be the more appropriate choice in patients at higher risk of bleeding or wound complications. These relative advantages have not been proven in high-quality RCTs of lower-extremity joint

arthroplasty patients and therefore clinical equipoise remains.

- Routine postoperative ultrasonographic DVT screening (e.g. to guide the need for prolonged prophylaxis or thromboembolism treatment) does not reduce the incidence of symptomatic DVT or PE, and is not recommended after TKA.
- The ideal length of time for venous thromboembolism prophylaxis after TKA has not been determined. Specifically, there is no definitive difference in venous thromboembolism and bleeding between short duration and extended duration chemoprophylactic regimens following TKA. However, high-quality evidence to guide this decision is lacking.

[2] Albany Health Campus, Department of Surgery, Albany, Australia

[3] Harris Orthopaedic Laboratory, Massachusetts General Hospital, Boston, MA, USA

[4] Department of Orthopaedic Surgery, Harvard Medical School, Boston, MA, USA

Top three questions

1. For patients with total knee arthroplasty (TKA), is highly cross-linked polyethylene (XLPE) more resistant to wear than conventional polyethylene (non-XLPE)?
2. For patients with TKA, does XLPE provide better clinical outcomes and a lower revision rate than conventional polyethylene (non-XLPE)?
3. For patients with TKA, does the addition of antioxidants to XLPE, compared to no antioxidants, make it more resistant to wear?

Question 1: For patients with total knee arthroplasty (TKA), is highly cross-linked polyethylene (XLPE) more resistant to wear than conventional polyethylene (non-XLPE)?

Rationale

The main purported benefit of XLPE is increased resistance to wear.

Clinical comment

Loosening and lysis related to wear are the most common reasons for TKA revision.

Available literature and quality of the evidence

- Level I: 1 meta-analysis, 3 randomized trials.
- Level II: 2 prospective cohort trial.
- Level III: 2 case-control studies.
- Nonclinical: multiple laboratory trials (Table 49.1).

Table 49.1 Clinical trials of TKAs using XLPE.

Author	Year	Trial design	Knees (n)	Follow-up (yr)	Implant and polyethylene	Radiolucency (%)	Osteolysis (%)	Aseptic loosening (%)
Hodrick et al.[10]	2008	CCT	100	6.3 (5.8–6.8)	Natural Knee II, CR (Zimmer); Durasul	2 (2.4)	0§	0§
Minoda et al.[9]	2009	CCT	89	2	NexGen, CR (Zimmer); Prolong	5 (5.6)	0*	0*
Kim and Park[11]	2014	RCT	308	5.9 (5–6.8)	NexGen LPS-Flex, PS (Zimmer); Prolong	—	0*	0*

Lachiewicz and Soileau[12]	2016	RCT	94	4.5 (2–8)	NexGen LPS-Flex, PS (Zimmer); Prolong	15 (16)	0†	0

§ Four patients had osteolysis in the conventional polyethylene group and four had aseptic loosening (p = ns).

* No patients in the conventional polyethylene group had osteolysis or aseptic loosening either.

‡ There were zero patients in the conventional polyethylene with osteolysis and three patients with aseptic loosening (p = ns).

† Two patients in the conventional polyethylene group had osteolysis and none had aseptic loosening (p = ns).

CCT: controlled clinical trial; RCT: randomized controlled trial; PCT: placebo controlled trial.

Findings

Knee simulator studies on the wear behavior of tibial knee inserts have looked at the effects of long-term testing, artificial aging, presence of third body particles, implant design, and malpositioning of implants. The studies uniformly showed improved adhesive/abrasive wear with XLPE compared to non-XLPE in both cruciate retaining and posterior stabilized designs.[1–8]

Two case-control trials reported an increase in radiolucent lines in patients with non-XLPE compared with XLPE. However, there was no evidence of loosening or osteolysis and no failures in either group.[9,10] Three randomized controlled trials (RCTs) and a prospective cohort study demonstrated no differences in radiographic outcomes between TKAs with XLPE and non-XLPE.[11–13] A meta-analysis that included all the above trials found no difference in incidence of radiolucent lines, osteolysis or prosthesis loosening between XLPE and non-XLPE.[14]

Analysis of synovial fluid aspirates of patients at one-year post TKA have shown significantly fewer polyethylene wear particles in knees with XLPE versus non-XLPE.[15–17] The particles produced from the XLPE are also smaller than those produced by non-XLPE.[15–17] The biological implications of these smaller particles, however, remain unknown.

Resolution of clinical scenario

- Knee simulator studies exhibit decreased wear.
- Postoperative knee synovial fluid aspirates have less polyethylene particles in TKAs with XLPE compared with non-XLPE.
- Clinical trials have not demonstrated any difference in radiographic outcomes.

Question 2: For patients with TKA, does XLPE provide better clinical outcomes and a lower revision rate than conventional polyethylene (non-XLPE)?

Rationale

For XLPE to be considered superior to non-XLPE, it needs to demonstrate a lower revision rate and/or provide better clinical outcomes.

Clinical comment

The key factors of importance to a patient undergoing TKA are clinical outcomes and prosthesis survivorship.

Available literature and quality of the evidence

- Level I: 1 meta-analysis, 3 randomized trials.
- Level II: 1 prospective cohort trial, 2 joint registries.
- Level III: 2 case-control studies.

Findings

At short-term follow-up (4–6 years), three RCTs did not detect a difference between XLPE and non-XLPE.[11,13] An RCT by Kindsfater et al. found no significant difference in survivorship or clinical outcomes, between patients randomized to either XLPE (n = 179) or non-XLPE (n = 189) at five-year follow-up.[13] Similarly, in another RCT, Lachiewicz and Soileau found no significant difference in survivorship or clinical outcomes between patients with XLPE and non-XLPE in 236 TKAs at a mean follow-up of 4.5 years.[12] Kim and Park randomized 308 patients undergoing bilateral TKA to receive XLPE in one knee and non-XLPE in the other knee.[11] Again, they found no significant difference in survivorship or clinical outcomes at a mean follow-up of 5.9 years.

A prospective cohort study of 114 consecutive TKAs with XLPE (64) or non-XLPE (50) reported no difference in survivorship at a mean of five-year follow-up.[19] There was an increased Knee Society Score (12 points, $p = 0.01$) and Short Form 36 (SF-36) physical function score (14 points, $p = 0.005$) in the XLPE group, but a selection bias toward younger patients in the XLPE group (by a mean of 3.5 years) compared to the non-XLPE group may explain the difference. A second study that contained the same cohort, as well as patients from other institutions for a total of 224 knees, had no wear-related failures at five-year follow-up.[18]

A meta-analysis that included all the above trials found no difference in clinical outcomes or survivorship comparing XLPE and non-XLPE.[14] It should be noted, however, that all these studies only present results from relatively short follow-up (2–6 years), and that samples sizes were small.

Data from the Australian Orthopaedic Association National Joint Replacement Registry 2017 which included 534 029 primary TKAs demonstrated that using XLPE had a revision rate of 3.7% at 10 years, compared to 5.7% for non-XLPE.[20] The main reason for this difference is a reduced incidence of loosening (0.7% at 10 years for XLPE compared to 1.5% for non-XLPE). The difference in revision is even greater in younger patients (in patients <65 years, XLPE 5.2% compared to non-XLPE 8.4%, p <0.001). However, these results may be confounded by differences in prostheses that use XLPE versus those that do not. To eliminate this potential bias, an analysis was performed comparing revision rates for 16 individual prostheses that have used both XLPE and non-XLPE bearings in at least 500 procedures. The revision rate was lower when XLPE was used in three of the prostheses and there was no difference for the others. A study looking at data from 77 084 primary TKAs the Kaiser Permanente Total Joint Replacement Registry between 2001 and 2011 found no difference in revision rate between XLPE and non-XLPE at five-year follow-up.[21]

Resolution of clinical scenario

- At short-term follow-up, in randomized clinical studies, XLPE demonstrates no clinical differences to non-XLPE.
- At medium-term follow-up, registry data show a reduced rate of revision for XLPE, but only in some prostheses.
- Longer follow-up clinical data are required to determine the real value of XLPE in TKA.

Question 3: For patients with TKA, does the addition of antioxidants to XLPE, compared to no antioxidants, make it more resistant to wear?

Rationale

The rationale behind the development of XLPE with antioxidants was that the residual free radicals from the radiation cross-linking could be stabilized by the antioxidant, eliminating the need for postirradiation melting for oxidative resistance. This should result in the retention of crystallinity and fatigue resistance.

Clinical comment

Oxidized polyethylene is linked to higher incidence of wear and damage in TKAs. Loosening and lysis related to wear are the most common reasons for TKA revision.

Available literature and quality of the evidence

- Level II: 1 joint registry.
- Level III: 1 retrospective study.
- Nonclinical: multiple laboratory trials.

Findings

In vitro biomechanical studies of antioxidant XLPE have reported decreased wear, greater fatigue resistance compared to postirradiation melted XLPE, and high resistance to oxidation.[22–25] Importantly, antioxidant XLPE performed superiorly in studies of accelerated aging.[22,23,26,27] In addition to these mechanical properties, wear particles of

antioxidant XLPE have been reported to produce fewer inflammatory cytokines than conventional polyethylene when exposed to mononuclear cells in a laboratory study.[28]

An in vivo literature review found minimal clinical evidence for the use of antioxidant XLPE in TKAs. A retrospective review of a practice registry included 163 knees at a mean follow-up of 3.2 years (range 6 weeks to 6.4 years).[29] They found no incidence of aseptic loosening at this early stage. The Australian Orthopaedic Association National Joint Replacement Registry 2017 report compared the revision rate of XLPE with antioxidants to XLPE without antioxidants.[20] There was a statistically significant decrease in revision rate for antioxidant XLPE (hazard ratio [HR] = 0.80; 95% confidence interval [CI]: 0.65–0.99; p = 0.044). However, it should be noted that the maximum follow-up was only five years, overall numbers using antioxidant XLPE were small and over 80% of the procedures used a single prosthesis (Attune, Depuy). If the Attune prosthesis were excluded, there would be no significant difference.

Resolution of clinical scenario

Minimal clinical evidence for the use of antioxidant XLPE in TKAs at this early stage of its adoption. Long-term follow-up studies are required.

Summary of answers

- In short- to medium-term clinical trials, XLPE demonstrates no clinical or radiographic differences to non-XLPE.
- Registry data show a reduced rate of revision for XLPE, but only in some prostheses.
- Laboratory trials have demonstrated benefits to XLPE and antioxidant XLPE over non-XLPE.

More long-term clinical data are required.

50 Exposure and Implant Options in Revision Total Knee Arthroplasty

Felipe Moreira MD, Maria Jurado MD, and Marcelo Casaccia MD
Hospital Vall d'Hebron, Barcelona, Spain

Clinical scenario

- A 72-year-old, active woman with a right total knee arthroplasty (TKA) performed 12 years ago complains of pain and locking in her right knee.
- She is having difficulty ascending and descending stairs for a year now, and requires a walking aid, even when walking a few hundred meters.
- On examination, the right knee is unstable in varus-valgus, and on X-ray, there is a valgus collapse of the tibia indicating the possibility of loosening.
- After ruling out infection a revision TKA is indicated.

Top three questions

1. In patients undergoing revision TKA, does one surgical approach, compared to others, result in optimal outcomes?
2. In patients undergoing revision TKA, does a tibial tubercle osteotomy (TTO), compared to quadriceps snip (QS), result in improved functional outcomes and fewer complications?
3. In patients undergoing revision TKA and requiring augmentation due to bone defects, do metaphyseal

cones, compared to sleeves, result in better outcomes ?

Question 1: In patients undergoing revision TKA, does one surgical approach, compared to others, result in optimal outcomes?

Rationale

Controversy exists when regarding the best surgical approach for revision total knee arthroplasty (rTKA). Such an approach should ideally have delicate management of the soft tissue envelope and reduce the risk of extensor mechanism complications.

Clinical comment

Obtaining an adequate surgical exposure is among the first and most important steps in performing an rTKA. Objectives include protecting the extensor mechanism, safely removing the implanted components, and obtaining adequate visualization to prepare the bony surfaces for the revision components.[1] Challenges to these goals include prior skin incisions, dense scarring, and the presence of patella baja.

Available literature and quality of the evidence

- Level I: 1 randomized controlled study.[2]
- Level II: 1 retrospective cohort study.[3]
- Level IV: 5 retrospective case series.[4–8]
- Level V: 1 cadaveric study.[9]

Findings

During the exposure there are three important decisions to be made while dissecting toward the prosthetic components.[10]

Skin incision

Blood supply to the anterior aspect of the knee is predominantly derived from the medial side, and it travels from deep to superficial layers. Hence, if there are many previous incisions, the most lateral one should be utilized, and full thickness skin flaps should be developed, as well as excision of the scar tissue. Transverse scars should be transected at a perpendicular angle to prevent skin necrosis. Patients with multiple scars and densely adherent skin may require a preoperative consultation with a plastic surgeon.

Capsular approach

The workhorse approach to the knee is the medial parapatellar capsular incision. When performed associated with an accurate anterior and posterior intra-articular synovectomy, it provides an adequate exposure for most revision TKAs.[8]

Using extensor mechanism tenolysis and scar removal technique, eversion of the patella and removal of components is readily accomplished for the vast majority of patients.[7] After that, the patella inversion method affords adequate exposure in most patients without violating the extensor mechanism.[4]

Mobilization of the extensor mechanism

If at this point in the procedure the exposure is inadequate, an extensive exposure of the knee is required to increase patellar excursion while maintaining the function of the extensor mechanism. It is a critical step, and it should aim

to minimize the risk of patellar tendon disruption, quadriceps tendon rupture, patellar crepitus, and soft tissue impingement, periprosthetic patella fracture, patellofemoral instability, and osteonecrosis of the patella. The decision to extend the incision proximally, distally, or in combination should be determined on an individual basis.

Proximally, relaxation of the quadriceps tendon can be achieved by a QS.[5],[11] Technically easier, it does not require an alteration in the postoperative physical therapy and it shows similar clinical outcomes as those achieved using an isolated medial parapatellar approach (MPA). However, some studies have demonstrated an increased risk of implant malalignment in primary TKA.[12] An extensive MPA increases the mobility and excursion of the patella to the same extent as the QS technique, and it is theoretically safer in terms of preservation of quadriceps tendon integrity.[9]

The V-Y modified quadricepsplasty (QP) is rarely indicated given the risk of postoperative extensor lag. Notwithstanding the possible extension lag, Zhamilov et al. conclude that QP is as effective as QS when extensile exposure is required and may be used safely, although weightbearing is delayed postoperatively.[3] In general, however, it is considered only when a TTO is contraindicated and there is severe stiffness. Distally, the exposure can be improved by a TTO, which gives the greatest degree of exposure and it is useful in patients with stiff or ankylosed knees, in cases of patella baja or when a well-fixed cemented tibial stem should be removed. TTO should be considered the gold standard in extensile exposure, but it is a technically demanding procedure and also associated with some complications if it is done without a strict technique.

Resolution of clinical scenario

- The appropriate surgical exposure for any revision procedure should be determined by careful preoperative planning based on the assessment of the previous exposures used, of the type of implant to be removed, and the extent of bone deficiencies to be reconstructed.
- A medial capsular approach with a thorough intra-articular release and extensor mechanism tenolysis provides adequate exposure for the majority of revision cases. If additional exposure is needed, a QS through tendon or an extensive MPA is often helpful, and does not alter the postoperative rehabilitation protocol.
- Surgeons performing difficult rTKA cases should be familiar with a range of approaches and must be aware of proximal and distal extension procedures.
- Further studies, preferably in a prospective randomized fashion, are required to define the differences between the more extensile approaches.

Question 2: In patients undergoing revision TKA, does a tibial tubercle osteotomy (TTO), compared to quadriceps snip (QS), result in improved functional outcomes and fewer complications?

Rationale

A MPA with a thorough intra-articular release provides adequate exposure for most revision cases. However, when

it is suboptimal and an extensive approach is needed, the next maneuver is typically a QS or a TTO.

Clinical comment

Common problems associated with multiple revisions are loss of bone stock, progressive scarring, deficits of the extensor mechanism, and stiffness. Therefore, technique modifications that focus on preservation of bone stock, maintenance of the extensor mechanism, and enhanced early mobilization bear importance. The extensile approach should ideally reduce the risk of complications while also considering the higher reinfection rate in cases of septic revisions.

Available literature and quality of the evidence

The quantity and quality of literature comparing QS and TTO is limited. Only one study prospectively compares, after randomization, both approaches.[7] A grade III study, retrospectively addressees the same question.[8] Most articles are case reports or case series that lack standardization of protocols and outcomes.

Findings

Regardless of the need for an rTKA, a safe surgical exposure and exquisite management of the soft tissue envelope is necessary. Various surgical approaches can be used at revision surgery including an MPA with synovectomy, a QS, TTO, and a V-Y quadricepsplasty, each associated with advantages and potential complications.

A medial capsular approach with a thorough intra-articular release provides adequate exposure for over 90% of revision TKA cases.[9],[11] When suboptimal, typically an extensive approach is indispensable. Most surgeons will typically opt for a QS or a TTO. The first releases the

proximal tension, while the latter allows for distal release of the extensor mechanism.

The advantages of the QS approach include its technical ease and the fact that the postoperative rehabilitation protocol does not need to be modified. Despite plausible clinical advantages in developing the plane between vastus medialis and rectus femoris, as opposed to cutting across the quadriceps tendon,[5] studies comparing QS to MPA found it to be a relatively safe approach with equivalent outcomes.[12–15]

Since TTO was first described by Dolin et al. in the 1980s,[14] it has become one of the exposures of choice for revision surgery; because of its low complications rate, it is useful in explanation and implantation, protects the extensor mechanism, lowers tourniquet time, and does not interfere with postoperative mobilization and weight bearing.[5,16,17]

Two studies have directly compared both approaches finding equivalent functional outcomes while complications rates appeared higher on QS than on TTO.[2,6]

Sun et al. enrolled 48 patients undergoing a two-stage RTKA for infected TKA using one of these two surgical approaches, 27 in the QS group and 21 on the TTO.[6] There was a significant improvement in the Knee Society Score (KSS), Hospital for Special Surgery (HSS) score, Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC) scores, and maximum flexion compared to the preoperative status in both groups, while there were no statistically significant differences between the two groups. Moreover, the femorotibial alignment and patellar height also showed no differences between the two groups. Regarding complications, they found patellar tendon partial avulsion was more commonly observed in the QS group than in the TTO group (five vs two cases). No cases of

complication related directly to the osteotomy were seen in the TTO group.

Bruni et al. prospectively followed 81 patients with chronic prosthetic knee infections who were randomized to receive a TTO or QS for exposure at the time of reimplantation.[2] Patients in the TTO group had a higher mean KSS and maximum knee flexion with a lower incidence of extension lag than the QS group. There were no differences in the reinfection rate between the two groups at last follow-up and no patient had rupture of the extensor mechanism.

Due to the risk of postoperative extensor lag, a V-Y quadricepsplasty is rarely indicated.[16–18]

Resolution of clinical scenario

- A medial capsular approach with a thorough intra-articular release provides adequate exposure for the majority of revision cases.
- Both TTO and QS in revision TKA are considered reasonable options regarding clinical results, healing potential, and complication rates.
- The TTO appears to be slightly superior to QS, both functionally and in procedure-related complications. Presenting a lower risk of patellar tendon partial avulsion, a superior KSS score, and not impairing the extensor mechanism function or increasing the reinfection rate.
- A V-Y quadricepsplasty is rarely indicated.

Question 3: In patients undergoing revision TKA and requiring augmentation due to bone defects, do metaphyseal cones, compared to sleeves, result in better outcomes?

Rationale

Managing metaphyseal bone loss in rTKA is a difficult task at the best of times. The use of metaphyseal sleeves and cones over modular augments appear to be on the rise. Sleeves are linked and implant specific, whereas cones are nonlinked and can be used with different implants. Knowing which fixation technique provides us with better outcomes with the least possible complications is important.

Clinical comment

When managing metaphyseal bone defects in rTKA, it is important to enter the operating room with all potentially required components available or on call. With metaphyseal sleeves and cones, most Anderson Orthopaedic Research Institute (AORI) type 2 and 3 defects can be addressed.

Available literature and quality of the evidence

The literature comparing the two techniques, sleeves versus cones, is scarce. Most of the papers are level IV evidence, with a few case-control (level III evidence). No randomized controlled trials are available.

Findings

The metaphyseal sleeves and metaphyseal cones are both good techniques to address metaphyseal defects, including

AORI type 2 and 3. Both clinical and radiological results are comparable between both techniques, providing good functional and radiological results. They can control rotational and axial stability immediately due to press-fit configuration, and long term, thanks to the bone ingrowth. None of the currently available, low-quality literature points to a difference in radiographic or functional outcomes between cones and sleeves.[19_31]

Resolution of clinical scenario

- The use of either sleeves or cones for rTKA with metaphyseal defects provide both similar and good outcomes.
- Clinical and radiological results are similar comparing both techniques.
- Further studies, with a higher level of evidence are needed in order to determine which technique has better outcomes.
- The current recommendation is to use the technique that the surgeon manages better.

Summary of answers

- There is no single best approach for revision TKA surgery, and the approach and augmenting techniques should be selected based on the previous surgery and the defects that need to be addressed .
- TTO is superior to QS both functionally and in terms of complications.
- Metaphyseal sleeves and cones provide similar and reliable outcomes for large tibial defects.

The Painful Total Knee Arthroplasty

Jason Werle MD FRCSC[1], Kelly Johnston MD FRCSC[1], Nicholas Desy MD FRCSC[1] and Stuart Goodman MD PhD FRCSC[2]
[1]Division of Orthopaedic Surgery, Department of Surgery, University of Calgary, Calgary, AB, Canada
[2]Department of Orthopaedic Surgery, Stanford University, Stanford, CA, USA

Clinical scenario

- A 57 year-old female presents with a painful total knee arthroplasty (TKA) 18 months postoperatively.
- She had pain relief for a few months postoperatively but she now has pain that interferes with her activities of daily living.
- The patient is dissatisfied with her functional outcome and the TKA.

Top three questions

1. For patients with painful TKA, what are the best evidence-based clinical investigations to assess for intra- and extra-articular etiologies in the initial work-up?
2. Are SPECT scans superior to nuclear medicine imaging or plain computed tomography (CT) scans in the evaluation of the painful TKA?

3. Are synovial biomarkers (i.e. alpha-defensin) superior to aspiration for microbiology and serum laboratory investigations in the evaluation of the painful TKA?

Question 1: For patients with painful TKA, what are the best evidence-based clinical investigations to assess for intra- and extra-articular etiologies in the initial work-up?

Rationale

As many as one in five primary TKA patients are not satisfied with the outcome of their TKA surgery.[1] This can be concerning for the patient and surgeon alike. TKA patients experiencing pain require significant healthcare resources to evaluate and manage. Ensuring that evidence-based investigations are employed will translate into appropriate use of these limited resources.

Clinical comment

Investigating the painful TKA requires a systematic approach that ensures both intra- and extra-articular etiologies are assessed.[2] Potential intra-articular etiologies include: infection, instability in flexion, mid-flexion, or extension, component malalignment, crepitation and patellar clunk syndrome, patellofemoral symptoms, such as maltracking, or avascular necrosis, aseptic loosening, hypersensitivity to metal or cement, complex regional pain syndrome, or pseudoaneurysm.[3,4]

Extra-articular causes of pain after TKA should be considered when infection and other intra-articular pathologies have been ruled out. Potential causes include

referred or secondary pain from spine, hip, foot, or ankle disease that has not yet been diagnosed, as well as vascular pathology, tendinitis, bursitis, iliotibial band syndrome, or medical comorbidities, such as metabolic bone disease or psychological illness.[5]

Understanding an algorithm with evidence-based investigations for common causes of painful TKA ensures that correctable problems are addressed. Intervening with revision TKA when the etiology is unclear generally leads to poor results.[6]>–[8]

Available literature and quality of the evidence

The quality of literature addressing appropriate investigations for a painful TKA is highly variable with level II–IV evidence. The majority of the outcome papers are case series or cohort studies. There are no randomized trials.

Findings

History/old records

A thorough pain history can assist with the diagnosis. This should include an assessment of the character, location, onset, radiation, intensity, and duration of the pain as well as provoking and palliating factors. A history of prior infection is a critical finding.[9] *Start-up* or *initiation* pain is consistent with aseptic loosening, whereas pain that is constant and does not abate should raise suspicion for periprosthetic joint infection (PJI).[7]

Details of the TKA surgery and postoperative course including odds ratio (OR) records and perioperative notes can provide information on surgical complications such as prolonged postoperative wound drainage, delayed wound healing, return trips to the operating room, and treatment with antibiotics following surgery.[7] The patient's medical

history, medications, allergies including metal sensitivities, and expectations for the surgical outcome of the TKA should also be assessed.

Physical examination

Physical examination should include a general exam with vital signs, height, weight, body mass index (BMI), general appearance, and gait. Detailed inspection of the skin can reveal the previous surgical scars, skin lesions, erythema, swelling/effusion, vascular changes, and draining sinus tracts. Gait should be specifically assessed for antalgia, varus/valgus thrust, and a Trendelenburg's sign.[7]

A focused examination of the knee should include measurement of active and passive range of motion, assessment for extensor lag, evaluation of stability to varus and valgus stressing in full extension, mid-flexion (30–60°), and 90° of flexion, and palpation for areas of focal tenderness or swelling. Patellar tracking should be examined throughout the range of motion.

A neurovascular examination should be performed assessing peripheral pulses, motor function, and sensation in the lower extremity.

Examination of joints above (hip, lumbar spine) and below (foot and ankle) the affected knee should be performed to rule out extra-articular sources of pain such as lumbar radiculopathy, vascular claudication, or referred pain from hip arthritis.[7]

Plain radiographs/three-foot standing images

Obtaining serial radiographs can assist with the evaluation of implant stability over time.[4,7] Lucent lines at the bone–implant or bone–cement interface that are complete or

greater than 2 mm may indicate loosening.[10] Implant position changes are pathognomonic for implant loosening.

Three-foot standing, anteroposterior, and lateral and patellofemoral radiographs of the affected TKA are useful for assessing the mechanical and anatomic axes of the lower extremity, as well as component positioning.

Computed tomography (CT) scans

CT assists with the evaluation of component rotation and areas of osteolysis, which are often underestimated on plain radiographs.[11]

Malrotation of the femoral component, typically internal rotation, can lead to pain following TKA through early failure due to instability.[12] Malalignment of the TKA can lead to failure due to implant wear and aseptic loosening.[13] CT can assist with diagnosis of both of these conditions.

Laboratory tests (CBC, ESR, C-reactive protein)

Complete blood count (CBC)/white blood cell count (WBC) Complete blood count or serum white cell count and differential testing is not useful in the evaluation of pain following TKA.[14] The sensitivity of the WBC count was 55% and specificity was 66% in the diagnosis of TKA infection in a recent study by Toossi.[15] However, a CBC may be helpful in the diagnosis of cases of acute hematogenous infection in the setting of a previously well-functioning arthroplasty.

Erythrocyte sedimentation rate (ESR) ESR remains elevated for up to three months post TKA. It is a sensitive but nonspecific test for the evaluation of PJI. Levitsky et al. reported that the ESR was statistically significantly higher in TKA patients with definitive infection. Also, they

reported that an elevated ESR (>30 mm/h) had a sensitivity of 60% and a specificity of 65% for PJI.[16]

Spangehl et al. identified a sensitivity of 0.82 and a specificity of 0.85 for the ESR in 202 revision arthroplasty patients.[17]

C-reactive protein (CRP) CRP can remain elevated for up to three weeks post TKA. Spangehl et al. identified a sensitivity of 0.96 and a specificity of 0.92 for CRP testing in patients with PJI.[17]

Hardcastle identified that a preoperative abnormality of either CRP or ESR significantly increased the risk of re-operation for all reasons (OR = 3.2; p = 0.0028), infection (OR 4.0; p = 0.034), and revision for aseptic loosening (OR = 3.69; p = 0.044).[18]

Alternatively, a normal ESR and CRP are reliable for predicting the absence of infection.[17]

Knee aspiration

If the ESR and/or CRP are elevated in a patient with a painful TKA, aspiration of the knee is necessary to rule out PJI.[19,20] Synovial fluid should be sent for cell count and differential, aerobic, and anaerobic culture and sensitivity, TB and fungal culture (depending on patient comorbidities, immunosuppression, and tuberculous infection prevalence).

A synovial fluid WBC count between 1100 and 3000 cells/mm^3 is strongly suggestive of a deep PJI.[19,21] These values are substantially lower than the 50 000 cells/mm^3 threshold for diagnosis of septic arthritis in a native knee. If the percentage of neutrophils is between 60 and 80%, infection is likely. As well, when the WBC count is below 1100 cells/mm^3 and the neutrophil percentage is less than 64%, the negative predictive value of knee aspiration is

98.2%; when both values are above these thresholds, the positive predictive value is 98.6%.[8]

It is important to note that these values are only accurate more than six weeks following TKA surgery due to postoperative inflammation that can impact cell count and differential aspiration results prior to that time period.

Preoperative aspiration had a sensitivity of 67% and a specificity of 96% and, therefore, has been identified as the most useful single test in the workup of the painful TKA.[16]

Resolution of clinical scenario as it relates to investigations

- A thorough history and physical examination can assist with appropriate use of ancillary tests including bloodwork, aspiration, and diagnostic imaging when evaluating a patient with a painful TKA.
- A CBC has a limited role in evaluating the painful TKA; however, normal ESR and CRP values are reliable for predicting the absence of infection.
- Aspiration of the knee is one of the most useful tests in the systematic workup of the painful TKA.
- Obtaining serial plain radiographs to assess for progressive lucencies at the bone–implant interface can be diagnostic for implant loosening.

Question 2: Are SPECT scans superior to nuclear medicine imaging or plain computed tomography (CT) scans in the evaluation of the painful TKA?

Rationale

A significant percentage of TKA patients have some complaint of pain related to the arthroplasty.[22] Often history and clinical exam can distinguish between pain generators that are self-limited or related to incomplete soft tissue rehabilitation versus those that are more sinister and can lead to revision arthroplasty. A diagnostic test that assesses alignment of a TKA but also correlates it to biologic activity or inflammation at the bone–prosthetic interface would be very helpful. single-photon emission computed tomography/computed tomography (SPECT/CT) imaging can potentially accomplish this.

Clinical comment

There has been rapid progress in diagnostic imaging of painful TKA.[23] CT scans have proven to be reliable for determining implant position within the skeleton, especially rotational alignment that cannot be appreciated easily on plain radiographs.[24] Typically, the rotation of the femoral and tibial component can be determined and correlated to the clinical picture. Radiolucent lines can be seen on plain x-rays and CT but do not necessarily mean that there is a problem with the arthroplasty. Three-phase, planar bone scintigraphy (bone scan) has been used to determine evidence of accelerated bone turnover at the implant–bone interface but is limited by lack of spatial resolution.[23] SPECT was developed to improve resolution but has been supplanted by SPECT/CT, which combines the maximum benefit of both bone scintigraphy and high-resolution CT. Information on both the mechanical and biologic aspects of TKA can potentially help to accurately diagnose the cause of pain status post TKA.

Available literature and quality of the evidence

Unfortunately, the literature on this subject is lacking as few studies directly compare SPECT/CT to three-phase planar bone scintigraphy or CT alone.

Arican et al. compared SPECT/CT to planar bone scan/SPECT in painful THA and TKA patients.[25] This was a retrospective study of patients that were taken for revision surgery. No patients were treated nonoperatively. Thirty TKAs were evaluated. SPECT/CT was shown to be more sensitive than three-phase planar bone scan (94% vs 77%) for diagnosing aseptic and septic loosening in hip and knee arthroplasty. When considering the femur and tibia components of TKA separately, SPECT/CT was more sensitive than planar bone scan, 87 versus 80% for femur and 93 and 86% for tibia. They also showed that both planar bone scan and SPECT/CT were more sensitive for making these diagnoses in knees compared to hips.

Most of the work on SPECT/CT as it relates to TKA has been done by a single research unit in Switzerland.[2226]>–[30] This group has performed a number of prospective and retrospective diagnostic studies, most with low numbers. The largest study by this group was a prospective diagnostic study of 100 painful TKAs excluding septic loosening.[27] SPECT/CT changed the diagnosis in 85% of painful TKs. Intraoperative findings confirmed the SPECT/CT diagnosis in 32/33 cases (97%). Femoral and tibial loosening and progression of patellofemoral osteoarthritis (PF OA) was correctly diagnosed on SPECT/CT in 100%. They concluded that “SPECT/CT should be part of the routine diagnostic algorithm for patients with pain after TKA.”

Al-Nabhani et al. conducted a retrospective case series of 69 patients with pain following TKA who underwent SPECT/CT.[31] They report an ability to detect loosening with a sensitivity of 100% and specificity of 95%. For

infection, the study was highly sensitive but only 88.1% specific and they noticed a more diffuse uptake pattern at the bone–prosthesis interface for infection compared to loosening which shows a more discrete uptake pattern typically around the tibial component. SPECT/CT was very helpful to determine progression of arthritis in unresurfaced compartments of the knee. SPECT/CT was inconclusive in 10 of 69 studies (14.5%) and was clinically useful in 85.5%. Only 24 cases ended up in revision and SPECT/CT diagnoses matched the revision diagnosis in 21/24 cases. The SPECT/CT report was inconclusive in three of the revised cases and turned out to be progression of OA after revision. To improve the specificity for infection, WBC scan was added bringing specificity to 100%. Specificity of SPECT/CT is affected when it is done within the first 12 months post operation.

Abele et al. and Chew et al. reported on the use of radionuclide arthrography SPECT/CT (RNA SPECT/CT) in joint arthroplasty.[32,33] The mode of radionuclide delivery is different in these studies, intra-articular instead of intravenous, in an effort to diagnose prosthetic loosening. Both of these studies are retrospective diagnostic studies with low patient numbers. Both studies looked at both THA and TKA. Abele et al. showed sensitivity of 100% and specificity of 96% for loose components. Chew et al. retrospectively compared their SPECT/CT results to planar radionuclide imaging and found higher sensitivity in diagnosing loose components, but specificity was not excellent. The sparse literature on this technique, with the potential to introduce infection into a prosthetic joint, does not show it to be a significant advance over intravenous administered radionuclide SPECT/CT. Perhaps the value in this technique would be to determine loosening in the first 12 months after TKA when there is still increased uptake

around the prosthesis with intravenous administered radionuclide.

Resolution of clinical scenario as it relates to SPECT/CT

- SPECT/CT is an advance over three-phase planar bone scintigraphy as spatial resolution is improved and it comes with the added advantage of a high-resolution three-dimensional (3D) CT scan which can accurately determine implant position in relation to mechanical and anatomic axes as well as bone and soft tissue changes around the arthroplasty.
- The sensitivity of a SPECT/CT is very high. A negative study in our particular case would be very reassuring that the pain being experienced is either referred pain or related to inadequate soft tissue rehabilitation and does not require revision surgery.
- The diagnostic dilemma is really between aseptic or septic loosening. At 1–2 years post TKA, there can still be nonpathologic radiotracer uptake around the arthroplasty, but the intensity of that uptake should be low. Aseptic loosening on SPECT/CT will be indicated as a more discrete area of increased radiotracer uptake, usually around the tibial stem versus a more generalized increased uptake around the entire TKA implant in the case of infection.
- If persistent ambiguity exists, an Indium-111 WBC scan (or even a leukocyte-labelled SPECT/CT) can be performed to increase the chances of an accurate diagnosis.

Question 3: Are synovial biomarkers (i.e. alpha-defensin) superior to aspiration for microbiology and serum laboratory investigations in the evaluation of the painful TKA?

Rationale

In the evaluation of the painful TKA, it is critical to differentiate between septic and aseptic causes. The efficacy in diagnosing PJIs utilizing synovial biomarkers is becoming increasingly evident.

Clinical comment

The diagnosis of a PJI in the assessment of a painful TKA can be challenging. The current use of serum inflammatory markers (CRP and ESR) as well as joint aspiration for leukocyte count and differential is not uniformly reliable. Therefore, there is a need to improve the efficiency and reliability in diagnosing a PJI as it relates to a painful TKA. Synovial fluid biomarkers have become of interest to improve the diagnostic accuracy of PJIs.[34,35]

Available literature and quality of the evidence

The current best available evidence consists of one level I diagnostic study[36] and several level II diagnostic studies[35,37>-41] that assess the use of synovial fluid biomarkers to diagnose PJIs. This includes one level II systematic review and meta-analysis.[41]

Findings

Bonanzinga et al. performed a prospective study to determine the sensitivity, specificity, as well as the positive

and negative predictive values of the synovial fluid alpha-defensin test to diagnose PJIs.[36] They also sought to determine factors that may lead to false-positive and false-negative results. Their study included 156 patients, 65 of whom had TKAs.

They found that the alpha-defensin immunoassay had a sensitivity, specificity, positive predictive value, and negative predictive value of 97, 97, 88, and 99%, respectively. Of the four false-positive patients, two had metallosis and one had polyethylene wear. Only one patient had a false-negative result who also had a draining sinus, and the intraoperative cultures were also negative.

Deirmengian et al. have performed several studies to evaluate the role of synovial fluid biomarkers in diagnosing PJIs. In 2014, they published two level II studies that examined alpha-defensin.[35,38] In one study, they found that alpha-defensin had a 100% sensitivity and specificity for the diagnosis of PJI.[35] They also found that alpha-defensin in combination with synovial fluid CRP also had a high sensitivity and specificity.[38] In 2015, this same group demonstrated that synovial fluid alpha-defensin had a higher sensitivity (100%) compared to the leukocyte esterase test strip.[37]

Koh et al. performed a prospective, multicenter study to determine the diagnostic efficacy of the leukocyte esterase strip test and to identify its correlation with serum inflammatory markers as well as a synovial WBC count and polymorphonuclear percentage.[39] They enrolled 60 patients scheduled for revision TKA for either PJI or aseptic failure. The sensitivity, specificity, positive predictive value and negative predictive value were 84, 100, 100, and 79%, respectively. This test was strongly correlated with a synovial WBC count and a polymorphonuclear leukocyte count. It was moderately correlated with CRP and ESR.

Tischler et al. prospectively evaluated the presence of leukocyte esterase in synovial fluid aspirates from hip and knee joint replacements.[40] Their cohort consisted of 189 patients, 154 of which were TKAs. They found a sensitivity, specificity, positive predictive value, and negative predictive value to be 66.0, 97.1, 89.7, and 88, respectively. They concluded that the leukocyte esterase strip test provides a high specificity, positive predictive value, negative predictive value, and a moderate sensitivity.

Wyatt et al. performed a systematic review and meta-analysis to evaluate the accuracy of alpha-defensin or leukocyte esterase in the diagnosis of PJIs.[41] They found 11 eligible studies. The pooled sensitivity and specificity for alpha-defensin were 1.00 (95% confidence interval [CI]: 0.82–1.00) and 0.96 (95% CI: 0.89–0.99), respectively. The pooled sensitivity and specificity for leukocyte esterase was 0.81 (95% CI: 0.49–0.95) and 0.97 (95% CI: 0.82–0.99), respectively. The area under the curve for alpha-defensin and PJI was 0.99 (95% CI: 0.98–1.00). The area under the curve for leukocyte esterase and PJI was 0.97 (95% CI: 0.95–0.98). They also found a lot of heterogeneity among studies.

Resolution of clinical scenario as it relates to synovial biomarkers/lab tests

- The differentiation between septic and aseptic causes of pain following TKA surgery is critical, especially prior to revision surgery.
- The use of synovial biomarkers can be helpful to diagnose a PJI.
- The leukocyte esterase colorimetric strip test is now part of the minor criteria from the International Consensus Group on PJI.[42]

- The alpha-defensin immunoassay demonstrates superior sensitivity and equal to superior specificity to the leukocyte esterase colorimetric strip test.

Summary of answers

- Serial plain radiographs, ESR, and CRP are useful for evaluating a painful TKA.
- SPECT/CT may help to distinguish between aseptic and septic loosening more accurately than three-phase planar bone scintigraphy.
- It is important to differentiate between septic and aseptic pain prior to revision surgery.

Diagnosing the Infected Total Knee Arthroplasty

Mina Tohidi MD and John F. Rudan MD
Division of Orthopaedic Surgery, Department of Surgery, Queen's University, Kingston, ON, Canada

Clinical scenario

- A 54-year-old male presents to clinic six months after right primary TKA. He reports a three-week history of progressive right knee erythema. He started using crutches in the last week due to worsening pain with activity.
- He was assessed in the Emergency Department earlier that week and prescribed oral cephalexin for suspected cellulitis of the right extremity. Bloodwork from that visit shows elevated erythrocyte sedimentation rate (ESR), elevated C-reactive protein (CRP), and normal serum white blood cell (WBC) count. An aspirate was not done.
- The patient denies any recent travel, illness, or dental visits.

Top three questions

1. In patients with signs and symptoms of infection, what is the sensitivity and specificity of synovial fluid cytology, compared to preoperative serologic investigations, for diagnosis of TKA infection?

2. In patients with signs and symptoms of TKA infection, what intraoperative measures can be used for identification of joint infection?
3. For patients with failed two-stage prosthetic exchange secondary to infection, how do patient outcomes compare for repeat attempts at implant exchange, compared to arthrodesis or amputation?

Question 1: In patients with signs and symptoms of infection, what is the sensitivity and specificity of synovial fluid cytology, compared to preoperative serologic investigations, for diagnosis of TKA infection?

Rationale

Identification of the microbial pathogen(s) is critical to the diagnosis of TKA infection. However, traditional aspiration and tissue cultures may not be sufficient to identify a pathogen for two main reasons: (i) it may be difficult to culture biofilm-associated organisms in the laboratory and (ii) the preoperative and postoperative use of antibiotics can make culture results negative.[1] For patients with this type of presentation, alternative, nonmicrobiological testing methods are critical for diagnosis of TKA infection.

Clinical comment

Identification of the microbial pathogen(s) is essential for diagnosis of TKA infection and for selection of appropriate pathogen-specific antimicrobial therapy. There has been growing interest in using nonculture-based methods to diagnose TKA infection.

Available literature and quality of the evidence

Level I and II evidence exists to answer this question.

Findings

The initial history and physical exam are crucial to the diagnosis of periprosthetic joint infection (PJI). Patient risk factors and perioperative risk factors should be identified.[2] Blood tests, including serum ESR and CRP have high sensitivity, good negative predictive value, and are cost-effective screening tools.[3] ESR sensitivity and specificity are 75% (95% confidence interval [CI]: 72–77%) and 70% (95% CI: 68–72%), respectively.[4] CRP sensitivity and specificity are 88% (95% CI: 86–90%) and 74% (95% CI: 71–76%), respectively.[4] These blood tests can be used as adjuncts to synovial fluid cytology with WBC differential and synovial fluid culture, which have sensitivities of 90% (95% CI: 78–96%) and 62% (95% CI: 50–74%) and specificities of 91% (95% CI: 80–96%) and 94% (95% CI: 91–96%), respectively, for diagnosis of TKA infection.[5,6] Since inflammatory markers such as ESR and CRP may remain elevated for up to several months following primary TKA, they may be less useful for identifying early postoperative infection.[7] Thresholds for chronic PJI have been identified.[8]

With sensitivity and specificity of 45% (95% CI: 41–49%) and 87% (95% CI: 85–89%), respectively, serum WBC count is not as useful as serum ESR or CRP for diagnosis of TKA infection.[2,4] Serum interleukin 6 (IL-6) may be a more specific marker of acute infection, but it is not be available in all laboratories.[2] Estimated sensitivity and specificity for IL-6 are 97% (95% CI: 93–99%) and 91% (95% CI: 87–94%), respectively.[4] Overall, the diagnostic accuracy for PJI is best for IL-6, followed by CRP, ESR, and WBC count.[4]

A novel approach to PJI diagnosis involves synovial fluid inflammatory biomarkers, such as alpha-defensin. The alpha-defensin assay offers another test with excellent sensitivity and specificity (100% CI: 79–100% and 95% CI: 83–99%, respectively) for diagnosis of PJI, and it is now available for clinical use.[2,9,10] Though preliminary data suggest that alpha-defensin 1 is at least equivalent to other diagnostic modalities, larger studies are required to confirm this finding.[10]

Clinical resolution

- ESR and CRP have excellent diagnostic test performance for chronic TKA infection and should be used as initial screening tools and adjuncts to synovial fluid cytology and culture (level I).
- The diagnostic accuracy of preoperative serologic investigations for PJI is best for IL-6, followed by CRP, ESR, and WBC count (level II).
- Emerging investigations, such as serum IL-6 and synovial alpha-defensin testing, demonstrate improved sensitivity and specificity for detecting TKA infection (level II).

Question 2: In patients with signs and symptoms of TKA infection, what intraoperative measures can be used for identification of joint infection?

Rationale

Infection is the leading indication for revision surgery after TKA, and yet there is no gold standard for diagnosis. For patients with an indeterminate presentation, adjunct

intraoperative investigations are required to confirm diagnosis of TKA infection.

Clinical comment

On some occasions, patients have poor function of their TKA without any abnormal preoperative investigations. In these situations, surgeons are faced with important challenges: (i) do we take the patient to the operating room despite clear documentation of infection and (ii) are there any intraoperative investigations that can help identify TKA infection?

Available literature and quality of the evidence

Level I evidence is available to answer this question.

Findings

The use of polymerase chain reaction (PCR) technologies to diagnose PJIs by detecting bacterial deoxyribonucleic acid (DNA) has received much attention in recent years. The theoretical advantages of PCR compared to intraoperative tissue cultures include higher sensitivity, faster turnaround time, and lack of dependence on prior antibiotic treatment.[11] Tissue, synovial fluid, and sonicated prostheses fluid samples can be used for PCR analysis.[11] Tissue samples have the highest sensitivity at 95% (95% CI: 91–99%), while sonicated prosthesis fluids have this highest specificity at 96% (95% CI: 92–100%).[11] However, this technology is expensive, may not be readily available, and unlike intraoperative tissue culture it does not offer the opportunity to test antibiotic susceptibility. Furthermore, though the use of traditional PCR to detect bacterial DNA has high sensitivity, results may be limited by potential false-positive results.[12] Since bacterial DNA persist after cell death, even an antibiotic-cleared infection could have a

positive result in an otherwise sterile sample. Alternatively, reverse transcription (RT) PCR targeting ribosomal ribonucleic acid (RNA), which degrade after bacterial cell death, has been shown to be a more sensitive and specific method of diagnosing PJI than serum ESR, serum CRP, and synovial fluid analysis.[13] Furthermore, early studies suggest that sequence analysis of the ribosomal RNA may be able to identify the bacterial species in monomicrobial infections.[13]

Sonication involves the use of low-intensity ultrasound to disintegrate the biofilm on removed prosthetic implants. The sonication fluid can then be cultured or subjected to PCR, as described above, to assist with diagnosis of joint infection.[14–17] Sonication of fluid cultures has a sensitivity of 90% (95% CI: 74–84%) and specificity of 95% (95% CI: 90–98%).[18] PCR of sonication fluid, either alone or in addition to culture, is being explored and may be a promising investigation for diagnosis of joint infection in patients treated with antibiotics or those with low-virulence pathogens.[15,16]

A systematic review compared seven categories of diagnostic tests, including blood tests, nuclear diagnostics, synovial fluid cytology, bacteriology, tissue histopathology, PCR, and sonication.[19] The diagnostic test with the highest likelihood of confirming PJI was implant sonication, while the diagnostic tests which were best for ruling out PJI included: serum IL-6, serum CRP, and synovial fluid cytology. This study highlights which tests are best for confirming or ruling out infection.

Still, sonication is expensive and requires an invasive procedure. Presently, if technologies are available, implant sonication may be a useful adjust to rule in joint infection in patients undergoing presumed aseptic revision procedures.[17,19,20]

The utility of intraoperative frozen section is under investigation, and the numerical threshold needed for diagnosis remains unknown.[2,21] New technologies, such as the use of direct analysis of tissue by mass spectrometry-based techniques, including the *iknife* and desorption electrospray ionization (DESI) offer a window into the future of diagnosing PJIs.[22]

Clinical resolution

- Application of various PCR technologies for diagnosis of PJI are still in development but offer advantages over traditional serologic and synovial fluid analysis, including higher sensitivity and specificity, as well as the ability to identify microbial species (level I).
- Assessment of sonication fluid may be used as an adjunct for diagnosis of joint infection in patients undergoing presumed aseptic revision procedures or in patients with suspected PJI who have been treated with antibiotics prior to culture (level I).

Question 3: For patients with failed two-stage prosthetic exchange secondary to infection, how do patient outcomes compare for repeat attempts at implant exchange, compared to arthrodesis or amputation?

Rationale

Two-stage reimplantation is an accepted procedure for management of first-time TKA infections. There is more

uncertainty on treatment of subsequent reinfections.

Clinical comment

TKA infection can be a devastating complication and is associated with significant morbidity to patients and tremendous costs to the healthcare system. The current standard of care for most chronic TKA infections is two-stage exchange arthroplasty, which involves removal of primary implants and placement of antibiotic spacer, treatment with organism-specific antibiotics, and reimplantation following completion of a course of antibiotics and a successful antibiotic holiday.[23] A two-stage reimplantation process requires that patients sacrifice both time and function in an attempt to eradicate the infection. We are faced with a significant challenge when a two-stage reimplantation for TKA fails and the patient has persistent signs and/or symptoms of infection. What is the next best step for the patient?

Available literature and quality of the evidence

Level I–IV literature exists to answer this question.

Findings

A retrospective, population-based study showed that one year after removal of primary implants, 62% underwent reimplantation, while 4.5% underwent arthrodesis, 3.1% underwent amputation, 14.5% underwent repeat debridement without reimplantation, 12.5% did not undergo any procedure, and 3.7% died in a hospital setting.[23] Even with negative cultures at the time of the second-stage reimplantation, nearly 20% of patients have failure of treatment secondary to infection at approximately one year; a three-month course of oral antibiotics following reimplantation surgery may decrease this risk.[24]

A simulated study used a decision tree analysis with previously published values to determine what treatment offered the highest quality of life for patients following a failed two-stage reimplantation TKA. Chronic suppression with antibiotics, arthrodesis, amputation, and repeat two-stage reimplantation were compared. They showed that knee arthrodesis had the highest quality of life after a failed two-stage revision; if there is sufficient residual bone stock, arthrodesis is most likely to provide infection control while maximizing patient function.[25] Utility values for health states were taken from published literature and serve as a proxy for clinical outcomes. Though the value and comparability of utilities may be challenged, this study offers an interesting perspective on procedures that maximize patient quality of life.

However, success with knee arthrodesis is not guaranteed. Bony fusion following primary arthrodesis in the setting of failed TKA is 75%, and 46.5% of patients had at least one complication.[26] Rate of fusion was highest with the intramedullary technique, compared to other fusion techniques.[26] In addition, use of an intramedullary nail was associated with higher functional status, compared to use of an external fixator.[27] Patients undergoing fusion have better function and ambulatory status than those undergoing above-knee amputation (AKA).[28] Seventy percent of patients who had undergone fusion would have repeated this procedure, rather than AKA, if they were presented with both options.[28]

On the other hand, it is argued that AKA can provide greater ability to recreate a functioning joint with an external prosthesis.[29] Consideration of ambulation status and patient factors that influence ability to use a prosthesis are important when deciding between fusion and AKA for failed two-stage revision surgery. The majority of patients

with AKA following TKA wished that they had undergone this procedure sooner.[30]

Clinical resolution

- A three-month course of oral antibiotics following second-stage reimplantation may decrease the risk of revision failure secondary to infection (level I).
- Knee arthrodesis is a treatment option for a failed two-stage revision TKA in the context of infection. Though initial complication rates may be high, knee arthrodesis may maximize patient function (level III).
- AKA should be considered for nonambulatory patients or for patients who are good candidates for an external prosthesis (level IV).

Summary of answers

- ESR and CRP remain mainstays of PJI diagnosis, while emerging investigations, such as IL-6 and synovial alpha defensin, are likely to help improve the accuracy and precision with which PJI can be detected going forward.
- PCR technologies offer some advantages over traditional synovial fluid analysis and have higher specificity and sensitivity.
- A course of oral antibiotics following second-stage reimplantation may decrease the risk of revision failure.
- Knee arthrodesis and AKA are salvage procedures in multiply failed revision TKA patients.

Management of the Infected Total Knee Arthroplasty

Ewout S. Veltman MD, and Dirk Jan F. Moojen MD PhD
OLVG, Department of Orthopaedic and Trauma Surgery, Amsterdam, The Netherlands

Clinical scenario

- A 78-year-old female presents herself at the Emergency Department of your hospital. Patient's history mentions a primary total knee arthroplasty (TKA) of the right knee 12 months earlier and type two diabetes treated with oral antidiabetics.
- The patient mentions initial unremarkable recovery, with discharge out of the hospital on the third postoperative day. In the past months, the knee has been alternatingly swollen and painful after long walks. During the last two days, the patient has developed a fever and the knee has become swollen, painful, and warm.
- Physical examination reveals a body temperature of 38.8 °C. You see a diffuse red erythema surrounding the scar on the right knee. There is no wound effusion. Flexion of the knee is painful and limited to 80°. A plain radiograph of the right knee shows an uncomplicated situation after TKA, without signs of loosening.

Top three questions

1. What is the role of debridement, antibiotics, and implant retention in patients with early/acute hematogenous versus chronic prosthetic joint infection?
2. Which type of revision surgery strategy provides the better outcome in chronically infected TKA: one-stage or two-stage revision?
3. Which type of spacer leads to superior outcome after two-stage revision TKA: a static or a dynamic knee spacer?

Question 1: What is the role of debridement, antibiotics, and implant retention in patients with early/acute hematogenous versus chronic prosthetic joint infection?

Rationale

Laboratory findings show an elevated C-reactive protein (CRP; 137 mg/L) and normal erythrocyte sedimentation rate (ESR; 18 mm/h). Sterile aspiration of synovial fluid reveals the aspect of a purulent hematoma, the fluid is sent for culture. You have now confirmed your suspicion of a periprosthetic joint infection (PJI).

Clinical comment

If untreated, the patient will become increasingly ill. Systemic antibiotics will treat the infection but will not eradicate it, as antibiotic penetration into synovial fluid is low. The patient's complaints have changed recently, matching a suspicion for hematogenously spread infection to the TKA of the right knee, even though some complaints have already been present during the past year. You want

to know if duration of infection influences chance of success of a DAIR (debridement, antibiotics, and implant retention) procedure.

Available literature and quality of the evidence

- The literature search showed two systematic reviews (including 31 case series) and four more case series on this topic.[1–6] In addition, there is one publication on irrigation and debridement from the International Consensus Meeting on PJI.[7]
- The quality of the evidence is scored as level IV.

Findings

The reported success rates of DAIR range between 16 and 100%.[6] Because of heterogeneity of and significant methodological inconsistencies between studies, it is not possible to find more precise numbers for early, acute hematogenous and chronic infection, respectively. However, the duration between onset of symptoms and treatment seems to be important; for each additional day that treatment is delayed the odds of success decrease by 7.5%.[1] Another study showed that if the infection were treated more than eight weeks after implantation, the RR for success decreased to 0.6 (95% confidence interval [CI]: 0.3–0.95).[8]

The consensus statement advocates a DAIR procedure as the first treatment option in case of early or acute hematogenous PJI.[7] Multiple (at least three, preferably six) intraoperative tissue samples should be taken for culture.[7] All mobile parts of the prosthesis (the insert) should be replaced during the DAIR procedure.[2,9] In patients with acute hematogenous infection, the same treatment algorithm can be chosen as for early infection.[9,10]

In chronic PJI, there is no role for DAIR procedures, as the chance of success diminishes with longer duration of infection.[1,3,8,9]

Resolution of clinical scenario

- We advise a DAIR procedure with exchange of modular parts in case of an early or acute hematogenous TKA infection.
- Multiple intra-articular tissue samples should be taken for culture to determine the exact causative micro-organism and its antibiotic susceptibility.[9]
- Antibiotics should be continued for three months.[9,11] If the causative bacteria are susceptible to rifampin, it should be administered as co-therapy.[12,13]
- In case of a chronic infection there is no role for a DAIR procedure and one should proceed to an implant revision.[3,7,8]

Question 2: Which type of revision surgery strategy provides the better outcome in chronically infected TKA: one-stage or two-stage revision?

Rationale

The patient is treated with a DAIR procedure and antibiotics for three months. Sixteen months after cessation of antibiotics the patient visits you at the outpatient clinic, complaining of knee pain while walking and intermittent swelling of the knee. Laboratory results show a CRP of 25 mg/L and ESR of 31 mm/h. A plain radiograph of the knee shows a radiolucent line under the medial side of the tibial

component. Culture of sterile aspirate shows growth of the same bacteria the knee was originally infected with.

Clinical comment

In case of persisting or chronic infection of a knee prosthesis, eradication of infection without revising the prosthesis is not possible.[9,11,14] In patients who do not wish further surgery, or cannot safely be operated on, suppressive antibiotics can be considered.[9,11] In healthy patients, revision of the prosthesis is indicated, in either one or two stages.

You want to know which of the options provides her with the better outcome, considering infection eradication as well as functional recovery.

Available literature and quality of the evidence

- The literature search showed three systematic reviews (including 118 case series) and two retrospective comparative studies on this topic.[15–19] In addition, there is one publication on one- versus two-stage revision from the International Consensus Meeting on PJI.[20]
- The quality of the evidence is scored as level III–IV.

Findings

Two-stage revision with the use of an antibiotic-loaded spacer is still the gold standard in case of a chronically infected TKA.[20] The spacer is used to deliver a high local dose of antibiotic, while at the same time keeping soft tissues around the knee at length to facilitate the reimplantation of a revision prosthesis.[11,21,22] In selected patients one-stage revision of infected TKA can be considered, when the patient's immune status and soft

tissues are not compromised and the cultures show a micro-organism susceptible to effective antibiotic therapy.[14,16,18,19]

Successful eradication of infection can be achieved in 89.8% of patients after two-stage revision arthroplasty (range 69.2–100%) and in 81.9% of patients after one-stage revision arthroplasty (range 73.1–100%).[23] When pooling the number of reinfections to calculate an overall odds ratio (OR), the comparative studies produced an OR of −0.06 (95% CI: −0.13 to 0.01), suggesting no significant difference in risk of reinfection between one- and two-stage procedures.[18]

Data on functional outcome after one-stage and two-stage are limited but seem to be in favor of one-stage revision, with the mean Knee Society Score increasing 56 points for one-stage revision and 45 points for two-stage revision ($p < 0.02$), which is a clinically important difference.[15]

Resolution of clinical scenario

- Two-stage revision and one-stage revision in selected patients provide comparable infection eradication rates.[15–19] Patient selection is of key importance when performing one-stage revision.
- Functional outcome after one-stage revision appears to be better, although evidence is limited.[15]

Question 3: Which type of spacer leads to superior outcome after two-stage revision TKA: a static or a dynamic knee spacer?

Rationale

After discussing the treatment options, you agree with your patient to perform a two-stage revision of the knee arthroplasty with the use of an antibiotic-loaded interval spacer. The patient wants to know if the range of motion of her knee will be limited afterward and if certain types of spacers provide superior functional outcome.

Clinical comment

The types of spacers available to be used in a two-stage revision arthroplasty of the knee can be divided into two groups: static and dynamic spacers. A static spacer usually is a nonarticulating block of antibiotic-loaded bone cement filling the joint space. A dynamic spacer is articulating and matches the shape of the femoral and tibial component and can be either from (pre)molded bone cement or a temporary new implant. Dynamic spacers have the advantage that patients are able to perform (non-weight-bearing) flexion-extension exercises during the spacer period.

Available literature and quality of the evidence

- The literature search showed four systematic reviews (including 52 case series)[23–26] and four retrospective case series on this topic.[27–30] In addition, there is one publication on spacers from the International Consensus Meeting on PJI.[22]
- The quality of the evidence is scored as level IV.

Findings

No clear differences exist between the two types of spacers comparing infection eradication rates.[22–26] The eradication rate in the dynamic group was 89.7% (range 63–100%;

standard deviation [SD] = 9.1) and in the static group 84.8 % (range 67–92.4 %; SD 7.8; p = 0.32).[26]

Dynamic spacers seem to provide a slightly better functional outcome after two-stage revision arthroplasty.[23,25] The final mean Knee Society Score was 82 points (range 76–89 points) for patients treated with a static spacer and 83 points (range 64–91 points) for patients treated with an articulating spacer (p = 0.64).[25] The final mean range of motion was 92° (range 78–105°) in patients treated with a static spacer and 100° (range 63–120°) in patients treated with an articulating spacer (p = 0.001).[25]

Resolution of clinical scenario

Dynamic spacers seem to provide slightly better functional outcome compared to static spacers without compromising infection eradication rate.[23–26]

Summary of answers

- DAIR procedures have a good success rate in early or acute hematogenous PJI after TKA.
- DAIR should not be performed in chronic PJI.
- Two-stage revision arthroplasty with the use of an antibiotic-loaded interval spacer is still the gold standard in chronic PJI after TKA.
- One-stage revision arthroplasty can be considered in selected patients with chronic PJI. Results on infection eradication appear comparable to two-stage and functional recovery possibly better.
- Dynamic spacers provide comparable infection eradication rate compared to static spacers, but may

lead to superior functional outcome.

- It is advised to treat PJI after TKA using a standardized protocol and a multidisciplinary team, including a microbiologist and an infection specialist.
- There is a lack of high-quality evidence on the treatment of PJI after TKA. Recommendations are therefore based on the consensus statement and (reviews of) case series. High-level evidence is needed.

Management of the Unstable Total Knee Arthroplasty

John Esposito MD FRCSC, and James L. Howard MD MSc FRCSC[1]
London Health Sciences Centre, Western University, ON, Canada

Top three questions

1. In patients who have undergone total knee arthroplasty (TKA), which risk factors, compared to others, predict instability?
2. Among patients with instability who undergo revision TKA, how do functional outcomes compare to primary TKA?
3. In patients undergoing revision TKA for instability, which surgical techniques, compared to others, produce optimal outcomes?

Question 1: In patients who have undergone total knee arthroplasty (TKA), which risk factors, compared to others, predict instability?

Rationale

Identifying the causes of instability prior to revision surgery is imperative for the treating surgeon so that the subsequent revision can be appropriately directed to the

underlying cause. Failure to do this could contribute to ongoing instability following revision TKA.

Clinical comment

Instability following TKA is not uncommon, the etiology of which may be multifactorial. Elucidating the causes of instability after TKA may help prevent their incidence, as well as allow the treating surgeon to specifically look for these underlying causes and correct them through subsequent revision surgery.

Available literature and quality of the evidence

- Level IV.

Findings

The unstable TKA may result from a variety of distinct etiologies,[1] and the identification and treatment of these etiologies at the time of revision is crucial in order to restore stability. The causes of instability that have been described include, flexion/extension gap mismatch, component malposition, isolated ligament insufficiency, extensor mechanism insufficiency, component loosening, and global instability.[1] Calliess et al. in a survey of 1449 TK revisions remarks the evolving etiology of TKA failure.[2] Low-grade infection and instability are two major causes that have increased over the years. To our knowledge, this study represents the largest published series evaluating the specific failure mechanisms in revision TKA.

Surgical treatment for instability may encompass a variety of procedures, especially when the instability results from more than one etiological factor. Technical errors such as flexion/extension gap mismatch and component malpositioning tend to present early. Other causes tend to

present late and result in attenuation of the soft tissue around the knee.[1] Isolated ligament insufficiency may be persistent or iatrogenic. Extensor mechanism insufficiency causing TKA instability may be categorized into patellar component problems, tendinous and patellar bone integrity problems, and soft tissue imbalance or instability of the patellofemoral joint.[3] Component loosening is often identified preoperatively and confirmed at the time of revision surgery. Knees with component loosening may progress to multidirectional instability.[4] Global instability has been subcategorized into soft tissue attenuation (due to chronic synovitis, recurrent hemarthrosis, or undersizing of the polyethylene [PE] insert), direct negative effects of the PE insert (post fracture or wear) and knee dislocation.[1] Knee dislocation after TKA has been attributed to severe flexion/extension gap mismatch and extensor mechanism insufficiency.[1]

Resolution of clinical scenario

- The unstable TKA may arise from one or more etiologies and identification of these etiologies is integral to the restoration of stability.
- Instability is a major cause of the need for revision. Often, increased constraint is needed to supplement or perform the function of incompetent ligament and soft tissue structures.[5]
- Revision TKA for instability should specifically address the causes of the instability.

Question 2: Among patients with instability who undergo revision TKA, how do functional outcomes compare to primary TKA?

Rationale

As the number of primary TKAs performed continues to increase annually, it is reasonable to expect an increase in revision TKAs performed. Outcome data on revision TKA for instability will presumably support it as a reliable pursuit and have the potential to identify predictors of success and failure.

Clinical comment

The efficacy in revision TKA for instability is upheld by its rate of success in restoring stability and by its survivorship.

Available literature and quality of the evidence

- Level III
- Level IV.

Findings

The reason for revision TKA may affect clinical outcome following surgery. Patients having revision surgery for aseptic loosening demonstrate better improvements in Visual Analog Scale (VAS) scores for satisfaction and pain and KSS (Knee Society Score) clinical scores, as well as lower complication rates, compared to those having revision surgery for malposition, instability from ligamentous laxity/insufficiency, septic loosening, and stiffness.[6] It is plausible that with aseptic loosening, symptoms are directly caused by component loosening,

which can be completely resolved with addressing the loosening with revision. Nonetheless, revision for instability ranging from subtle to gross ligamentous laxity results in significant improvements in functional status (as measured by Knee Society and SF-36 scores) and range of motion (ROM).[7,8] The largest improvements in clinical outcomes following revision surgery, irrespective of reason for revision, tend to occur during the first three months after revision with smaller improvements demonstrated in the subsequent 12–24 months.[6]

The rate of success in restoring stability and alleviating symptoms following revision TKA for instability has been shown to be as high as 78% at an average follow-up of three years.[7] Survival rates of revision TKA (re-revision as endpoint) for aseptic causes (i.e. instability) range from 82 to 85% at five years.[9,10] Based on the Norwegian Registry, the cumulative survival rate of revision TKA for aseptic causes was 78% at 10 years and 71% at 15 years. Deep infection, instability, loose tibial component, and pain alone were the most frequently observed causes of re-revision following aseptic revision.[9] Patients with septic revision have a higher risk of revision failure than those who have an aseptic indication for revision.[10]

Resolution of clinical scenario

- Revision surgery for instability from aseptic loosening results in better postoperative clinical outcomes as well as lower complication rates compared to other causes of instability.
- The greatest improvements in clinical outcome following revision TKA occur within three months after surgery.

- Revision TKA for instability has a high rate of success with regards to restoring stability which parallels a high survival rate.

Question 3: In patients undergoing revision TKA for instability, which surgical techniques, compared to others, produce optimal outcomes?

Rationale

The surgical technique for TKA instability may predict surgical outcomes, particularly restoration of stability. It is important to identify those techniques which restore stability in order to decrease re-revision rates.

Clinical comment

An understanding of the surgical techniques that predispose to stability following revision TKA for instability will increase the survivorship of the revision.

Available literature and quality of the evidence

- Level III
- Level IV.

Findings

The type of revision for instability may affect surgical outcomes. Factors that significantly predict the attainment of a stable knee following revision, evidenced by surgeon assessments of knee stability at follow-up, are revising both the femoral and tibial components and the use of femoral augments TKA.[7] Elevation of the joint line correlates

significantly with failure to achieve a stable TKA.[7] Proper restoration of the joint line after revision arthroplasty correlates with better functional outcome.[11] Revision of both the femoral and tibial components is also a predictor of improvement in knee function.[7] Revising both the femoral and tibial components allows the possibility for implanting a more constrained construct, which has been associated with improved stability.[7] Based on survivorship data from the Norwegian Registry, revisions done with exchange of only the femoral component or the tibial component had a 1.7 times higher risk of re-revision (95% confidence interval [CI]: 1.1–2.6) than complete revisions.[9]

Isolated exchange of PE insert has a high incidence of failure in treating instability.[7,12,13] The rate of failure (i.e. persistent instability) following isolated PE insert exchange is as high as 60%.[7] Based on survivorship data from the Norwegian Registry, isolated PE insert exchange tended to have a higher risk of re-revision than complete revision (risk ratio [RR] = 1.5; 95% CI: 0.9–2.3).[9] However, isolated PE insert exchange may be useful in select cases with posterior cruciate ligament insufficiency and concomitant anteroposterior instability, especially when exchange is to a PE insert with more anteroposterior constraint.[1,11] Also, excellent results have been reported for isolated PE insert exchange when coronal instability is the direct result of PE bearing wear.[14]

Resolution of clinical scenario

- In revision surgery for TKA instability, revision of both components and the use of femoral augments offers the most predictable outcome.
- Improvement in component positioning, restoration of the joint line, and better balance of the flexion and

extension gaps can all be facilitated by revision of all components, as well as by the use of metal augments.

- Isolated exchange of PE inserts usually results in poor and unpredictable outcomes; however, it may be successful in select cases of isolated anteroposterior instability or isolated PE bearing wear.

Summary of answers

- Unstable TKA can be due to myriad causes, and is a major cause for revision. Increased constraint is often necessary in a revision setting.
- Revision TKA for instability has a high rate of success with regards to restoring stability.
- In the context of revision surgery for instability, revision of both components and the use of femoral augments is the most reliable option.

Stem Choices in Revision Total Knee Arthroplasty

Pablo A. I. Slullitel MD[1] Gerard M. J. March MD FRCSC[2], and Paul R. Kim MD FRCSC[1]
[1]Division of Orthopaedic Surgery, Adult Reconstructive Service, University of Ottawa, Ottawa, ON, Canada
[2]Bluewater Health, Sarnia, ON, Canada

Introduction

The use of stemmed components in revision total knee arthroplasty (TKA) has been well established. Stems can aid in diaphyseal referencing which is thought to improve mechanical alignment intraoperatively in addition to offloading stress upon damaged or absent metaphyseal bone.[1–9] The optimal fixation method of these stemmed components is still not established. Hybrid fixation with cemented articular components and a press-fit uncemented stem has gained popularity along with the use of metaphyseal cones. This chapter will review the available literature regarding revision TKA with a focus upon the use of cemented, hybrid, and uncemented stemmed components in addition to the use of metaphyseal cones.

Clinical scenario

- An 82-year-old male presents with a painful and unstable cemented primary TKA performed 17 years ago for osteoarthritis.

- Radiographs show tibial component loosening with significant loss of medial tibial bone stock and osteolysis (Figure 55.1A and B).

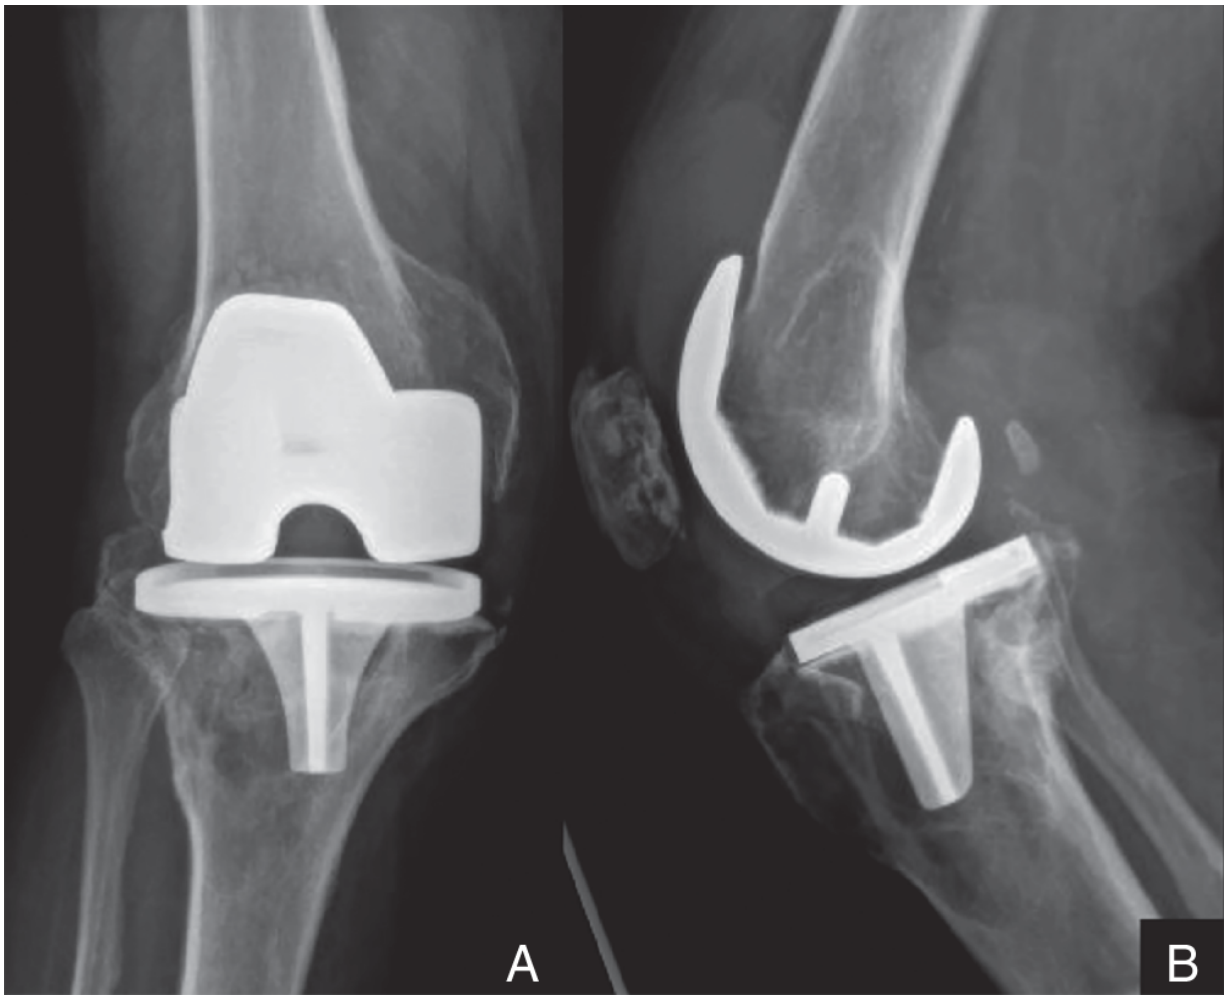

Figure 55.1 Preoperative radiographs demonstrating a loose primary TKA with significant loss of tibial bone stock.

Top three questions

1. In patients undergoing revision TKA, how do uncemented components, compared to cemented components, perform in terms of outcomes?
2. In patients undergoing revision TKA, how do hybrid components, compared to fully cemented or

uncemented components, perform in terms of outcomes?

3. In patients undergoing revision TKA, how do cemented components, compared to uncemented components, perform in terms of outcomes?

Question 1: In patients undergoing revision TKA, how do uncemented components, compared to cemented components, perform in terms of outcomes?

Rationale

A press-fit stem has the theoretical advantage of reduced bone loss with component insertion and ease of extraction if this becomes necessary. Concerns with uncemented stems include a lack of bone ingrowth, increased incidence of malalignment, and an increased incidence of stem tip pain.[10,11]

Clinical comment

An uncemented total knee revision technique offers several advantages, including endosteal referencing and subsequent stabilization of the construct without the difficulty of future extraction compared to cemented fixation.[10] Cementless revision TKA was originally described by Whiteside using a mixture of loosely packed cancellous allogeneic and autogenic morselized bone with a component that had fluted press-fit titanium long stems and a sintered-bead porous tibial under-surface.[12]

Available literature and quality of the evidence

Five studies (levels II–III) are available to answer this question.

Findings

In his prospective series of 110 cases, Whiteside evaluated the results of cementless fixation and morselized allografting of metaphyseal defects at 60 to 127 months of follow-up.[12] He described an apparent increase in radiodensity in the profile views of 31 tibias and 28 femora at postoperative intervals greater than 1 year, suggestive of bone remodeling. Only 1 tibial component was revised for loosening.[12] Hanna et al. reviewed 56 cases of revision TKA using Whiteside's technique (cementless long-stemmed components in combination with morselized bone graft) at a mean of 7.3 years (range 4–10 years), obtaining a 98% survival at 10 years. They reported a 9% reoperation rate including all-cause revision.[13]

Further interest in uncemented components has increased in recent years with the advent of foam metal technology. These metals are made of elemental tantalum or titanium and are highly porous to allow for significant bio-interlock. Foam metal has a modulus of elasticity similar to that of cancellous bone, allowing for a more physiological transfer of force from the implant to the bone interface. In 2015, Kamath et al. showed excellent medium-term (minimum five years) results of a porous tantalum cone used in 15 cases with severe metaphyseal bone stock deficit.[14] Although the authors have described the surgical technique with cementation of the tibial implant after the cone was impacted, it has also been used with allografts, bio-composite scaffolding, or in a fully cementless fashion in more rare situations. These cones may increase bone loss during bone preparation, lead to stable long-term fixation,

and have predictable bony ingrowth with a reduction in proximal stress shielding.[14]

Stem tip pain remains a disadvantage of uncemented fixation. This issue can also occur with cemented stems but at a lower incidence.[5] At a minimum follow-up of two years, Barrack reported localized pain at the end of the stem in 11% of uncemented femurs and 14% of uncemented tibias.[6] Methods to reduce stem stiffness with fluting or slots have been undertaken by some manufacturers to minimize stem tip pain. There is, however, limited evidence comparing fluted and nonfluted stems.[15,16]

Concerns about proximal stress shielding with cementless fixation remain, especially if the stem is well fixed distally.[17–19] There is also no definitive answer on optimal stem size relative to the endosteal canal. Canal filling stems would seem to provide better initial stability and alignment compared to thinner dangling stems, but long-term concerns regarding proximal stress shielding also remain with canal filling stems.[20–22]

Theoretical concern exists with uncemented implants due to greater access areas for polyethylene wear debris to enter the metaphyseal bone compared to a cemented implant.[23] It is thought that cement offers an immediate barrier to third-body debris that is absent with an uncemented prosthesis, especially in cases with increased levels of constraint. The presence of radiolucent lines and its potential association with loosening also remains a concern with uncemented prostheses.[13] It has been demonstrated that when trying to encourage biological interlock, establishing secure initial stability is crucial.[24] Minimal tolerances to micro-motion must exist if true osseointegration is to occur. Porous metals may have

advantages over fiber metal coatings in this regard due to their rougher surfaces.[24]

Finally, a long uncemented stem will not be useful in cases with severe deformities, marked osteopenia, or excessive femoral bowing. There is also an increased risk of periprosthetic fracture on stem insertion.[25] The basis of press-fit stability is also reliant upon complete canal fill when significant proximal bone stock is absent.[26]

Resolution of clinical scenario

- In the setting of severe bone loss, cement augmentation may be less than ideal. Uncemented revision TKA, alone or in combination with allografting, is an attractive option in these situations. Due to a lack of randomized controlled trials (RCTs) there is no ideal method and treatment should be individualized for each patient (level II–III).[27–29]
- Application of foam metal technology to revision TKA has been applied with successful medium-term outcomes (level III).[12,27]
- It has yet to be characterized if an uncemented prosthesis is more or less susceptible to third-body-induced osteolysis in the long term (level III).[19]
- Uncemented stems may not be useful in cases of severe femoral or tibial shaft deformities or in cases of marked osteopenia. Increased risk of periprosthetic fracture has been reported in these types of cases (level III).[27,28]

Question 2: In patients undergoing revision TKA, how do hybrid components, compared to fully cemented or uncemented components, perform in terms of outcomes?

Early work by Bertin et al. introduced the concept of smooth uncemented intramedullary stems with surface cemented tibial components.[7] The polymethylmethacrylate bone cement replaced small surface defects and afforded immediate stable fixation.[7] Parsley et al. showed that tibial anteroposterior alignment was more predictable with long cementless stems that achieved a canal-filling ratio (CFR) greater than 0.85.[1] Intramedullary canal fill and not stem length or diameter was the strongest predictor of failure with hybrid stems at a five-year follow-up period, with the risk reduced by 41.2% for each additional 10% canal fill.[29]

Stem length and diameter should be tailored according to each patient's anatomy. It has been shown that axial load can be reduced by 23 to 39% when stem length reaches 70 mm; however, with a length of at least 150 mm, secondary stress shielding of the proximal tibial cortex and a doubling of strain at the stem tip can occur.[30,31] A long stem can also lead to suboptimal position of the articular components. Gobba et al. showed that a 120 mm tibial stem forced the tibial tray into valgus alignment, and a 200 mm tibial stem deviated the tray position medially and posteriorly.[32] In this scenario, using a hybrid technique with a porous metal cone in the metaphysis and an uncemented stem can allow for the use of shorter stems to avoid articular malpositioning.[15]

Gofton et al. published a review of 89 revision TKAs completed with a hybrid fixation technique at a mean of six years; only five cases had a re-revision surgery, with a Kaplan–Meier survivorship of 93.5% at 8.6 years.[4] Wood et al. reported long-term results of 135 revision TKAs using a press-fit hybrid technique; Kaplan–Meier survivorship analysis calculated a 13% revision rate at 12 years.[3] Although the use of antibiotic impregnated cement is a known advantage to the fully cemented stem technique, in Wood's paper there was no increase in the rate of septic loosening with uncemented stems.[3] Only Shannon et al. reported on a relatively high failure rate (19%) of hybrid fixation components, with additional nonprogressive radiolucencies being found in over 90% of the surviving prosthesis with no effect on clinical outcome.[28]

Concerns have been raised regarding the ability to gain appropriate fixation in the face of poor bone quality. Loss of cortical contact through the tibial tray can increase strain across the proximal tibia. Bottner et al. recommended using fully cemented stems in scenarios of severe bone loss that lead to increased strain at the periarticular region.[11] In an RCT with radiostereometric analysis, Kosse et al. reported on the outcome of 23 (12 cemented, 11 hybrid) revision TKAs with mild to moderate bone loss at a mean of 6.5 years. There were no differences in median micromotion and clinical outcome between either technique.[30]

Gililland et al. performed a multicenter retrospective review of 82 revision TKAs performed for aseptic failure. Re-revision and radiographic failure rates were similar between the cemented and hybrid groups at an average of 76 and 121 months, respectively.[31] In a retrospective study, Gómez-Vallejo et al. found no significant difference in the clinical and radiographic outcomes of 29 cemented and 38

hybrid revision TKAs at a mean of seven years.[33] Although the outcomes were similar between the two groups, hybrid fixation tended to produce better results than cemented fixation and they therefore recommended this approach over fully cemented fixation.[33] In another retrospective study of two-stage revisions for infected TKA, hybrid diaphyseal-engaging stems had a lower rate of radiographic failure than did cemented stems at a mean follow-up of 45 months.[34]

The hybrid fixation technique is able to achieve stable fixation in the properly selected patient (i.e. one with adequate diaphyseal bone stock and minimal diaphyseal deformity) in the medium to long term.[27]

Resolution of clinical scenario

- A cemented articular prosthesis with an uncemented stem (hybrid technique) is able to achieve immediate and stable fixation. Small bony surface defects are easily dealt with by a cemented articular prosthesis (level III).[7,25]
- Lengthy stems can lead to a suboptimal position of articular components. Adding porous metal cones to reconstruct the metaphysis can allow the use of shorter stems (level III).[15,25,27,28]
- Selection criteria for full cementation include low-demand patients, large canals, and diaphyseal deformity (level III).[3,6,11]
- The hybrid technique has successful outcomes when compared to a fully cemented technique at medium and long term, but evidence is lacking (level III).[2531–33]

Question 3: In patients undergoing revision TKA, how do cemented components, compared to uncemented components, perform in terms of outcomes?

Rationale

Fully cemented stems have good long-term results, but potential difficulty with future extraction is a major downside to their use.[9,13,19]

Clinical comment

Proponents of fully cemented fixation are supported by the successful published long-term results of cemented tibial components in primary knee arthroplasty.[35] The use of cement offers immediate fixation with the benefit of intramedullary elution of antibiotics (if utilized) and the reduction of end-of-stem pain.[27] Additionally, cemented fixation is able to distribute load evenly across the prosthesis, preventing point stress shielding. However, difficulty in future extraction and malalignment due to decreased diaphyseal reference remain concerns.[35]

Available literature and quality of the evidence

Five studies (level III) are available to answer this question.

Findings

In a retrospective review of 70 fully cemented revision TKAs, Mabry et al. showed a 10-year survivorship of 92%.[36] Fehring et al. presented a retrospective review of 475 revision TKAs, including 107 fully cemented and 95 press-fit stems.[37] The diaphyseal-engaging stems had a re-

revision rate for aseptic loosening of 4%, while the cemented group had no such cases.[37] However, a recent meta-analysis was unable to find superiority of either type of fixation, as no difference in failure rates was found between the two groups.[38]

Biomechanical data have also shown similar outcomes between both techniques.[39] Despite noting no significant decrease in proximal tibial strain with the use of either cemented or cementless stems, Jazrawi et al. reported that cemented metaphyseal engaging stems had significantly less tray motion than a cementless construct of the same length.[40] Similar to the hybrid technique, the fully cemented one has also proven successful at medium-term follow-up in combination with porous tantalum cones in severe bone defects, with 100 mm being the most common stem length.[40] Therefore shorter stems may be used if a cemented metaphyseal-engaging technique is used and porous tantalum cones help to reduce the incidence of radiolucent lines even further.[40]

The literature supports the use of fully cemented stemmed components as a stable and durable construct. Nevertheless, the lack of randomized trials comparing these two fixation methods (hybrid vs cemented) poses a challenge when selecting the ideal technique.

Resolution of clinical scenario

- Cemented stems have shown excellent long-term outcomes, providing an easy technique and avoiding limb deformity. The major concern with fully cemented stems is the difficulty with later extraction (level III).[10,33]
- When compared to the hybrid technique, no categorical clinical differences were found between the two

techniques (level III).[38]

- Biomechanical data support the stability of fully cemented stemmed components, being noninferior to that of hybrid components. However, metaphyseal-engaged cemented components may enable the use of shorter components, performing better in combination with porous metal cones (level III).[39,40]

Clinical scenario continued

The patient was diagnosed with aseptic loosening and underwent revision TKA. Due to significant loss of tibial and femoral bone stock, a varus-valgus constrained system with a hybrid technique (uncemented stems and cemented metaphyseal components) along with a porous metal cone on the tibial side was implanted. Bone loss was classified as Anderson Orthopaedic Research Institute (AORI) type 3 on the tibial side and as AORI type 2B on the femoral side Figure 55.2a and b. At two-year follow-up of revision surgery, the patient remains asymptomatic with radiographs demonstrating solid fixation of the reconstruction technique (Figure 55.3a and b).

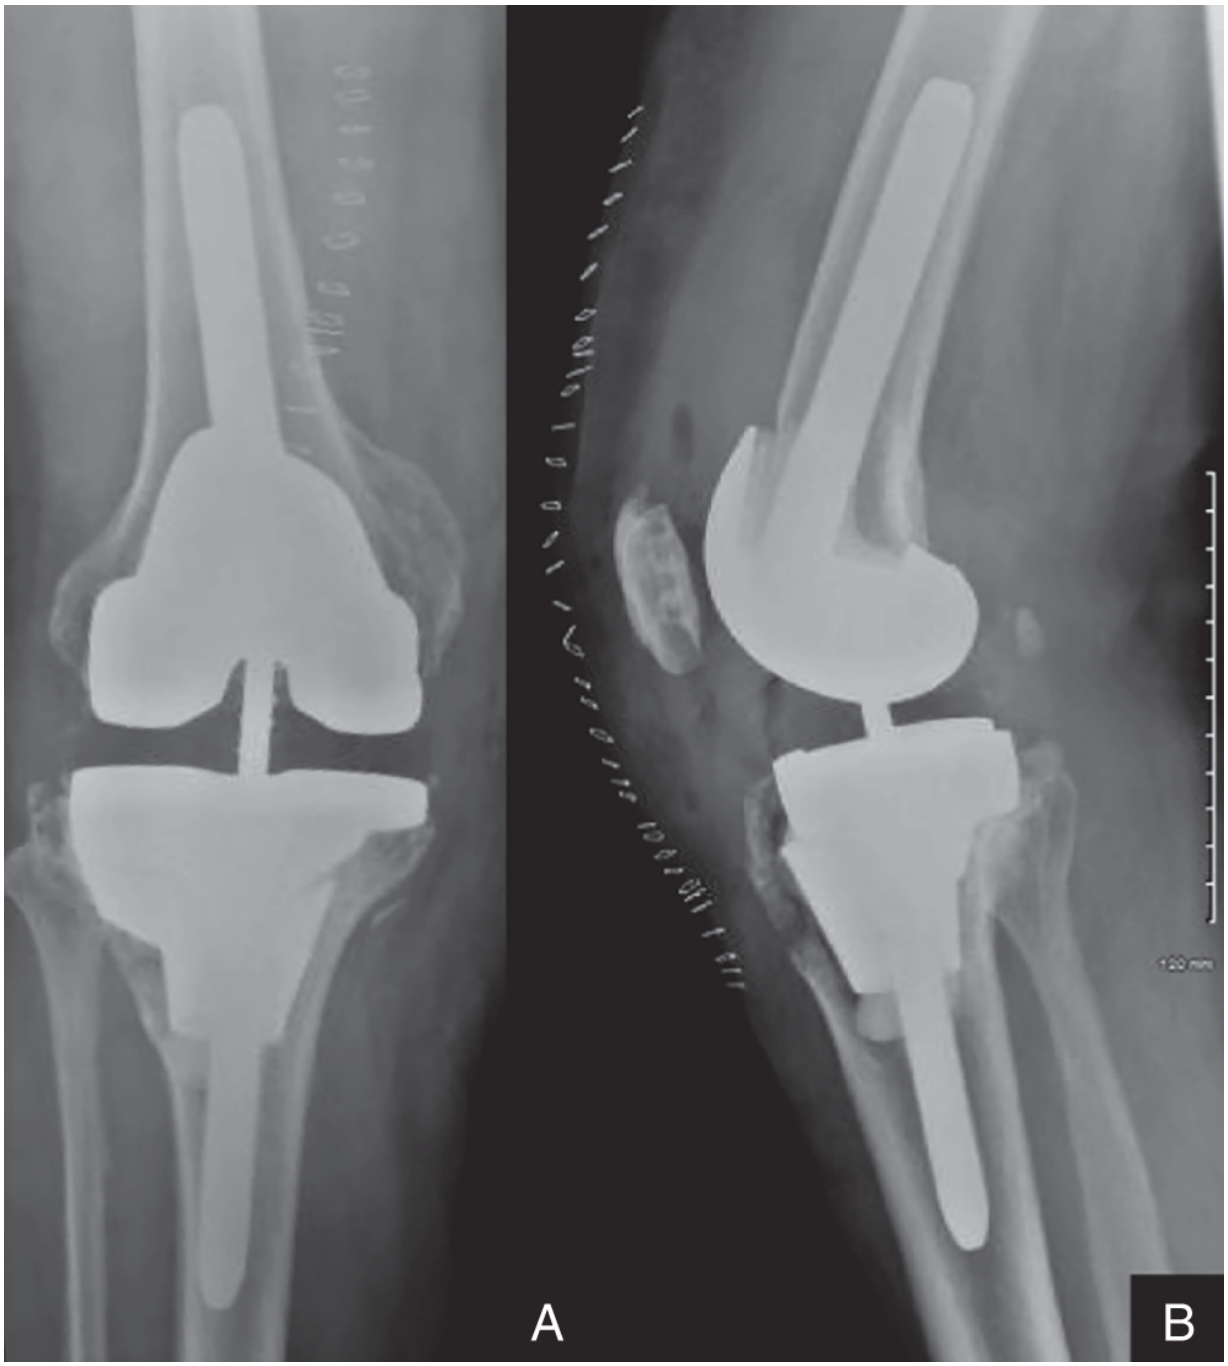

Figure 55.2 Postoperative radiographs showing a revision TKA utilizing a porous cone and hybrid cemented stem technique on both the tibial and femoral sides.

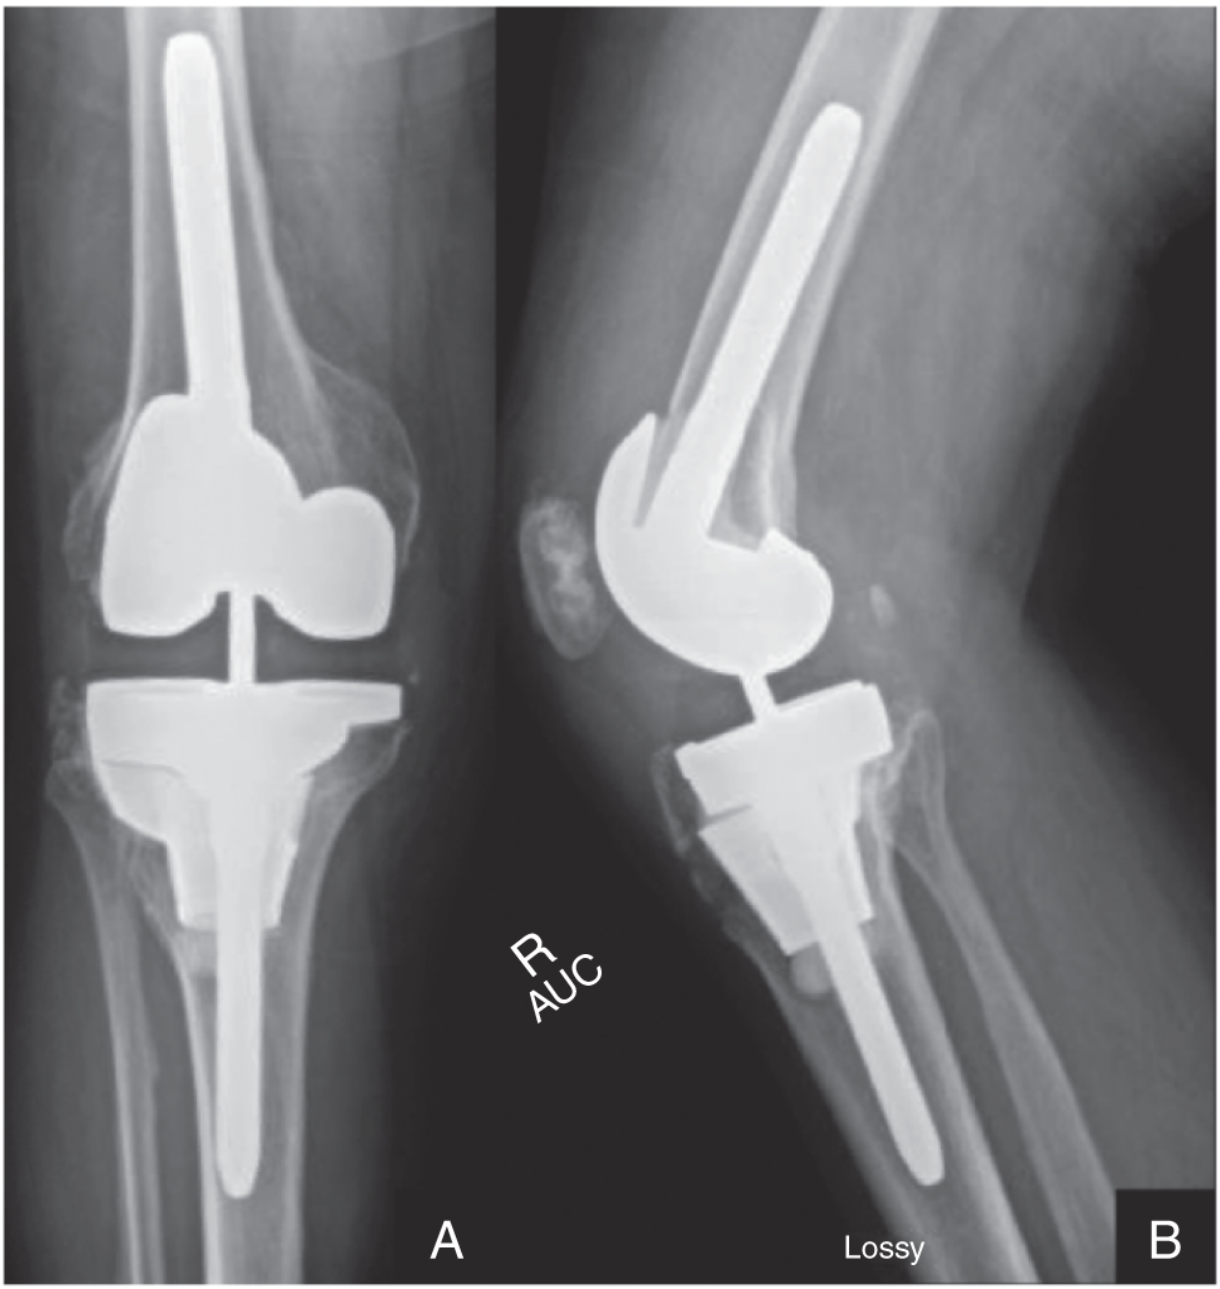

Figure 55.3 Radiographs at two-year follow-up.

Summary of answers

- From the available data, we recommend the use of a hybrid cement technique in the optimal patient where diaphyseal press-fit stemmed components are appropriate.

- Using a stem of the shortest stem length is helpful when considering future revision surgery.
- In cases of severe loss of bone stock, mostly AORI class 2B or 3, the combination of porous metal cones with only metaphyseal cementation can aid in employing a shorter stem with adequate canal filling.
- Patients with large intramedullary canals or diaphyseal deformity would be better served with a cemented component.
- Use of a cement restrictor and having an adequate cement mantle around the stem are recommended technical points when utilizing this technique.

Periprosthetic Fractures: Knee

Jesse Wolfstadt MD MSc FRCSC[1] and Aaron Nauth MD MSc FRCSC[2]
[1]Division of Orthopaedic Surgery, Department of Surgery, McMaster University, Hamilton, ON, Canada
[2]Division of Orthopaedic Surgery, Department of Surgery, University of Toronto, Toronto, ON, Canada

Clinical scenario

- A 78-year-old female patient with a previously well-functioning right total knee arthroplasty (TKA) presents to the Emergency Department after suffering a fall from standing height. She is complaining of pain in her right thigh and has an obvious deformity.
- Radiographs demonstrate a distal femur periprosthetic fracture originating at the proximal aspect of a stable femoral component and no evidence of loosening or osteolysis around the tibial components (Figure 56.1).

Top three questions

1. In elderly patients with displaced periprosthetic distal femur fractures, are outcomes improved with open reduction and internal fixation (ORIF) compared to revision TKA?
2. In elderly patients with displaced periprosthetic distal femur fractures, are outcomes improved with retrograde intramedullary nailing (RIMN) compared to periarticular locked plating?

3. In elderly patients with displaced periprosthetic distal femur fractures, what is the minimal remaining bone stock required to successfully perform ORIF?

Question 1: In elderly patients with displaced periprosthetic distal femur fractures, are outcomes improved with open reduction and internal fixation (ORIF) compared to revision TKA?

Rationale

The management of periprosthetic distal femur fractures can be challenging and is often complicated by poor bone quality or bone stock. The ideal management strategy to achieve the best short-term (morbidity, rehabilitation) and long-term (knee function, implant survivorship, union rates, complications) outcomes remains unclear.

Clinical comment

Most patients with distal femur periprosthetic fractures are low-demand, medically complex patients. Careful assessment should be performed preoperatively to assess the quality and amount of bone stock, stability of components, and integrity of the collateral ligaments. Stable components with adequate bone stock are often treated with ORIF with either an RIMN or periarticular locked plating. In patients with unstable components or inadequate bone stock or quality, a revision TKA with either revision components or a distal femoral replacement (DFR) may be indicated.

Figure 56.1 Preoperative radiographs of a 78-year-old female patient demonstrating a distal femur periprosthetic fracture above a previously well-functioning TKA (A and B). Nine-month postoperative radiographs demonstrating healing following treatment with locked plating (C–E).

Available literature and quality of the evidence

PubMed, Ovid MEDLINE, and Cochrane databases were searched with the following terms: *periprosthetic femur fracture*, *distal femoral replacement*, *periarticular plate*, *locked plate*, *open reduction internal fixation*, *intramedullary nail*, and *reamed intramedullary nail*. The quality of evidence available to answer the question is limited to four retrospective studies of level III evidence.

Findings

While there are many studies investigating the outcomes of ORIF of distal femur periprosthetic fractures,[1,2] there is a lack of studies investigating revision to a DFR for these fracture types.[3,4] There were only four level III studies that directly compared the outcomes of ORIF and DFR.[5–8]

Thirty-nine patients treated with ORIF using either a conventional or locked plating were retrospectively compared to 29 patients treated by revision to a DFR.[5] Treatment selection with regard to ORIF versus DFR was selected at the discretion of the surgeon based on the fracture pattern. All non- or minimally displaced fractures were treated with ORIF and all fractures with femoral component loosening were treated with DFR. Displaced fractures with a stable femoral component were treated with both techniques (33 with ORIF and 12 with DFR). There was no statistically significant difference between ORIF and DFR regarding clinical outcome ($p = 0.3$), survivorship (0.729, hazard ratio [HR] = 1.19; 95%

confidence interval [CI]: (046–3.09)), and infection (1.000). The only significant difference found was the occurrence of nonunion (15.4% with ORIF group vs 0% with DFR, p = 0.03). Five of the six cases of nonunion eventually underwent conversion to DFR. Three patients (10.3%) in the DFR group required repeat surgery for patellar maltracking.

Ruder et al. performed a retrospective review to assess the functional outcomes of 23 patients treated with DFR and 35 patients treated with ORIF for a distal femur periprosthetic fracture (PPF).[6] The only significant difference found preoperatively was in patient age, with older patients being more likely to receive a DFR (78 in ORIF vs 83 in DFR, p = 0.008). There was no difference in total complications (p = 0.46), hospital length of stay (p = 0.51), ambulatory status (p = 0.08), or mortality. The authors suggested that age is the predominant factor predicting ambulatory status and functional outcomes following distal femur PPF, irrespective of treatment modality.

A recent retrospective study by Hoellwarth et al. reviewed 87 patients treated with locked plating and 53 treated with DFR.[8] There was no significant difference between locked plating and DFR for 90-day mortality (9% vs 4%, p = 1.0), one-year mortality (22% vs 10%, p = 0.41), revision surgery at one year (9% vs 3%, p = 0.36), and maintaining ambulation (77% vs 81%, p = 0.30).

The final study was a retrospective review of 35 patients (36 knees) who underwent primary DFR for periprosthetic fractures and 13 patients with failed ORIF who were converted to a DFR.[7] Thirteen of 141 patients (9.2%) had failed primary ORIF for distal femur periprosthetic fracture, requiring conversion to DFR. The most common causes for failure include nonunion, infection, and refracture. There was a trend toward greater postoperative

complications for patients who failed ORIF and were converted to DFR compared with primary DFR (38.5% vs 16.7%, p = 0.09).

Resolution of clinical scenario

- Primary DFR may be associated with lower rates of complications and revision surgery compared with ORIF for periprosthetic distal femur fractures. However high-level evidence confirming this is lacking.
- DFR allows immediate weight bearing but does not have a clear benefit regarding long-term functional outcomes.

Question 2: In elderly patients with displaced periprosthetic distal femur fractures, are outcomes improved with retrograde intramedullary nailing (RIMN) compared to periarticular locked plating?

Rationale

The optimal choice of implant for ORIF of periprosthetic distal femur fractures with stable components remains unclear.

Clinical comment

Modern implants, including RIMN and locked plating, have been used to treat periprosthetic distal femur fractures. The stability of the femoral component, presence and size of an open femoral box, and location of the fracture must be taken into consideration when choosing the fixation

construct. It is unclear which construct is superior with regards to clinical outcomes, rate and time to union, complications, and need for revision surgery.

Available literature and quality of the evidence

PubMed, Ovid MEDLINE, and Cochrane databases were searched with the following terms: *periprosthetic femur fracture*, *periarticular plate*, *locked plate*, *open reduction internal fixation*, and *intramedullary nail*. The quality of evidence available to answer the question is poor and was limited to four studies with level III evidence and seven studies with level IV evidence. Only studies which directly compared locked plating and intramedullary nailing were included in the review.

Findings

Two biomechanical studies have investigated the ideal construct for periprosthetic distal femur fractures. The first compared a nonlocked plate, polyaxial locked plate, intramedullary fibular strut allograft with polyaxial locked plate, and RIMN and found that the addition of a fibular strut allograft did not improve the strength of the polyaxial locking plate.[9] RIMN had lower stiffness under cyclic torsional loading than the other constructs ($p = 0.046$) but the highest axial stiffness ($p = 0.036$). In contrast, a second biomechanical study found that RIMN with two locking bolts and two oblique distal locking screws had the best combined (torsional and axial) biomechanical stability in osteoporotic distal femur fractures when compared to locked plating, RIMN with two uniplanar locking screws, and RIMN with one screw and one spiral blade.[10]

Most studies comparing locked plating to RIMN have failed to demonstrate a difference in outcomes or complications between the two.[11–17] Bezwada et al. found no difference in

the rates of union, malunion, complications, and ROM between RIMN and ORIF, although it was unclear if they used modern periarticular locked plates or conventional nonlocked plates in the ORIF group.[11] The RIMN group had shorter operative times (45 minutes vs 74 minutes) and less intraoperative blood loss (100 cc vs 450 cc, $p < 0.05$) compared to ORIF. Hou et al. retrospectively compared 34 patients treated with minimally invasive locked plating and 18 patients treated with RIMN.[12] They showed no significant differences in time to union (4.0 ± 0.27 months vs 3.4 ± 0.30 months, $p = 0.95$), intraoperative blood loss (177.5 ± 23.4 mL vs 182 ± 31.6 mL, $p = 0.91$), operative time (87.4 ± 6.4 minutes vs 91.6 ± 6.8 minutes, $p = 0.46$), and complications between the two groups. A retrospective case series comparing seven patients treated with RIMN and nine patients treated with locked plating demonstrated no difference in mean time to union (3.9 months in locked plating group vs 3.8 months in RIMN group, $p = 0.149$), Knee Society Score (KSS), or malalignment in the sagittal or coronal planes.[13] Meneghini et al. compared 22 periprosthetic distal femur fractures treated with a modern RIMN with fixed angle distal locking screws to 63 cases treated with locked plating.[14] A mean of 5.0 distal screws was used in locked plating versus 3.8 distal screws in RIMNs ($p = 0.001$).The two groups had similar rates of nonunion (9% vs 19%, $p = 0.34$), time to union ($p = 0.64$), and malunion, although the RIMN group had a quicker mean time to resume full weight bearing (9.1 weeks vs 11.7 weeks, $p = 0.001$). Gondalia et al. found no difference between 24 patients treated with locked plating and 18 patients treated with RIMN with respect to time to union (49.8 ± 42.5 weeks vs 38.3 ± 25.5 weeks, $p = 0.649$), KSS (77.2 ± 12.7 vs 81.8 ± 8.7, $p = 0.379$), KSS functional score (76.5 ± 14.5 vs 80.6 ± 10.9, $p = 0.310$), change in ROM (11.1° ± 14.5° vs 7.2° ± 14.7°, $p = 0.364$), operative time

(135.0 minutes ± 31.9 vs 125.0 minutes ± 38.5, p = 0.223), and complications (29.2% vs 27.8% p = 0.900).[15] Park et al. performed a retrospective comparison of 20 patients treated with RIMN and 21 patients treated with locked plating using minimally invasive plate osteosynthesis (MIPO) technique.[16] There was no statistical difference between the RIMN and the locked plating groups in range of motion arc at one year (p = 0.642), one-year postoperative Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC) score (p = 0.135), time to union (p = 0.081), or malalignment (p = 0.343). Most recently, Matlovich et al. compared 38 cases treated with locked plating and 19 cases treated with RIMN.[17] This study reported no statistical difference between the mean time to full weight bearing (p = 0.94), including a comparison within groups of fractures above and below the TKA flange (p = 0.11 for locked plating and p = 0.72 for RIMN). There was no difference in postoperative extension and flexion between locked plating and RIMN (p = 0.18 and p = 0.81, respectively), time to union (p = 0.64), and sagittal or coronal alignment (p = 0.76 and p = 0.84, respectively). The authors did find a higher reoperation rate (26.3% vs 2.7%) and incidence of subjective instability (17.6% vs 0%, p = 0.04) in the RIMN group, but no difference in requirement of gait aids (p = 0.81) or chronic postoperative pain (22.7% vs 22.2%, p = 0.94). There were two nonunions in the RIMN group in patients who suffered fractures below the TKA flange.

A single level IV study was the only paper to report a difference in rates of nonunion between RIMN and locked plating.[18] The retrospective review of 63 patients with displaced periprosthetic distal femur fractures pooled from three academic institutions found that the rate of nonunion was significantly higher in the RIMN group compared with the locked plating group, at 36 weeks postoperatively

(10/35 in the RIMN vs 2/28 in the locked plating group, p = 0.05). Despite this difference in union rate, the times to full weight bearing for both groups were not significantly different, with an average of 12.4 weeks for the RIMN group and 11.5 weeks for the locked plating group (p = 0.54, 95% CI: 22.02–3.80). The RIMN group had lower transfusion rates (22.9% vs 53.6%, p = 0.02) and mean operative time (113 minutes vs 155.3 minutes, p <0.01), but higher rates of revision surgery (40% vs 14.3%, p = 0.05), mostly to address nonunion.

Ristevski et al. performed a systematic review comparing nonoperative and various operative treatments for periprosthetic distal femur fractures.[1] They showed that locked plating and RIMN had several advantages when compared with nonoperative management and conventional (nonlocked) plating. Locked plating and RIMN demonstrated no significant differences in nonunion rates (odds ratio [OR] = 0.39; 95% CI: 0.13–1.15, p = 0.09) or rate of repeat surgery (OR = 0.65; 95% CI: 0.31–1.35, p = 0.25). However, RIMN had a significantly higher malunion rate when compared to locked plating (OR = 2.37; 95% CI: 1.17–4.81, p = 0.02).

Resolution of clinical scenario

- Biomechanical studies are inconclusive as to the optimal construct for torsional and axial stability in the treatment of periprosthetic distal femur fractures.
- Limited evidence suggests that there is no difference in the nonunion rate, time to union, need for revision surgery, and complications when comparing RIMN and locked plating for the treatment of periprosthetic distal femur fractures. Implant selection can be made based on surgeon discretion and fracture pattern.

- Surgeons should check the manufacturer's information before selecting RIMN for treatment to determine whether the femoral component is compatible with retrograde nailing (i.e. has an open box of adequate size to accommodate a RIMN).[19]

Question 3: In elderly patients with displaced periprosthetic distal femur fractures, what is the minimal remaining bone stock required to successfully perform ORIF?

Rationale

A major concern with ORIF of periprosthetic distal femur fractures is the ability to achieve stable fixation in a short, osteoporotic fragment of distal bone.

Clinical comment

Periprosthetic distal femur fractures with stable femoral components are typically treated with ORIF. Stable fixation can be difficult to achieve because of poor bone stock and quality. Modern intramedullary nails and periarticular locking plates allow for increased fixation in far distal fragments to increase the strength of the overall construct. The exact size of the distal fragment and number of screws required for adequate fixation remains uncertain.

Available literature and quality of the evidence

PubMed, Ovid MEDLINE, and Cochrane databases were searched with the following terms: *periprosthetic femur fracture*, *periarticular plate*, *locked plate*, *open reduction internal fixation*, and *intramedullary nail*. The quality of

evidence available to answer the question is limited to three retrospective studies of level III and IV evidence.

Findings

The three studies did not specify an exact measurement that was used to identify an extreme periprosthetic distal femur fracture, rather they used the Su or Rorabeck classifications.[20] Streubel et al. performed a retrospective review of 61 patients with unilateral periprosthetic distal femur fractures treated at three level I trauma centers with locked plating.[21] Thirty-three of these fractures extended distally from the anterior flange of the femoral component (considered by the authors to be “extreme distal”), with an average follow-up of nine months. The authors found that extreme distal periprosthetic femur fractures can be managed with ORIF with results similar to more proximal fractures. The two groups had similar rates of delayed healing (6% for distal fractures vs 18% for proximal fractures, $p = 0.23$) and nonunion (15% vs 11%, $p = 0.72$).

A second retrospective study followed 32 patients at an average follow-up of 25.3 months.[22] Eighteen patients were treated with a single MIPO locking plate and 14 with double plating. The authors' technique included dual plating in 14 of 21 patients with Su type III fractures (fractures extending distal to the anterior flange of the femoral component), specifically those with medial comminution or severe osteoporosis. There was no difference in nonunion (1/11 vs 1/21, $p = 1.0$) and mean time to union (3.8 vs 3.6 months, $p = 0.914$) between Su type I/II and Su type III fractures. The authors suggested using a second medial plate as an adjuvant for Su type III fractures.

The final study was a retrospective review of 26 patients with displaced periprosthetic distal femur fractures treated

with an RIMN with an average 81 months of follow-up. The number of distal locking screws (1 or 2 vs 3 screws) correlated with both nonunion ($p < 0.1$) and the need for revision surgery ($p < 0.1$), suggesting better outcomes if more fixation could be achieved in the distal fragment.

Resolution of clinical scenario

- Extreme distal periprosthetic femur fractures (those which extend distal to the anterior flange of the femoral component) can be adequately managed with ORIF in the setting of a stable femoral component.
- More points of fixation in the distal fragment are associated with lower rates of nonunion and revision surgery, regardless of construct (locked plating or RIMN).

57
Femoral Bone Defects in Revision Total Knee Arthroplasty

Adam Katchky MD MSc FRCSC[1] and David J. Backstein MEd MD FRCSC[2]
[1]Niagara Health System, Welland, ON, Canada
[2]Mount Sinai Hospital, University of Toronto, ON, Canada

Clinical scenario

- Active 69-year-old male with a history of remote right total knee arthroplasty.
- Presents with increasing right knee pain and instability.
- Examination reveals instability to varus and valgus forces with good range of motion and normal neurovascular exam.

Introduction

One challenge of revision total knee arthroplasty (RTKA) is assessment and restoration of bony defects. Bone loss is often classified according to the Anderson Orthopaedic Research Institute (AORI) Bone Defect Classification.[1]

Defects may be characterized as contained or uncontained. Contained defects may be cavitary, representing loss of cancellous bone with intact cortical rim. By contrast, uncontained defects represent cancellous bone loss in addition to significant loss of surrounding supportive cortical bone. Uncontained defects may be segmental

involving the medial or lateral side of the femur or circumferential, involving the entire bone.[2]

In 2008, Lawrence et al. estimated that clinical osteoarthritis affects up to 27 million adults in the US, with 18 million affected by knee osteoarthritis.[3] For patients with end-stage knee arthritis, TKA is a common and successful procedure with over 95% survivorship at 10 years[4–6] and 90% survivorship at more than 15 years follow-up.[7–10] In spite of the relative success of this procedure, increasing TKA utilization has carried with it increasing rates of RTKA. Increased RTKA costs are driven by longer operating times, costlier implants, additional materials, longer hospital stays, and longer periods of convalescence.[11] Therefore, any treatment modality which can reconstruct bone defects in an efficient manner, while allowing for immediate weight bearing and mobilization, is preferable in the opinion of the authors.

Unfortunately, outcomes and success rates of RTKA are not comparable with primary TKA.[12,13] Structural bone defects commonly contribute to the complexity of RTKA.[14,15] The major etiologies of bone loss include implant wear and osteolysis, aseptic loosening, infection, and stress shielding.[16,17]

Top three questions

1. In patients with periprosthetic distal femoral bone defects, does computed tomography (CT) scan more accurately estimate defect size when compared to x-ray?
2. In large contained distal femoral defects with metaphyseal compromise, does metallic reconstruction

(cones/sleeves) yield improved survivorship compared to structural allograft reconstruction?

3. In patients with large, uncontained structural distal femoral defects (type 3), does distal femoral replacement revision knee arthroplasty yield superior clinical results compared to reconstruction with segmental allograft or allograft-prosthetic composite?

Question 1: In patients with periprosthetic distal femoral bone defects, does computed tomography (CT) scan more accurately estimate defect size when compared to x-ray?

Rationale

A detailed understanding of the location and extent of osteolysis/bone loss, and the quality/quantity of remaining distal femoral bone, is essential for proper planning and management. This is particularly important for surgeons operating in a facility which does not have the equipment and implants necessary to all modalities of reconstruction readily available.

Clinical comment

A thorough clinical assessment is essential prior to knee revision surgery to evaluate the patient's health status with possible consultation from internal medicine and anesthesia. The operative site is assessed for previous incisions and potential wound complications and workup for infection is performed using blood tests, imaging, and possibly joint aspirate for culture.

The reason(s) for TKA failure should be established and a management plan formulated. Component position, stability, and degree and location of bone loss should be assessed with x-rays and CT. Adequate assessment of these aspects of the clinical scenario will allow the surgeon to plan the reconstructive technique and ensure availability of all necessary equipment.

Available literature and quality of the evidence

Multiple studies help address this question, including one prospective study,[18] two retrospective studies,[19–21] and one cadaveric study.[22] Overall quality of evidence is moderate.

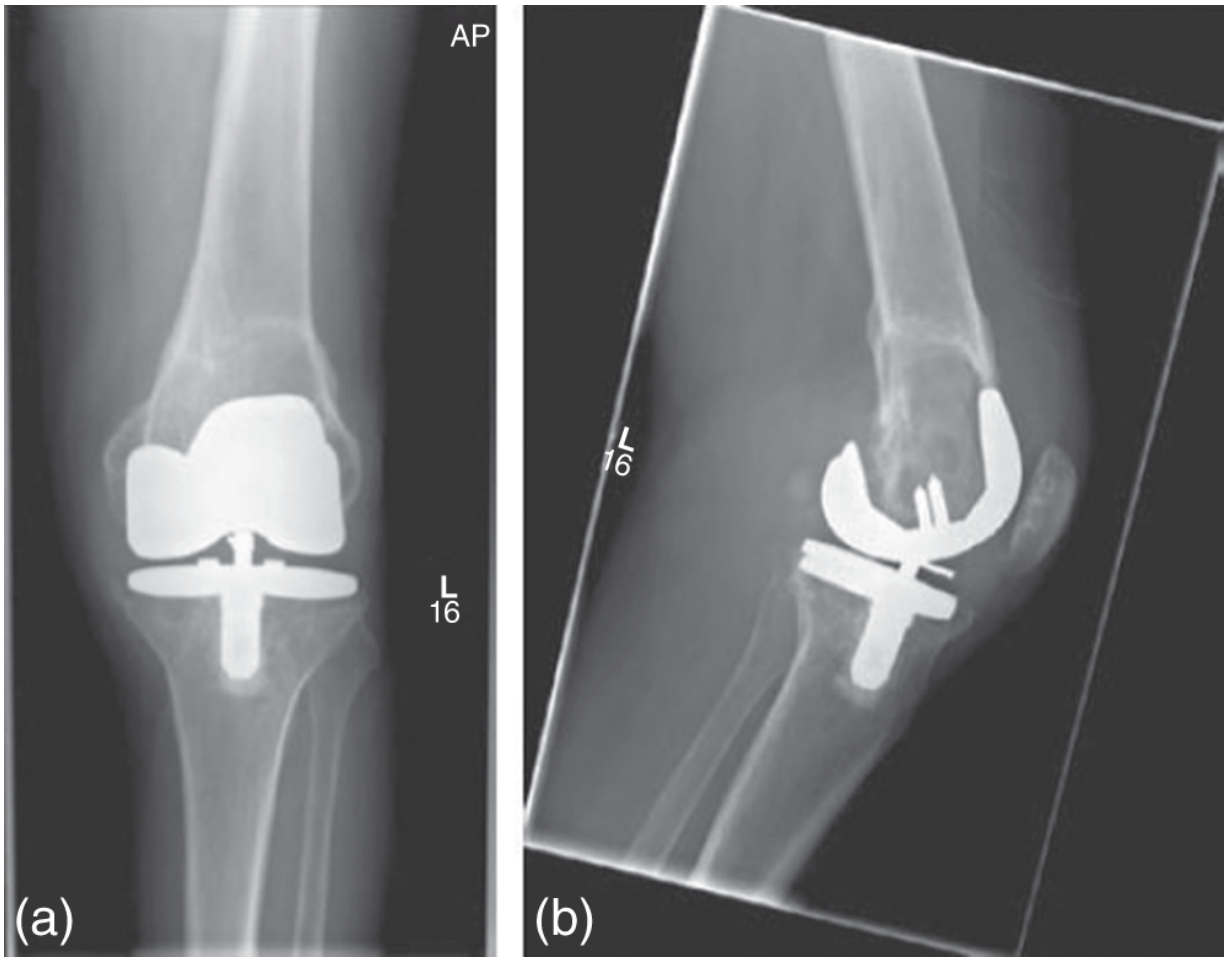

Figure 57.1 Representative radiographs of 69-year-old man with osteolysis around TKA implants. (a) Anteroposterior and (b) lateral radiographs of TKA with femoral bone loss secondary to osteolysis.

Findings

Assessment of bone loss using routine x-rays has been shown to lead to underestimation, and further imaging should be obtained including oblique views or CT scan to achieve reasonable prediction of defect size (Figure 57.1 and 57.2).[18–20,22] Agreement between plain x-ray and intraoperative assessment of bone loss has been shown to be fair based on the AORI classification.[22] Also, analysis of 31 patients who had osteolytic lesions confirmed by

multidetector CT, plain radiography detected only 17% of lesions.[21]

Resolution of clinical scenario

- A CT scan should be performed in cases of suspected bone loss for more accurate delineation of defect size and location.

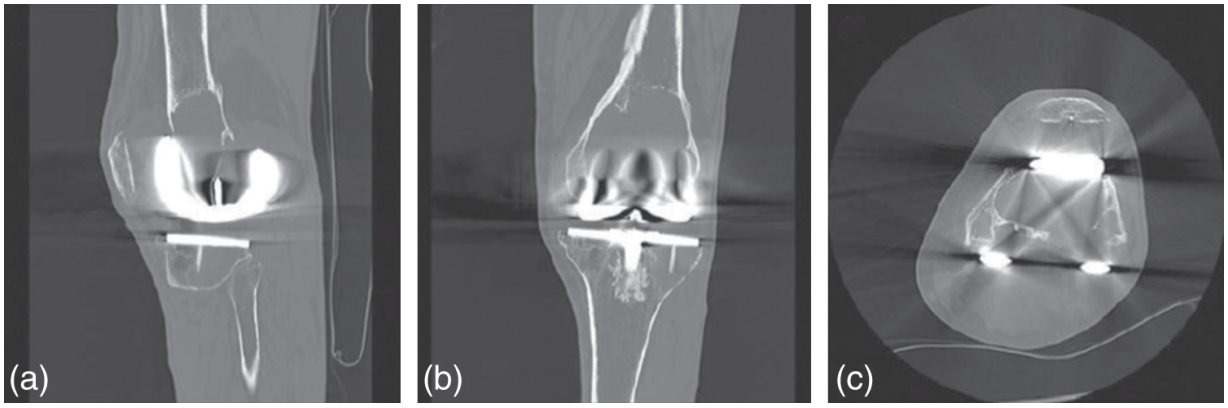

Figure 57.2 CT scan showing femoral bone loss due to osteolysis on cross-sectional imaging in the same 69-year-old patient. Representative (a) sagittal, (b) coronal, and (c) axial images showing degree of bone loss.

Question 2: In large contained distal femoral defects with metaphyseal compromise, does metallic reconstruction (cones/sleeves) yield improved survivorship compared to structural allograft reconstruction?

Rationale

While smaller contained defects are simpler to manage, larger structural defects often require the use of advanced

reconstructive strategies. Multiple reconstructive techniques have been proposed to manage these defects, with the goal of optimizing patient outcomes following this technically demanding procedure.

Clinical comment

Small, contained defects can be filled with cement[23,24] or with impacted morselized bone graft. Cement has been shown to provide inferior load transfer with poor fatigue properties,[25–27] and bone grafting may be preferred due to its biological advantage.[28,29] Smaller uncontained defects may be treated successfully with metallic block augments.[30,31]

Large defects with metaphyseal bone loss must be reconstructed to achieve implant stability, and may require augmentation with allograft or synthetic materials. Traditionally, these defects have been managed with structural and/or morselized allograft in the setting of RTKA. Similar to smaller defects, allograft reconstruction of large bone defects has the advantage of restoring bone stock. Advances in material science and the development of highly porous metal reconstructive augments (titanium sleeves, tantalum cones) has created new strategies for managing femoral defects, which avoid some of the pitfalls of allograft implantation (disease transmission, graft resorption, poor availability).

Both metallic options represent somewhat different philosophies. Tantalum cones are nonlinked to the prosthesis. The preparation of the bone bed for cones is more demanding as precise bone contouring is required while sleeves utilize a simple broaching technique. Sleeves are directly linked to the prosthesis in order to form a single unit, while cones require cement for connection to the TKA prosthesis.

Available literature and quality of the evidence

No studies were identified which directly compare the results of these reconstructive approaches. Four retrospective case series[32–35] (level IV evidence) report outcomes following reconstruction with tantalum cones, while a further two prospective[36,37] and three retrospective studies[38–40] report outcomes using porous titanium sleeves. Outcomes of structural allograft reconstruction are reported in one prospective cohort,[41] two cross-sectional studies,[42,43] and five retrospective case series.[2,44–47] Overall quality of evidence is moderate due to heterogeneity of patient population, reconstructive techniques, and outcome measures reported.

Findings

A single comparative study was identified comparing reconstruction with and without structural allograft;[43] however, the population is heterogeneous, as are the techniques utilized in the nonstructural allograft group. As a result, conclusions which address this question are difficult to draw. The Knee Society knee and functional scores (KSS) are the most commonly reported patient-reported outcome measures (PROMs)[2,32,36,37,40,41,44,45] and scores appear to be highest in titanium sleeve reconstruction (81.0, 78.8) than with tantalum cones (66.0, 61.1) or structural allograft (79.3, 60.0); however, the clinical and statistical significance of this difference is unknown.

When reported,[32–35,37,38,40,42,45,47] range of motion was also slightly greater following metallic metaphyseal reconstruction (108° vs 98°). In the short to medium term (2–5 years), metallic metaphyseal reconstruction was found to have surgical complication and reoperation rates

ranging from 6 to 19%.[32–34,37–39] When infection was excluded, however, all studies reported over 95% aseptic survivorship of metaphyseal sleeves and cones.[32–37]

By contrast, the literature indicates that the results of structural allograft may be less consistent. In addition to the rare but notable risk of disease transmission, structural allografts may be time consuming to sculpt, and resorption has been documented. Mow and Wiedel reported a reoperation rate of 20% in their cohort of 16 RTKA with structural allografts at a mean of four years;[42] however, there were no cases where the femoral component or femoral allograft were revised (100% survivorship). Additionally, several studies have reported graft healing and femoral implant survivorship rates between 77% and 90%.[2,44–47] The study by de Waal et al. stands in contrast to these findings, as only 37.5% of grafts could be confirmed to be healed at three-year follow-up.[41] For the remainder, it was reportedly unclear whether the graft had healed, or there was clear resorption.

Resolution of clinical scenario

- Porous titanium sleeves, tantalum cones, and structural allograft bone may all be considered for reconstruction of large metaphyseal defects.
- Metallic reconstruction options confer more reliable construct healing and survivorship, as well as marginally improved clinical results, while avoiding some challenges associated with the use of allograft bone.

Question 3: In patients with large, uncontained structural distal femoral defects (type 3), does distal femoral replacement revision knee arthroplasty yield superior clinical results compared to reconstruction with segmental allograft or allograft-prosthetic composite?

Rationale

These defects present unique management challenges, as reconstructive strategies must address potential compromise of implant stability, joint stability, and significant bone stock deficiency.

Clinical comment

AORI type 3 defects feature “extensive structural bone loss, involving a major portion of one or both femoral condyles.”[48] Multiple challenges arise in managing these defects: the total volume of bone loss is generally greater than in other lesion types; a segment of structural cortical bone may be absent, leading to difficulties containing and stabilizing cancellous bone or reconstructive implants; and the attachments of the collateral ligaments may be compromised, leading to knee joint instability and failure of conventional primary or revision TKA implants. Reconstruction of type 3 defects must address each of these challenges. Traditionally, these lesions have been most commonly managed with the use of segmental structural allograft. These allografts may be fixed in multiple ways. A sized allograft may be fixed to the residual native bone to restore the architecture of the distal femur,

with a stemmed RTKA implant subsequently impacted to bypass the newly placed graft. Alternatively, the RTKA implant may be cemented onto the sized and prepared allograft to create a single construct comprising the implant and structural allograft, termed an *allograft-prosthetic composite* (APC). This construct is then stabilized to the native bone by the RTKA stem. In both cases, the collateral ligaments (generally with epicondyles attached) must be stabilized to the allograft construct to restore their function. These strategies also help to restore bone stock via the addition of allograft bone. Newer hinged and distal femoral replacing implants may also be used in this circumstance. These implants can accommodate both the degree of bone loss as well as the compromised knee stability. They fail to restore bone stock, and in fact may require further bone removal to accommodate the implant. However, they restore immediate stability of the knee joint and do not rely on allograft incorporation.

Available literature and quality of the evidence

One prospective[49] and four retrospective[50–53] series reported on the results of segmental allografts and APCs, while one prospective[54] and six retrospective[55–60] reported results of hinged or distal femoral replacing implants in this setting. Overall, quality of evidence is moderate due to lack of comparative studies and inconsistency in outcomes reported.

Findings

The literature does not reveal significant differences in clinical outcomes between these two strategies. Three studies report range of motion following allograft/APC reconstruction, with an overall mean of 95.6° among 115 knees at four- to eight-year follow-up.[49,52,53] Only Jones et

al. reported specifically on range of motion following hinged TKA for bone loss, with a mean of 105° among 19 knees at four years postoperatively.[55] Marczak et al. also reported nine out of nine knees with over 90° range of motion at five years; however, exact range of motion was not reported.[56]

Once again the most commonly reported PROM was the KSS. Cumulative mean KSS across three studies (mean two- to eight-year follow-up)[50,52,53] was 86.8 following allograft reconstruction. This appeared to be slightly better than the cumulative mean KSS of 80 seen across three studies of distal femoral replacing TKA at a similar time point.[56,57,60] Statistical comparison could not be performed due to a lack of primary or statistical data reported. Reported failure rates of allograft reconstruction at up to five-year follow-up, including revisions, reoperation, fracture, and patient dissatisfaction, range between 11 and 25%.[49–51] Backstein et al. reported on one of the largest cohorts (68 grafts), reporting a 21% failure rate at a mean of 5.4 years.[51] By contrast, Engh et al. report 100% construct survivorship at a minimum two-year follow-up (mean 50 months), despite only 67% confirmed graft healing.[52] Bauman et al. published the longest term study identified, with five-year survivorship of 80% (95% confidence interval [CI]: 71.7–90.8) and 10-year survivorship of 76% (95% CI: 65.6–87.8).[53] Similar to the results of metallic reconstruction of metaphyseal defects, complication and reoperation rates were shown to be quite high following endoprosthetic reconstruction. Pour et al. reported a 20% one-year failure rate and 32% five-year failure rate following hinged TKA for massive bone loss.[54] Similarly, Marczak et al. reported a 22% failure rate at a mean five years following reconstruction with a distal femoral replacement megaprosthesis.[56] Concerningly,

Kostuj et al. reported up to 30% infection rate within 3.5 years following megaprosthetic RTKA with massive bone loss.[59] With infections excluded, most studies reported very good aseptic survivorship in the medium term (Höll[57] 87%, Kostuj[59] 91%, Marczak[56] and Jones[55] 100%).

Resolution of clinical scenario

- Available evidence is unable to definitively indicate superiority of either endoprosthetic or allograft reconstruction for type 3 femoral bone loss; however, endoprostheses have some inherent advantages.
- Both strategies necessitate technically demanding operative intervention with high complication rates.
- The patient's age, medical status, functional demands, life expectancy, and risk for future revision surgery must be considered when selecting a reconstructive strategy.

Summary of answers

- Determination of the extent of femoral defects:
  - CT scan should be performed in cases of suspected bone loss for more accurate delineation of defect size and location.
- Treatment of large contained metaphyseal defects:
  - Porous titanium sleeves, tantalum cones and structural allograft bone may all be considered for reconstruction of large metaphyseal defects
  - Metallic reconstruction options confer more reliable construct healing and survivorship, as well as marginally improved clinical results, while avoiding

some challenges associated with the use of allograft bone.

- Treatment of large segmental (type 3) defects:
  - Available evidence is unable to definitively indicate superiority of either endoprosthetic or allograft reconstruction for type 3 femoral bone loss; however, endoprostheses have some inherent advantages.
  - Both strategies necessitate technically demanding operative intervention with high complication rates.
  - The patient's age, medical status, functional demands, life expectancy, and risk for future revision surgery must be considered when selecting a reconstructive strategy.

Management of Structural Defects in Revision Knee Arthroplasty: Tibial Side

Sebastián León MD[1], Jennifer Leighton MD FRCSC[2], Xin Y. Mei MD[2] and Paul R. Kuzyk MD MASc FRCSC[2]
[1]Hospital San José, Santiago, Chile
[2]Mount Sinai Hospital, University of Toronto, Toronto, ON, Canada
[3]Division of Orthopaedic Surgery, Department of Surgery, University of Toronto, Toronto, ON, Canada

Clinical scenario

- A 59-year-old male who is eight years out from a right total knee arthroplasty (TKA) presents with a three-month history of pain dating back to a ground level fall; no infectious symptoms.
- Radiographs reveal tibial loosening with periprosthetic fracture and significant tibial bone loss (Figure 58.1 and 58.2).

Top three questions

1. In patients with moderate tibial bone loss at revision TKA, are porous metal block augments a better option for implant survival compared to cement filling?
2. In patients with moderate to severe tibial bone loss at revision TKA, is impaction bone grafting (IBG),

compared to other options, a viable technique in terms of survival – specifically aseptic loosening?

3. In patients with severe tibial bone loss at revision TKA, do metaphyseal trabecular metal (TM) sleeves and cone augments improve implant survival compared to structural allografts?

Question 1: In patients with moderate tibial bone loss at revision TKA, are porous metal block augments a better option for implant survival compared to cement filling?

Rationale

Current recommendations are that cement-filling techniques be limited to defects <5 mm in depth, and that larger defects be treated with structural augmentation. However, recent evidence suggests that cement may be appropriate in larger defects.[1]

Clinical comment

In planning for any revision TKA, one must estimate the amount of bone loss. Defects are identified and classified using radiographs and computed tomography (CT). The Anderson Orthopaedic Research Institute (AORI) classification is most commonly use.[2] Type 1 defects are minor, contained, with intact cortical bone, and the component sits above the level of the fibular head. Type 2 defects represent considerable loss of cancellous bone and the component sits at or below the proximal fibular head. Type 3 defects have a deficient metaphyseal segment, with possible compromise of ligament or tendon insertions.

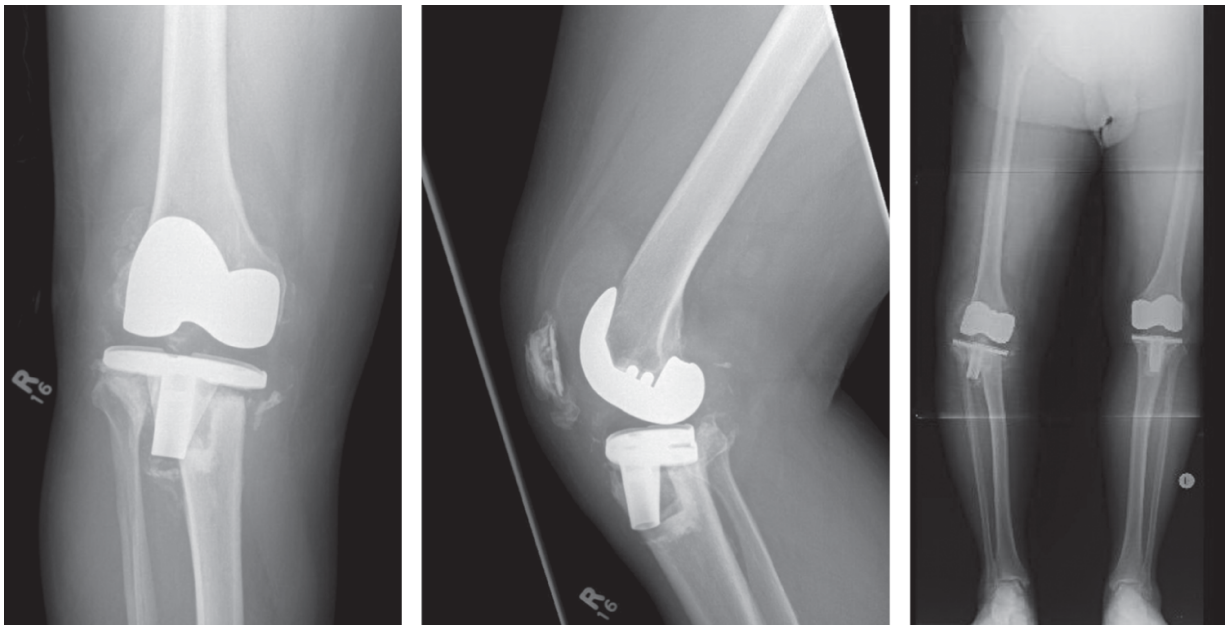

Figure 58.1 Preoperative radiographs.

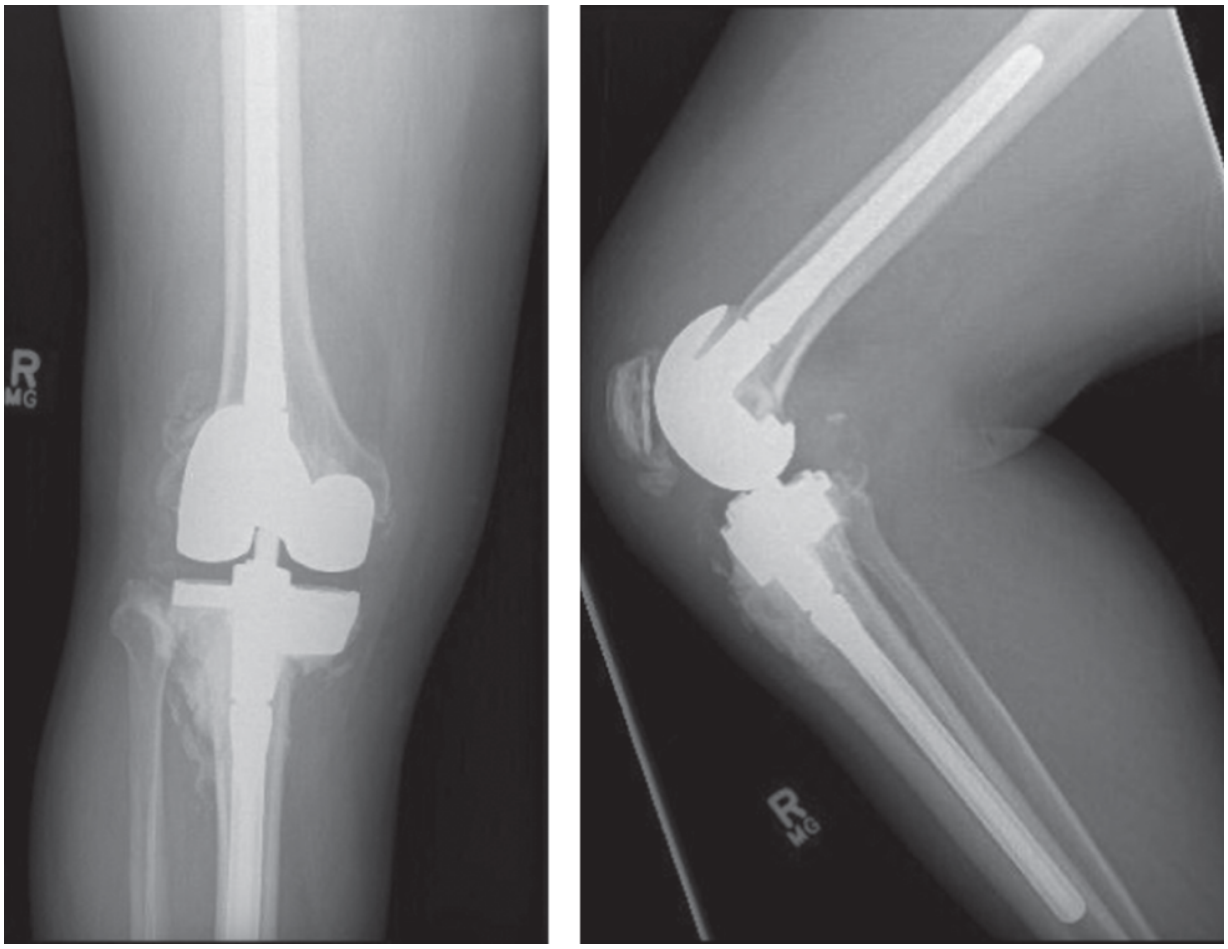

Figure 58.2 Postoperative radiographs.

AORI-1 defects <5 mm in depth have classically been treated using cement or morselized allograft. More recently, AORI-2A defects <20 mm in depth and involving <50% of either plateau have been treated by cement-fill alone.[1] Biomechanical studies comparing cement with metal augments show superiority of metal augments in wedge-shaped defects.[3] However, when converted to a step-cut pattern, cement is comparable to metal augments in resisting axial load.[4] Several studies have reported good results using cement in uncontained defects.[1,5–7] This is an economical way to manage select bone defects.

Alternatively, modular augmentation allows the surgeon to create a “custom” implant and re-establish the normal joint

line. Blocks range in size from 5 to 25 mm, and are fixed to the tibial tray. These are often indicated in AORI-2 defects of >25% of cortical bone, or if >40% of the base plate is unsupported by host bone.[8] Uncontained defects of 20–45 mm can be managed with metal augmentation and a thick polyethylene liner. Larger defects are unsuitable for block augmentation alone, as this places the base plate too distally.[9] In these scenarios, additional diaphyseal fixation using stemmed tibial components is typically needed to offload the metaphyseal augmentation and protect the cement–implant interface from failure.[10]

Cement fixation is inexpensive, readily available, and versatile due to its ability to readily fit and fill the size and shape of the bone defect. Bone cement should be vacuum-mixed to reduce its porosity. The tibia should be cleaned using pulsatile lavage and dried with clean sponges to reduce cement lamination secondary to blood and tissue debris. Some authors have recommended using 3.5 mm drill holes in patients with sclerotic bone to enhance cement penetration and increase surface contact.[11] The routine use of antibiotic-laden bone cement in revision total joint arthroplasty is well supported by the literature.[12]

Available literature and quality of the evidence

- Level IV evidence: 6 case series.[13–18]

Findings

Berend et al. investigated the use of screws and cement for large tibial bone defects in primary TKA.[13] Screws should be sunk into the cement enough to avoid contact between their heads and the implant. The authors report a 20-year survival probability of 98.97 and 93.39% with screws and cement versus cement alone, respectively. Defects treated

with screws were significantly worse than those without ($p < 0.0001$), ranging from 5 to 30 mm in depth. Berend et al. also reported on 609 revision procedures at 17 years' follow-up.[14] Of these, 264 had tibial defects >5 mm. Survival was 98.59 and 98.48%, when a defect was managed using cement with screws and without, respectively. Screws were, again, used in more severe defects ($p < 0.0001$). When primary prostheses were used, there was a trend toward a higher revision rate, though statistical significance was not reached (4.2% vs 1.2%, $p > 0.05$).

Patel et al. prospectively looked at 79 knees with AORI-2 defects treated with metal augments and stemmed prostheses.[18] Mean follow-up was seven years. They found nonprogressive radiolucent lines around 14% of augments, but no correlation with implant survival. They reported 92% survival at 11 years. Hass et al. reported 83% survival of tibial wedges at eight years.[15]

Panni et al. reported on 38 revision TKA with AORI-2 and -3 defects treated with modular augments (blocks: 46 femoral, 38 tibial blocks; wedges: 2 tibial; TM cones: 5 tibial, 4 femoral).[17] Three patients (7.9%) required reoperation, none due to loosening (2 infections, 1 instability). They noted two cases of nonprogressive radiolucent lines around the medial tibia, without platform subsidence.

Hockman et al. reported on 54 revision TKA, using non-modular trays with porous metal wedges.[16] Interestingly, 17 knees failed and 59% of these had only moderate defects. These were revised with metal augmentation alone.

Resolution of clinical scenario

- Defects <30 mm in depth can be managed by augmentation with metal blocks or cement with screws, with comparable results. Porous metal wedges demonstrate inferior results.

Question 2: In patients with moderate to severe tibial bone loss at revision TKA, is impaction bone grafting (IBG), compared to other options, a viable technique in terms of survival – specifically aseptic loosening?

Rationale

IBG has been shown to be a viable option in treating bone loss in revision THA. Its use in revision TKA remains controversial.

Clinical comment

IBG was first described by Hastings and Parker,[19] and later standardized by Sloof et al. for the treatment of large acetabular defects in THA.[20] Its successful use in the hip led to its use in knee revision, [21–23] as first described by Ullmark and Hovelius.[24]

IBG restores bone stock, filling irregular defects without need for further bone removal.[25] Morselized grafts have a higher rate of incorporation, with near-complete substitution by host bone, whereas bulk allografts only incorporate peripherally.[26–29] Several studies have established the mechanical stability of IBG,[30–32] including its use in tibial defects with stemmed implants. Toms et al. demonstrated superior initial stability of long-stemmed

tibial trays, and that migration was inversely proportional to the density of impacted bone.[33]

Bone chips used should be as large as practical (approximately 3–5 mm in diameter) to ensure early stability. Adequate impaction force makes morselized bone grafts strong enough to carry physiologic load, while excessive impaction force reduces host bone ingrowth.[34] Bone grafts are usually preferred in younger patients in whom future revisions are anticipated and potential bone stock restoration is desirable.[35] Incorporating autograft with morselized allograft bone may add osteoinductive properties to the construct.[36]

Available literature and quality of the evidence

- Level IV evidence: 4 case series.[25][37–40]

Findings

Lotke et al. studied the medium-term results of 48 revision TKA treated with IBG.[25] At 3.8 years (mean follow-up) they reported no mechanical failures and 100% radiographic graft incorporation. IBG has become their preferred technique for management of substantial bone loss. Similarly, Lonner et al. reported no re-revision in 14 patients with revision TKA using IBG at a mean follow-up of 16 months.[38] They noted nonprogressive tibial radiolucencies in three patients. Rudert et al. evaluated 28 revision TKA with IBG and found 93.1% (95% confidence interval [CI]: 74.5–98.4%) survival at 27.7 months.[39]

Conversely, Steens et al. reviewed 34 revision TKA using IBG for management of severe bone loss.[40] With 2–9 years' follow-up, five knees failed due to aseptic loosening. Five-year survival was 76% (95% CI: 56–96). In their follow-up

study, they noted 50% at 10 years.[37] This is the longest follow-up published to date.

Resolution of clinical scenario

- Medium-term outcomes for the use of IBG in large tibial defects are conflicting. There may be a role for its use with long-stemmed prostheses, or with adequate containment. Long-term and comparative studies are lacking. Bone grafts are usually preferred in younger patients in whom further revisions are predictable.

Question 3: In patients with severe tibial bone loss at revision TKA, do metaphyseal trabecular metal (TM) sleeves and cone augments improve implant survival compared to structural allografts?

Rationale

In major tibial defects, implant survival depends largely upon achieving stability of the tibial tray and union at the host–implant interface.

Clinical comment

The most frequently used techniques in treating severe bone loss are impaction grafting, structural allograft, and TM metaphyseal cones and sleeves. The latter two are most commonly used in uncontained defects.

Structural allografts were the gold standard in treating uncontained defects until TM implants were introduced. Several studies have reported structural allograft

survivorship between 67 and 92% at five years[41–43] and 72–91% at 10 years.[42,44] High rates of complication (20%) and failure (22.8%) were noted.[42] However, the potential for bone stock restoration is an advantage to consider, particularly in young patients who may require multiple revisions.

The development of TM has revolutionized the treatment of structural defects; with low stiffness and a high coefficient of friction,[45] it is designed to promote bony ingrowth. TM obviates the concern for disease transmission, graft fracture or resorption, and provides early stability.[46] Drawbacks include the inability to restore bone stock, need for further resection to accommodate the augment, and difficulty in implant removal.[8]

Available literature and quality of the evidence

- Level III evidence: 1 retrospective cohort.[47]
- Level IV evidence: 1 systematic review and meta-analysis of level IV studies.[48]

Findings

Sandiford et al. reviewed 450 TKA revisions, of which 45 required augmentation using either structural allografts (75%) or TM cones (25%).[47] With a mean follow-up of nine years, they compared functional outcomes, radiographic loosening, revision, and complication rates. Five-year survival was 93% in the allograft group and 91% in the TM group, demonstrating no significant difference between the two ($p = 0.699$).

Beckmann et al. systematically reviewed studies evaluating failure rates of TM cones and structural allografts.[48] They found 10 studies on TM cones (254 cones in 223 revisions)

and 17 studies on structural allografts (551 bulk allografts in 476 revisions) that met inclusion criteria. They reported an odds ratio (OR) for graft-related aseptic loosening of the prostheses of 0.263 (95% CI: 0.085–0.816, p = 0.021) in favor of TM cones. No differences in infection or overall revision rates were found, though a trend toward lower revision was seen in the TM cones. Interestingly, the two cases of aseptic loosening in TM cones were both on the femoral side. During reoperation, all tibial TM cones were well fixed.

Resolution of clinical scenario

- Defects with major metaphyseal bone loss can be treated with either structural allograft or TM cones, as the best available evidence reports no difference.
- TM cones appear to have excellent integration by host bone, and may have a lower rate of aseptic loosening (level IV).
- Structural allograft may be beneficial in young patients in whom restoration of bone stock is a priority, but no studies have specifically examined this benefit.

Summary of answers

- AORI-2 defects up to 30 mm in depth can be managed by augmentation with porous metal blocks or by cement with screws, with comparable results.
- Results for the use of IBG in large tibial defects are conflicting. There may be a role for its use with long-stemmed prostheses, or with adequate containment. Long-term and comparative studies are lacking.
- Defects with severe metaphyseal bone loss can be treated with either structural allograft or TM cones, as

the best available evidence reports no difference.

- TM cones appear to have excellent rate of integration by host bone, and level IV evidence suggests they may have a lower rate of aseptic loosening.
- Structural allograft may be more beneficial in young patients in whom restoration of bone stock is a priority, but no studies have specifically examined this benefit.

Patellar Options in Revision Total Knee Arthroplasty

Jesse Wolfstadt MD MSc FRCSC[1] and Paul Zalzal MASc MD FRCSC[2]
[1]Division of Orthopaedic Surgery, Department of Surgery, McMaster University, Hamilton, ON, Canada
[2]Oakville Trafalgar Memorial Hospital, Oakville, ON, Canada

Clinical scenario

- A 65-year-old woman with rheumatoid arthritis presents with a painful right total knee arthroplasty (TKA) five years after index surgery.
- She notes anterior knee pain, difficulty ascending and descending stairs, and pain when standing up from a seated position.
- X-rays, bone scan, and inflammatory markers suggest aseptic loosening of her cemented, metal-backed patellar component.

Top three questions

1. In patients with deficient patellar bone stock, does the use of bone grafting or trabecular metal-backed components improve outcomes compared to patellectomy?
2. In patients with anterior knee pain following TKA with an unresurfaced patella, does secondary resurfacing

reduce anterior knee pain compared to conservative management?

3. When revising a femoral component for aseptic loosening, does retaining a well-fixed patellar component improve outcome compared to revision to compatible patellar and femoral components?

Question 1: In patients with deficient patellar bone stock, does the use of bone grafting or trabecular metal-backed components improve outcomes compared to patellectomy?

Rationale

Patellofemoral complications are the most common cause of re-operation after a TKA. Poor patellar bone stock presents a challenging technical problem during revision TKA, as there is a high risk of fracture, osteonecrosis, and difficulty achieving stable fixation.

Clinical comment

Poor patellar bone stock may be encountered at the time of revision TKA. Historically, patellectomy has been associated with unfavorable outcomes due to poor quadriceps strength and abnormal knee function, and is considered a last resort for compromised patellar bone stock. Patellar resection arthroplasty (patelloplasty) may result in improvements in function when no options are available for resurfacing the deficient patella. More recently, options such as gull-wing osteotomy, bone graft augmentation, cemented all-polyethylene biconvex prostheses, and trabecular metal prostheses have been

introduced to address poor patellar bone stock at the time of revision TKA.

Available literature and quality of the evidence

We found one study with level III evidence, 20 studies with level IV evidence, and one study with level V evidence. Most evidence is drawn from small case series from single institutions with short- to medium-term follow-up.

Findings

The lowest morbidity at the time of revision TKA involves retaining a well-fixed patellar component, but the surgeon must ensure there are no signs of loosening, wear, patellofemoral maltracking, or incompatibility between the femoral and patellar components.[1,2] Most authors advocate revising a well-fixed metal-backed component due to high rates of failure,[3–8] although some small case series have shown high rates of complications and secondary surgery.[5,9] Several options have been proposed to address deficient patellar bone stock at the time of revision TKA.[10] Patellectomy should be avoided because of poor outcomes, including persistent pain, quadriceps weakness, and extensor lag.[1,11,12] Patellar resection arthroplasty is a reasonable option and is preferred to patellectomy,[13] although one-third of patients have persistent anterior knee pain and there is a 15% complication rate.[14] Barrack et al. found a higher level of satisfaction in patients with a retained patellar component compared to patellar resection arthroplasty (98% vs 79%, $p < 0.01$).[15] Of those studied, 47% of patients with a patellar resection arthroplasty had difficulty using stairs compared to 24% with a patellar component in place ($p < 0.05$), and there was a higher rate of dissatisfaction, difficulty with stair climbing, and difficulty with squatting and kneeling. For cases with

central bone loss with only 5–10 mm thickness remaining, an all-polyethylene, biconvex, inlay-type prosthesis can be used.[1] Biconvex patellar components for revision TKA with bone stock as thin as 5 mm have low complication rates at up to seven-year follow-up.[16,17]

Hanssen described packing cancellous bone graft into a tissue flap to restore patellar bone stock, with significant improvements in Knee Society function and pain scores at a mean follow-up of 36.7 months.[18] Another group experimented with adding an Achilles tendon allograft to augment the Hanssen bone graft technique in three patients to allow early mobilization and protect against patellar fracture.[19] These techniques are technically demanding and described by only a few authors. A sagittal *gull-wing* osteotomy has been used with promising results in two studies.[20,21] A sagittal osteotomy is made through the articular surface followed by anterior displacement of the medial and lateral borders of the patella to create a *gull-wing* or *V* pattern that articulates with the concave trochlear groove. Thirty knees in 28 patients with deficient patella during revision TKA (less than 8 mm thickness and cortical rim not intact) were treated with a novel technique involving an onlay prosthesis, cement, and transcortical wiring. At a mean follow-up of 36.6 months, the Knee Society Score (KSS) improved significantly with only one complication (patellar fracture one week after surgery).[22] Fisher described a rebar technique with threaded Kirschner wires (k-wires) to create a buttress to prevent displacement of the pegs in 15 patients with deficient patellar bone stock.[23] Porous tantalum patellar components have demonstrated excellent survivorship. One study found 83% survivorship (19 of 23 patients) at a mean follow-up of 7.7 years. Risk factors for failure were thin or avascular patellar bone and components that were secured directly to

soft tissue.[24] Nasser and Poggie found no evidence of failure, excellent patient satisfaction, and improvements in function scores at 32-month follow-up for patients treated with a porous tantalum implant.[25]

Resolution of clinical scenario

- Patellar components should be retained during revision TKA unless they are metal-backed or show evidence of loosening or maltracking.
- Patellectomy and patelloplasty have poor outcomes in revision TKA and should be avoided in lieu of novel options for managing the deficient patella.
- Bone grafting, osteotomy, biconvex cemented patella, and porous metal components offer good short- and medium-term results for deficient patellae in revision TKA.

Question 2: In patients with anterior knee pain following TKA with an unresurfaced patella, does secondary resurfacing reduce anterior knee pain compared to conservative management?

Rationale

Surgeons must understand the current evidence before offering a secondary resurfacing to patients with anterior knee pain and an unresurfaced patella.

Clinical comment

Persistent anterior knee pain following TKA can be a source of frustration for both patients and surgeons, particularly in the setting of an unresurfaced patella. Current opinion suggests that if a patient has persistent anterior knee pain in the presence of an unresurfaced patella then an isolated secondary resurfacing is a reasonable option for patients, but it is not without its shortcomings.

Available literature and quality of the evidence

We identified eight studies with level IV evidence.

Findings

In a meta-analysis of TKA with or without resurfacing of the patella, Parvizi et al. found that 8.7% of knees with nonresurfaced patellae required secondary resurfacing. However, they did not specifically comment on the outcomes of those patients treated with secondary resurfacing.[26] Barrack et al. reported on seven patients who underwent a secondary resurfacing of the patella: four of the seven patients continued to experience anterior knee pain at an average follow-up of 36.8 months.[27] Daniilidis et al. observed a significant improvement in mean KSS (60.1 ± 8.3 to 77.0 ± 6.3, $p = 0.0063$) and function scores (42.7 ± 2.3 to 60.2 ± 3.9, $p = 0.001$), although a subgroup of six patients (27.3%) remained dissatisfied after secondary resurfacing.[28] Garcia et al. studied seventeen patients with symptomatic anterior knee pain after primary TKA without resurfacing who underwent secondary resurfacing.[29] Fifteen patients with minimum two-year follow-up (average 47.1 months) had significant improvements in their mean Knee Society knee (53 points to 82 points, $p < 0.001$) and function scores (43 points to 69 points, $p < 0.001$). While 40% were completely asymptomatic at the time of most recent follow-up, 47% had persistent anterior knee pain.

Karnezis et al. reported significant improvements with delayed secondary resurfacing of the patella (mean patella score improved from 13.5 (standard deviation [SD] = 5.9) preoperatively to 19.3 (SD = 5.5) at final follow-up, p = 0.01; 95% confidence intervals for the mean difference, 1.6–10.0), although these results were inferior to primary resurfacing.[30] The authors noted that longer delays between primary TKA and secondary resurfacing correlated with worse outcome and concluded that secondary resurfacing should be considered early. Muoneke et al. reported on 20 patients who underwent a revision procedure to resurface only the patella for anterior knee pain and found that 44.4% reported some improvement in pain, with the remainder reporting no change or deterioration.[31] Other authors have had similar results with improvements in mean knee scores but a significant subset of patients remaining unsatisfied after secondary resurfacing.[32,33] Toro-Ibaguen and colleagues in a retrospective study of 46 patients reported there was an improvement of the Knee Society Score scale (from 54 ± 11 to 64 ± 16 points; $p < 0.05$) in patients undergoing secondary patellar resurfacing (SPR).[34] However, in 59% of the cases there was no pain improvement, and 65% of patients were not satisfied. Four patients developed complications (8.7%) and in two cases re-operation was necessary. We did not find any preoperative predictive factor for a favorable outcome after SPR.

Resolution of clinical scenario

- Secondary resurfacing of an unresurfaced patella can result in an improvement in pain and function scores, although a large group of patients may remain unsatisfied due to persistent anterior knee pain.

- Earlier intervention with secondary resurfacing may optimize the outcomes in patients with persistent anterior knee pain following TKA with an unresurfaced patella.

Question 3: When revising a femoral component for aseptic loosening, does retaining a well-fixed patellar component improve outcome compared to revision to compatible patellar and femoral components?

Rationale

Most modern patellar components are symmetrical domes and compatible with the trochlea of most femoral components. We endeavored to identify literature to support the common practice of retaining a well-fixed patellar component regardless of geometric mismatch with the femoral component.

Clinical comment

Revision of the patellar component is associated with several complications, including fracture, avascular necrosis, and aseptic loosening. However, retaining a well-fixed patellar component may not be ideal in the presence of significant wear or a geometric mismatch between the patellar and femoral component. The decision to revise a well-fixed patellar component has significant implications on the outcomes following revision TKA.

Available literature and quality of the evidence

We found one study with level III evidence and five studies with level IV evidence.

Findings

Several studies have shown isolated revision of malrotated femoral or tibial components results in improved outcomes and does not require revision of a well-fixed patellar component unless there are signs of significant wear, damage, or geometric mismatch.[35,36] Barrack et al. retrospectively compared the results of retention versus revision of patellar components in 73 knees with a mean follow-up of 36 months (minimum 24 months).[37] In 34 cases, a well-fixed and well-positioned patellar component with minimal to no surface damage was retained; 12 of these knees had metal-backed components. The remaining 39 cases involved patellar component revision for reasons such as loosening, wear, osteolysis, and malpositioning. Both groups were assessed clinically and radiographically and the authors found no difference in clinical results or patient satisfaction between the two groups. Masri and colleagues retrospectively reviewed 111 patients undergoing a revision TKA.[38] A subgroup of 24 patients undergoing knee revisions already had a well-fixed patellar component present and were left in situ. The authors found no difference in WOMAC, Oxford-12, Short Form 12, and patient satisfaction scores between patients with a patellar component left in situ and those who had the patella removed, leaving only a bony shell. Lonner et al. reviewed a series of 202 revision TKAs that retained a well-positioned and well-fixed all-polyethylene patella.[39] They reported that 10% of patients had anterior knee pain at an average follow-up of 7.3 years and concluded that retaining a well-positioned, stable all-polyethylene patellar component at the time of revision TKA can be successful, provided that the polyethylene has not oxidized. Manufacturing mismatch

is acceptable with most contemporary designs if the patellar component articulates appropriately with the femoral implant. They noted a higher rate of patellar component failure if the component was gamma irradiated in air compared to those sterilized with another method ($p = 0.0008$).

Resolution of clinical scenario

- If the patella is a well-fixed, all-polyethylene component and articulates well with the revision femoral component, it should be left in situ despite manufacturer mismatch.
- If the patella is a metal-backed component and there is good bone stock, it should be revised at the time of revision TKA even if it is well-fixed.

Implant Design Options in the Treatment of Shoulder Osteoarthritis

Chad Myeroff MD[1], Michael Knudsen MD[2], and Michael D. McKee MD FRCS(C)[3]

[1]University of Minnesota Department of Orthopaedic Surgery, Regions Hospital and TRIA Orthopedic Center, St. Paul, MN, USA

[2]Department of Orthopaedic Surgery, University of Minnesota, Minneapolis, MN, USA

[3]Department of Orthopaedic Surgery, University of Arizona College of Medicine, Phoenix, AZ, USA

Clinical scenario

- A 70-year-old active, healthy male with left shoulder pain and stiffness. He has been diagnosed with glenohumeral osteoarthritis.
- He is no longer responsive to injection therapy and wishes to discuss operative options.

Top three questions

1. In this patient with end-stage shoulder osteoarthritis, what is the ideal surgical treatment?
2. If an anatomic total shoulder arthroplasty (TSA) is elected, what is the ideal glenoid component design?
3. If an anatomic TSA is chosen, what is the ideal humeral component design?

Question 1: In this patient with end-stage shoulder osteoarthritis, what is the ideal surgical treatment?

Rationale

Several options are currently available for shoulder reconstruction, each with unique indications, benefits, risks, and functional outcomes that must be considered.

Clinical comment

Personal training biases, local trends, and isolated reviews of the literature can be persuasive in clinical decision-making. When deciding on the ideal reconstructive option, it is important to have an unbiased and complete view of the literature.

Available literature and quality of the evidence

This question is best answered with a systematic review of level III and IV studies.

Findings

This is a 70-year-old active individual with end-stage osteoarthritis and a Walch type A1 glenoid. Walch type A glenoids are centered, with or without central deformity. Walch type B glenoids are posteriorly eroded with or without deformity, and Walch type C glenoids are considered dysplastic.[1] The later varieties are more likely to undergo progressive deformity, subluxation, and pose biomechanical challenges that are potentially time sensitive.[2,3] Since this glenoid is concentrically worn, there is less concern for progression and continued injection treatment can be considered (Figure 60.1 and 60.2).

If conservative treatment fails, hemiarthroplasty or anatomic TSA are common reconstructive options. Both of these options require an intact rotator cuff for ideal function, to avoid anterosuperior escape and early glenoid failure from eccentric loading.[4] Fortunately, full thickness rotator cuff tears are only present in 7.6% of patients presenting with primary osteoarthritis, and partial thickness tears have not been shown to influence outcome.[5] This patient has a centered head without radiographic signs of cuff tear arthropathy,[6] but advanced three-dimensional imaging may be obtained when there is clinical concern. A full thickness irreparable supraspinatus tear, or any infraspinatus or subscapularis tear, would be a contraindication to primary TSA.

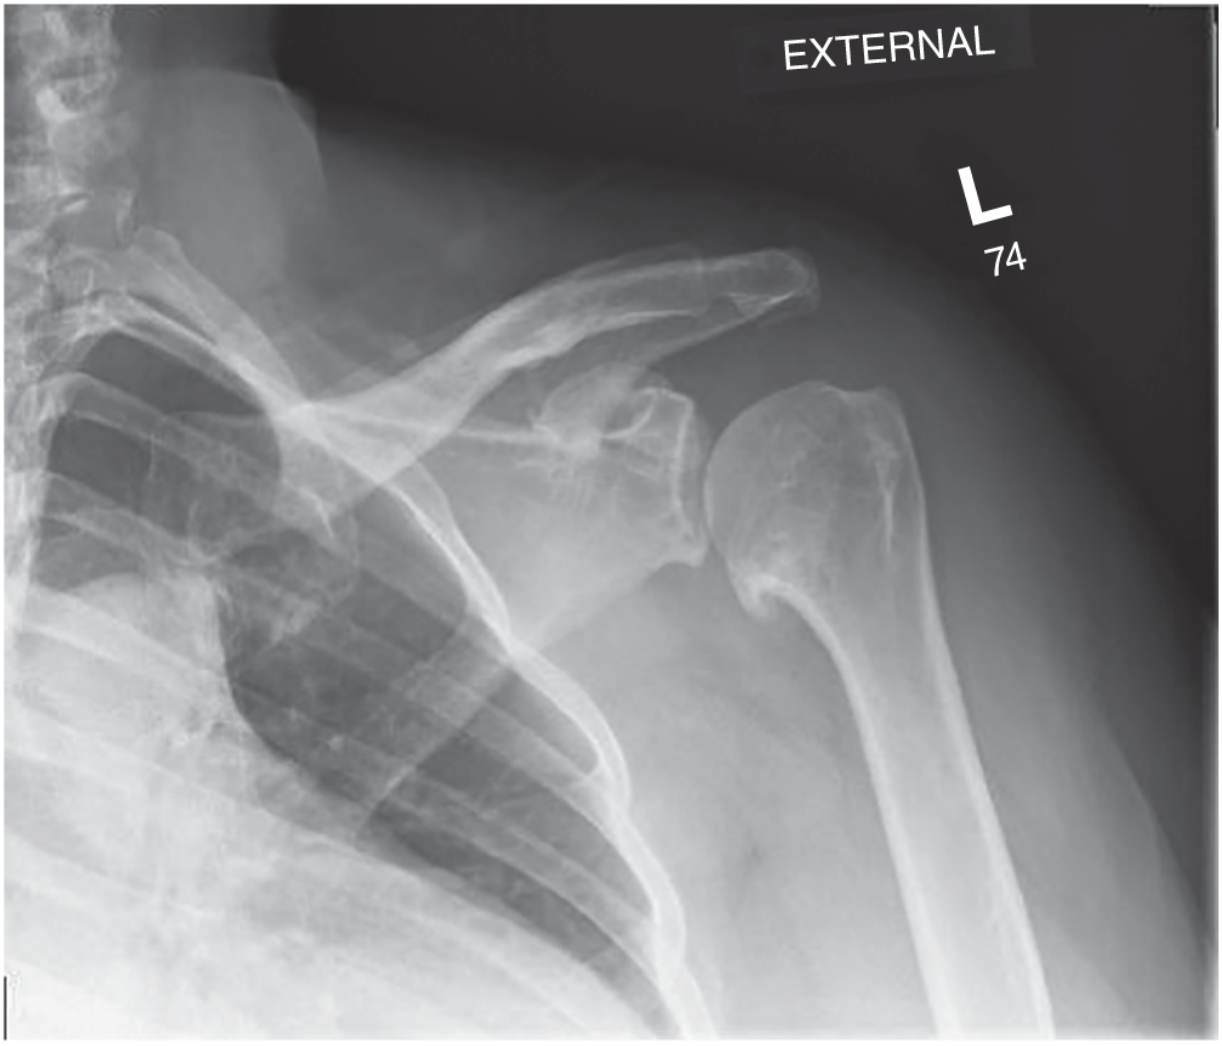

Figure 60.1 True AP radiograph of the left shoulder shows joint space collapse, subchondral sclerosis, inferior humeral osteophytes and medialization of the humerus without signs of rotator cuff insufficiency. Source: Chad Myeroff, Michael Knudsen, Michael D. McKee.

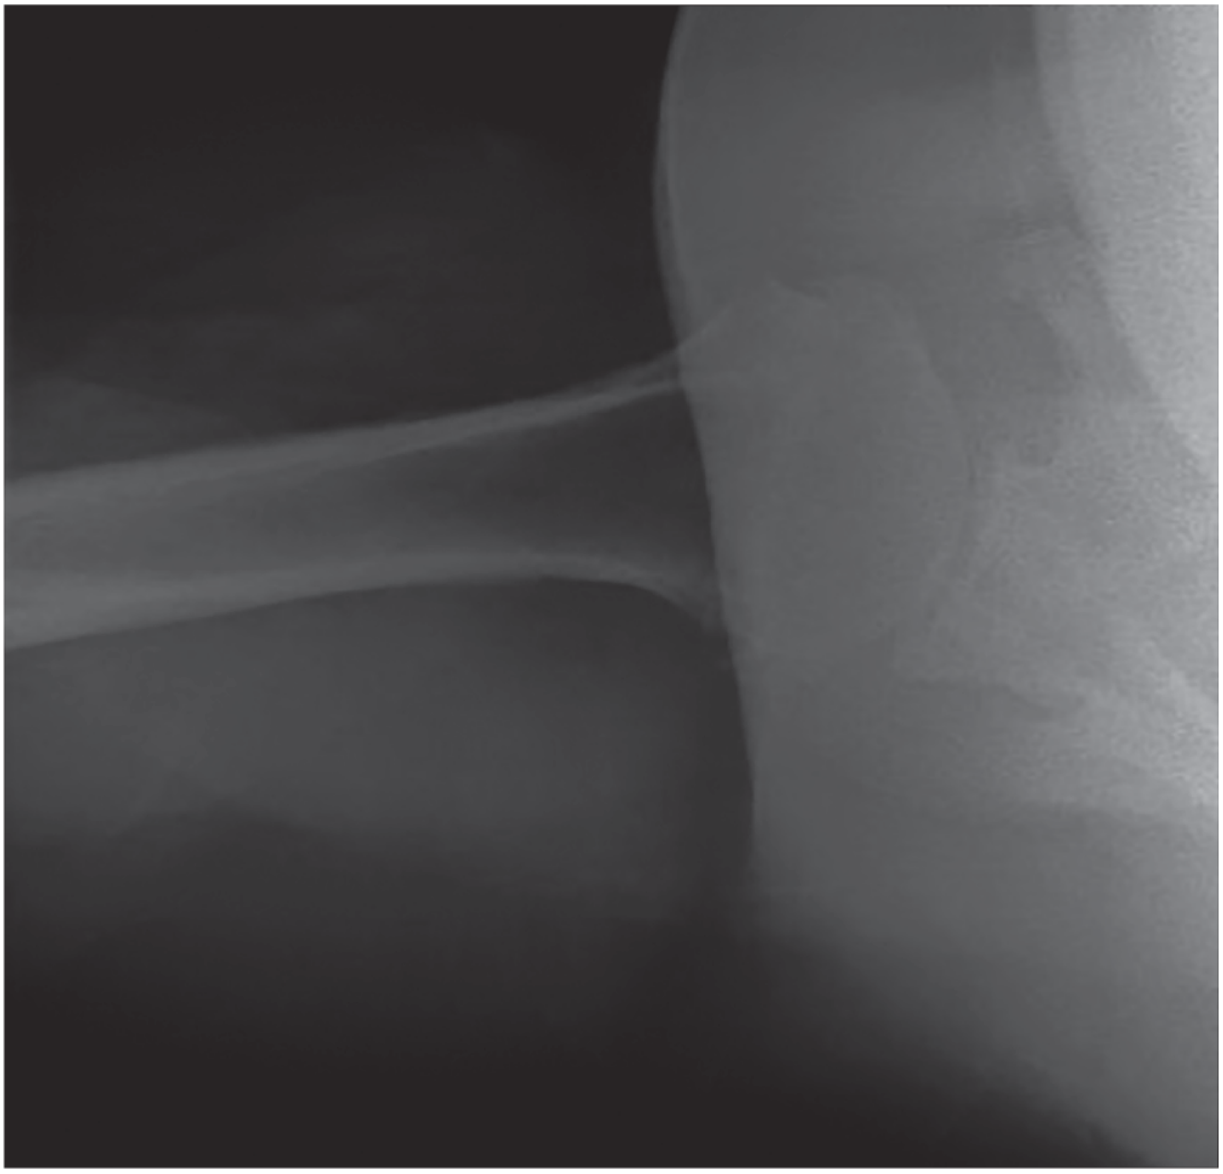

Figure 60.2 Axillary radiograph of the left shoulder showing concentric glenohumeral joint space loss without subluxation of the humeral head or any eccentric ware. Source: Chad Myeroff, Michael Knudsen, Michael D. McKee.

Hemiarthroplasty offers the benefits of preserving glenoid bone stock, less operative time, and less blood loss, and eliminates the risk of glenoid implant failure when compared with TSA. However, hemiarthroplasty carries the inherent risk of progressive glenoid arthritis and pain.

While the results have been variable, some authors report success, especially in young active laborers with intractable pain, especially those with a high degree of posterior wear and subluxation where glenoid components would have a higher risk of failure.[7–9] In TSA, resurfacing of the glenoid theoretically decreases long-term pain and restores physiological tension on the rotator cuff, with the traded risk of glenoid implant failure necessitating later revision surgery.

A randomized controlled trial (RCT) of 42 arthritic shoulders comparing hemiarthroplasty to TSA showed a trend toward improved disease specific quality of life for TSA as measured by the previously validated Western Ontario Osteoarthritis of the Shoulder (WOOS) score,[10] (WOOS 90.6 for TSA vs 81.5 for hemiarthroplasty; $p = 0.18$) but was underpowered to show a difference.[11] Radnay et al. published a systematic review of 23 studies (1952 patients) with an average level of evidence of 3.72 with a mean 43.4 months' follow-up.[12] TSA provided significantly greater pain relief (86 vs 78; $p < 0.0001$), forward elevation ($p < 0.0001$), external rotation ($p = 0.0002$), patient satisfaction (97% vs 80%; $p < 0.0001$), and lower revision rate (10.7% hemiarthroplasty vs 1.7% for TSA with all polyethylene cemented glenoids; $p < 0.025$). Of the included hemiarthroplasties, 10.2% required revisions, 79.4% of which (8.1% of all hemiarthroplasties) were converted to TSA for pain.[12] Economically, TSA is more cost-effective. Mather et al. created a Markov decision model using available literature to compare cost utility and reported that a TSA is $1970 cheaper per patient than hemiarthroplasty and provides more quality-adjusted life years (QALYs).[13] Hemiarthroplasty would not be preferred unless the TSA annual revision rate reached 8.52% or $50 000 in initial cost.[13] In 2011, the American Academy of Orthopaedic Surgeons (AAOS) concluded there was

moderate evidence to recommend TSA over hemiarthroplasty in the surgical management of glenohumeral osteoarthritis.

Resolution of clinical scenario

- TSA is preferred over hemiarthroplasty for advanced glenohumeral osteoarthritis, offering improved outcomes for motion, pain relief, patient satisfaction, lower revision rate, and lower overall cost.

Question 2: If an anatomic total shoulder arthroplasty (TSA) is elected, what is the ideal glenoid component design?

Rationale

Metal-backed (MB) glenoid components were introduced to theoretically offer a better mechanical interface, allow surgical correction of complex glenoid deformity, and allow modularity between TSA and reverse total shoulder arthroplasty (RTSA). All-polyethylene (AP) glenoids have two traditional fixation options: in-line pegged components are relatively bone preserving, while keeled implants may be technically easier in difficult exposures and lower the risk of vault perforation in smaller glenoids.

Clinical comment

The glenoid component is the most technically demanding aspect of TSA and is the most likely reason for mechanical failure postoperatively, necessitating meticulous technique and thoughtful implant choice.

Available literature and quality of the evidence

The vast majority of technical principles have come from level III and IV studies. There are several RCTs comparing glenoid resurfacing options, supported prevalently with level III and IV retrospective studies and biomechanical research.

Findings

Glenoid reconstruction remains the weak link in TSA with a 0.8% risk of glenoid revision per year and is the most common underlying reason for humeral sided revision as well.[14–16] It has been shown that restoring close to normal version (to <10–15° retroversion) lowers radiographic osteolysis and cement mantle shear forces.[17,18] Conservative reaming should maintain the subchondral plate to minimize failure.[19] It is recommended that glenoid surface and humeral head have a 4° radius of curvature mismatch to avoid edge loading and best restore anatomic translation and motion.[20]

Although anatomic glenoid reconstruction has an overall 95% 10-year survivorship on the aggregate, there is variability in implants. Clinical results for MB glenoid components have shown increased failure and revision rates. In Radnay et al.'s systematic review of 1952 patients, they found a higher risk for revision for MB implants (6.8% MB vs 1.7% AP).[12] Cil et al. showed higher humeral sided 10-year revision-free survival with AP glenoids in a systematic review of 1584 implants (96.5% vs 86.8%).[15] Fox et al. reviewed 1542 TSAs and found that revision-free survival was superior for AP glenoids ($p < 0.01$).[21] Clitherow et al. performed a registry study of 1056 AP glenoid implants versus 540 MB glenoid implants placed in

New Zealand. They found a 4.4-fold higher risk for revision in MB (1.92% vs 0.44%; p <0.001).[22]

Boileau et al. published an RCT on 39 patients comparing AP pegged glenoid design to MB glenoid design with 36 months' follow-op and found higher radiolucent lines for AP component (85% vs 25%; p <0.01);[23] however, the majority of AP radiolucencies were nonprogressive and there was no correlation with functional outcome (p = 0.3). Radiolucent lines are rare with MB implants but progressive and sinister when present (clinical loosening/failure: 20% MB vs 0% AP; p <0.001). Additionally, these authors found that MB glenoid implants correlated significantly with decreased functional results and increased pain (p <0.05).[23] The same authors published long-term outcomes of 165 MB glenoids and reported only 46% revision free survival at 12 years.[24] They have subsequently returned to an AP component in their clinical practice. The early failure of MB components initiated interest in hybrid options. Bony ingrowth with hybrid monoblock glenoids was nearly universal, but metal debris and mechanical failure plagued early designs.[25,26] Newer designs offered early peripheral cement fixation followed by central peg ingrowth with more optimistic early- to medium-term clinical results. Nelson et al. reported five-year outcomes on a hybrid option with a central porous titanium peg and peripheral cemented polyethylene pegs showing 64% (29/45) asymptomatic radiographic osteolysis and 2.2% (1/45) mechanical failure at the metal peg-polyethylene junction.[27] Most recently, Friedman et al. reported a large cohort study comparing 316 patients with hybrid cage design to 316 historical controls with a traditional cemented polyethylene pegged component with an average of 50 (24–79) months' follow-up.[28] They found significantly lower glenoid radiolucent lines (9% vs 37.5%; p <0.0001), humeral radiolucent lines (3% vs 9.1%; p = 0.0088), and revision rate (2.5% vs 6.9%;

p = 0.0088) in the hybrid group.[28] While the frontier is promising, cemented AP components remain the gold standard of clinical success.

The surgeon has a choice between pegged and keeled AP components. Two radiostereometric clinical studies to evaluate glenoid component motion reported conflicting results. Rahme et al. found no difference in micromotion,[29] while Nuttall et al. reported increased migration in keeled components.[30] Edwards et al. published results of an RCT of 53 patients randomized to pegged or keeled AP cemented glenoid implants.[31] There was no statistical difference in radiolucent lines immediately (0% peg vs 15% keel; p = 0.128) but at 26 months postoperatively, keeled components had higher radiographic lucency (46% vs 15%; p = 0.003).[31] Two systematic reviews were published in 2013 on the topic. Papadonikolakis et al. found no difference in clinical outcomes.[14] Vavken et al. looked at eight studies (1460 patients) and found a lower pooled risk of revision for pegged implants (0.27; 95% confidence interval [CI]: 0.08–0.28), but they noted the benefit is small and may only be clinically relevant in high volume centers.[32] The AAOS Clinical Practice Guidelines reported weak evidence and support a surgeon's preference between pegged and keeled AP glenoid implants. Radiographic and clinical studies report conflicting conclusion, but overall there was a slight preference toward pegged implants.

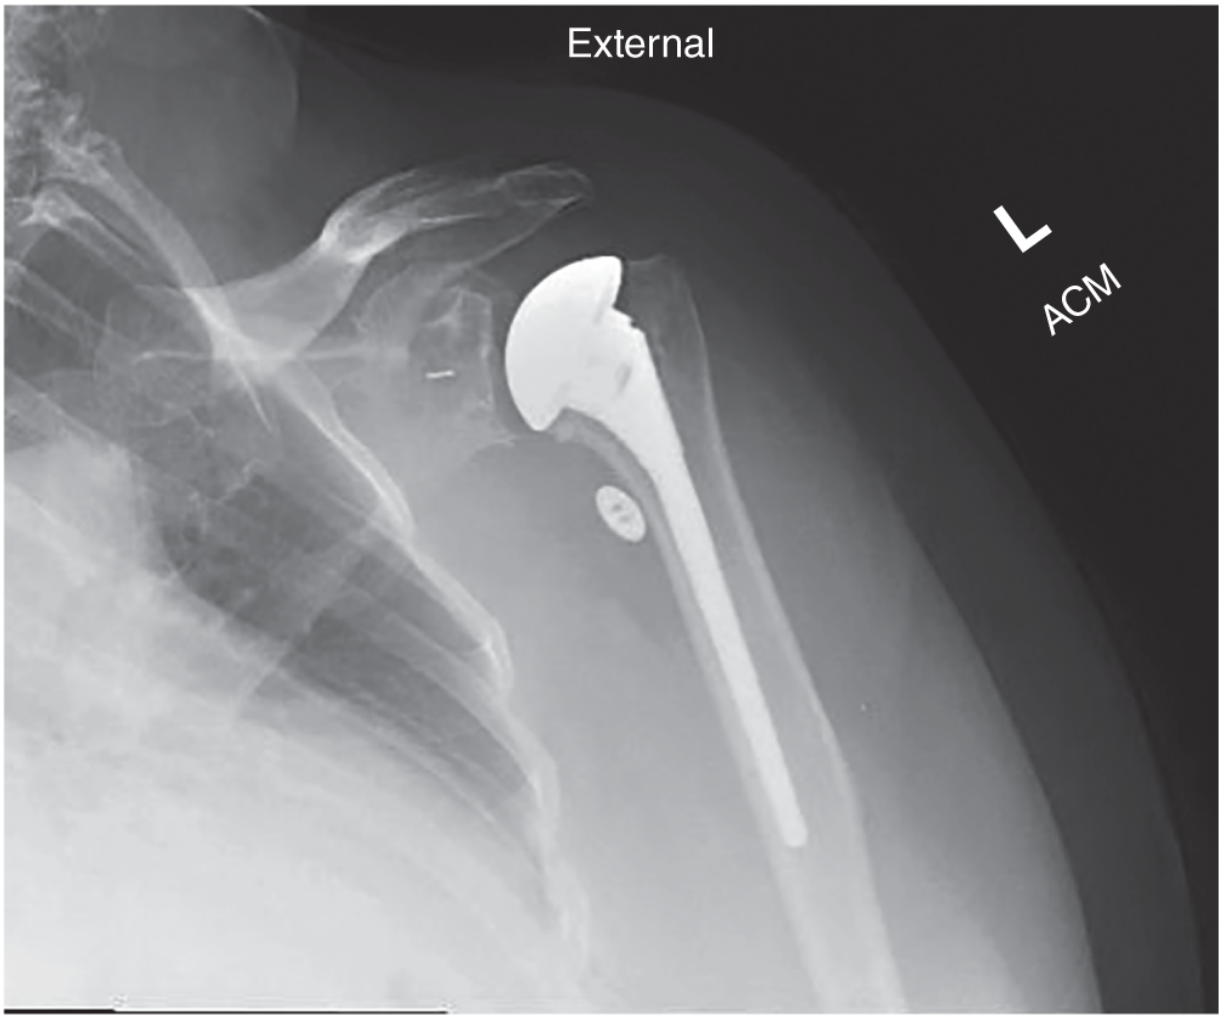

Figure 60.3 Postoperative true AP radiograph of the left shoulder showing anatomic TSA with a cemented, pegged, all-polyethylene glenoid and a press-fit humeral stem. Source: Chad Myeroff, Michael Knudsen, Michael D. McKee.

Resolution of clinical scenario

- Cemented AP glenoids are the gold standard for clinical success in TSA (Figure 60.3).
- The choice between pegged and keeled AP implants are at the surgeon's discretion.

- Pegged implants have lower rates of radiographic lucency and conflicting evidence leaning toward a slightly lower clinical failure rate.

Question 3: If an anatomic TSA is chosen, what is the ideal humeral component design?

Rationale

Aseptic loosening of the humeral component in TSA is rare. Despite this success, the industry continues to develop a variety of different designs, including short-stem and stemless components. Regardless of stem size, proper humeral component size and position are paramount for a balanced, functional, and durable shoulder arthroplasty.

Clinical comment

The treating shoulder surgeon should understand the difference between theoretical advantages and technical imperatives for a well-fixed, well-positioned humeral component.

Available literature and level of the evidence

Most of the data on humeral implants in TSA come from level III and IV studies. There is one RCT comparing cemented and uncemented humeral stems in TSA and one small RCT comparing stemmed and stemless humeral fixation.

Findings

The humeral components of positioning and sizing are critically linked to success.[33] The goal is to recreate the articular anatomy, replicating the anatomic center of

rotation, height, retroversion, and neck shaft angle to minimize impingement and optimize motion with a stable implant that allows for long-term stability.[34] Third-generation stemmed humeral components provide modularity in head size, thickness, and eccentricity to recreate the native articular anatomy. Preoperative templating and intraoperative findings can be used.[35] However, implant design features cannot make up for technical errors in this regard.

Humeral component loosening is rarely a clinical problem. Cil reviewed humeral component survivorship in 1584 arthroplasties and showed an 82.8% 20-year survival.[15] Of the humeral revisions, more than half were due to underlying glenoid failure. Associations with failure were age <65 (1.5×), male gender (2.3×), post-traumatic arthritis (2×), and uncemented (2.7×).[15] Although cementation may marginally decrease loosening,[36] it profoundly complicates revision surgeries[37] and continued trends have led to an increased enthusiasm for uncemented designs, considered by most experts the current gold standard in primary arthroplasty.

Interestingly, only a single double-blind RCT has closely examined the question of cemented versus uncemented humeral stem fixation in TSA. This multicenter trial compared 80 cemented and 81 uncemented TSAs, and found that cemented stem fixation was associated with significantly better WOOS scores at 12, 18, and 24 months postoperatively (cemented 87.9 vs uncemented 79.3 at final follow-up; $p = 0.03$). However, there were no statistically significant differences in Short Form 12 scores, ASES scores, MACTAR scores, motion, complication rates, loosening rates, or revision rates.[38] Additionally, there were no differences in outcome scores in women. It remains unknown if a difference of 8.6 in WOOS score is

significant enough to warrant advocacy for cementing all stems in TSA, as the minimal clinically important difference (MCID) has not been studied for this patient reported outcome score. In 2014, a retrospective comparative series of 395 anatomic TSAs (103 uncemented metaphyseal stems vs 292 cemented stems) demonstrated similar clinical results at a mean follow-up of eight years.[39]

Traditional stems have an approximate 1% complication rate.[40,41] As such, the majority of these stems are well fixed, which can pose significant challenges for revision surgery. Fourth-generation stems include short stems and stemless designs with metaphyseal fixation termed *canal sparing* or *stemless*. The driving force for these designs is the goal of bone preservation, avoidance of stress shielding and diaphyseal stress risers, anatomic reconstruction, shorter operative time, and less morbid revision procedures.[42]

Convertible platform modular stems offer the attractive advantage of allowing humeral stem retention in revision surgery, as they allow for exchange of a TSA/hemiarthroplasty humeral head implant for a RTSA implant, and early reports from the literature are promising. Crosby et al. published results on a multicenter retrospective study of 102 consecutive shoulders that underwent revision of an anatomic shoulder arthroplasty to a reverse shoulder arthroplasty.[43] During that time period, 73 of the shoulders required humeral stem revision and 29 convertible platform stems allowed for stem retention. Stem retention allowed for shorter operative times (130 vs 195 minutes; $p < 0.001$), lower estimated blood loss (292 vs 492 mL; $p = 0.034$), fewer intraoperative complications (0% vs 15%; $p = 0.027$), better postoperative external rotation (26° vs 11°; $p = 0.006$), and better active forward elevation (112° vs 96°; $p = 0.055$). The authors concluded that well-

fixed and positioned convertible platform humeral stems offer numerous advantages over traditional stems if and when the need for revision arises.[43] Previous studies have found similar encouraging medium-term clinical and radiological results in favor of convertible platform technology.[44,45]

Stemless anatomic TSA designs first became available in Europe in 2004. Most recently, stemless designs have gained significant excitement and popularity in the United States. Hawi et al. published their findings of a systematic review that identified 11 studies published between 2010 and 2016 on stemless, or *canal-sparing*, anatomic shoulder arthroplasty implants. They identified 929 cases with a mean follow-up of 26 months.[46] The rate of humeral complications ranged between 0 and 7.9%. Only one case of radiological loosening was identified in this review. Most recently in 2017, Uschok et al. reported on their prospective randomized trial of 40 patients undergoing TSA.[47] They randomized 20 patients to receive a standard stemmed humeral implant and 20 patients to receive a stemless humeral implant. There were no significant differences in Constant Score, active range of motion, or humeral loosening. Excitement for stemless or canal sparring technology in TSA should be tempered as the clinical benefits of stemless fixation is debated, and long-term studies are not yet available.

Resolution of clinical scenario

- Aseptic loosening of the stemmed humeral components in TSA is rare.
- Limited evidence exists to provide strong recommendations regarding humeral stem implant choices; however, revision of well-fixed long stems and cemented stems is well documented to have significant

complication rates and difficulty at the time of revision procedures. Early results of convertible platform stems are promising.

- Innovations such as short-stemmed and stemless designs in TSA are still under investigation, and medium-long term data are lacking.

Summary of answers

- TSA is preferred over hemiarthroplasty for surgical treatment of glenohumeral osteoarthritis.
- Cemented, pegged, AP glenoid components are the gold standard for clinical success in TSA.
- Aseptic loosening of stemmed humeral components is rare.

Cement in Shoulder Arthroplasty

Midhat Patel MD[1] and Niloofar Dehghan MD FRCSC[1,2]
[1]Department of Orthopaedic Surgery, University of Arizona College of Medicine, Phoenix, AZ, USA
[2]The CORE Institute, Phoenix, AZ, USA

Clinical scenario

- A 55-year-old right-hand-dominant man, semiretired accountant with progressively increasing left shoulder pain and decreasing range of motion.
- He complains of pain with use of the affected extremity, difficulty golfing and playing with his grandchildren, and sleeping on his left side due to shoulder pain.
- On physical exam, active and passive range of motion is forward elevation to 100°, abduction to 60°, and external rotation to neutral, with notable grinding and catching during range of motion. He has good strength of his rotator cuff. He is neurovascularly intact.
- Radiographs of shoulder show end-stage osteoarthritis, with no proximal migration of the humeral head.

Top three questions

1. In patients with advanced shoulder osteoarthritis, does cemented fixation of the humeral component result in improved functional outcomes compared to uncemented fixation?

2. In patients undergoing anatomic total shoulder arthroplasty (TSA), is there a difference in implant survival with a cemented versus uncemented technique?
3. In patients undergoing anatomic TSA with a cemented glenoid and/or humeral component, is there a difference in infection rates with the use of antibiotic-impregnated cement compared to plain cement?

Question 1: In patients with advanced shoulder osteoarthritis, does cemented fixation of the humeral component result in improved functional outcomes compared to uncemented fixation?

Rationale

Both cemented and uncemented humeral stems can be utilized in TSA. Cemented fixation may provide better stability in osteoporotic bone; however, bone ingrowth into the proximal porous coating of an uncemented humeral stem may provide improved survivorship and functional outcome.[1] An uncemented implant has a shorted operative time, and potentially simpler revision surgery compared to a cemented stem (in case of revision surgery for infection or loosening).[2,3] These theoretical benefits have not been empirically validated and it is important to consider risks/benefits of TSA with a cemented humeral component as compared to an uncemented stem.

Clinical comment

Current opinion suggests that most surgeons prefer to use an uncemented humeral component in North America, and implant manufacturers have therefore developed and marketed uncemented implants over recent years.[4] However, there is limited evidence comparing functional outcomes of cemented versus uncemented humeral components in TSA.

Available literature and quality of the evidence

- Level I: 1 prospective randomized study.
- Level III: 2 retrospective cohort studies.

Findings

In a prospective randomized study, Litchfield et al. compared cemented (n = 80 patients) with uncemented (n = 81) humeral components (Bigliani/Flatow Total Shoulder Solution, Zimmer, Warsaw, IN, USA) for TSA. They showed a significant difference in Western Ontario Osteoarthritis of the Shoulder (WOOS) score at postoperative intervals of 12, 18, and 24 months ($p = 0.009$, 0.001, 0.028, respectively) in favor of the cemented humeral component. The authors reported no difference in motion or strength improvement between the two groups, compared to preoperative values. Operative time was significantly less for the uncemented group: 1.7 hours versus 2.3 hours ($p = 0.03$). The authors concluded that a cemented humeral component provides better quality of life than an uncemented humeral component. It is important to note that in this study there was a significantly higher number of men in the cemented group compared to the uncemented group, and the differences between the two groups may be due to improvement in male participants. Additionally, the prosthesis used in this study was not specifically designed for bony ingrowth, which could significantly alter outcomes

for the uncemented group.[5] Therefore, it may be difficult to extrapolate the results of this study to other implants.

Though there are no other studies directly comparing outcomes in anatomic TSA between cemented and uncemented humeral components, there are two retrospective cohort studies comparing outcomes with cemented and uncemented humeral stems in reverse total shoulder arthroplasty (rTSA). In a review of 100 operations (51 with cemented and 32 with uncemented humeral stems) performed using the Exactech Equinoxe® System, King et al. showed significant improvement in the 12-item Simple Shoulder Test, 12-item Short Form, Shoulder Pain and Disability Index 130 (SPADI-130), American Society of Shoulder and Elbow Surgeons (ASES) score, and normalized Constant scores for both groups, with no significant differences between the two at two-year follow-up. Additionally, there was no significant difference in complication rate between the two groups.[1]

In a second retrospective cohort study comparing outcomes between cemented and uncemented humeral components in rTSA, Wiater et al. compared 64 cases of cementless rTSA with 37 cases of cemented rTSA. Outcome measures included Constant–Murley scores, American Shoulder and Elbow Surgeons scores, Visual Analog Scale (VAS) pain scores, range of motion, patient satisfaction, and radiographic evidence of complication. Findings included significant improvements in all functional scores, forward flexion, and internal rotation with no significant difference between these values in cemented versus uncemented rTSA. Similarly, there were no differences in radiographic evaluation or complication rate between the two cohorts.[6]

Resolution of clinical scenario

- At the current time, there is only one study comparing outcomes with cemented versus uncemented humeral stem fixation in anatomic TSA. While this is a level I study, a limitation of this study is that results can be applied to the use of the Zimmer BF implant, and not necessarily generalizable to all uncemented humeral components. Additionally, while the differences in functional outcome scores were significantly different, improvements in strength and range of motion were similar when compared to baseline measurements. Finally, this study only reports on the short-term outcomes, and the results may not be extrapolated to long-term follow-up.
- Two level III retrospective cohort studies examine differences between cemented and uncemented humeral stem fixation in rTSA. Both studies suggest that there is no significant difference in functional outcomes, radiographic outcomes, or complications between the two cohorts. It is important to note that the applicability of these studies to anatomic TSA is limited.
- At this time, there is not indisputable evidence demonstrating improved functional outcomes with cemented or uncemented humeral stem fixation in anatomic TSA. The authors recommend discussing factors including ease of revision, implant survivorship, and complications with the patient. Patient factors such as age, expectations, functional level, and proximal humeral bone quality must also be considered. The final decision should be individualized on the basis of these parameters.

Question 2: In patients undergoing anatomic total shoulder arthroplasty (TSA), is there a difference in implant survival with a cemented versus uncemented technique?

Rationale

In the setting of a TSA, loosening of the humeral component increases the need for revision surgery. The use of cement in joint arthroplasty has the potential to decrease stem loosening, especially in patients with poor bone health, or large humeral canals with implant size mismatch.[7] There is concern that press-fitted, uncemented implants will have higher rates of loosening.[8] There is no consensus evidence-based opinion to justify the use of cemented or uncemented implants (either press-fit or ingrowth) for humeral component fixation. However, each option has advantages and disadvantages.

Clinical comment

Component loosening is a significant complication, resulting in significant morbidity and increased risk of secondary surgery.

Available literature and quality of the evidence

- Level I: 1 prospective randomized study.
- Level III: 3 retrospective cohort studies.

Findings

In a small prospective randomized study of 26 patients with rheumatoid arthritis undergoing TSA with a two-year

follow-up, Rahme et al. reported on loosening and micromotion in cemented and uncemented groups. There was no significant difference between the two groups after radiographic analysis with respect to rotation or translation around the x-, y-, or z-axis. The authors conclude that for patients with rheumatoid arthritis a well-fitted press-fit component is equivalent to a cemented component. However, it should be noted that the size of this study sample was likely too small to detect significant differences between the two groups.[9]

A review of 4636 patients undergoing shoulder arthroplasty was conducted, including 1167 patients receiving a cemented humeral component and 3469 receiving an uncemented humeral component. Propensity score-match analysis was performed to match for nine different covariates, and 551 pairs of well-matched patients were identified. At 20 years postoperatively, implant survival without humeral loosening was significantly higher in the cemented group: 98.7% (95% confidence interval [CI]: 97.5–100) versus 91.0% (95% CI: 86.3–95.9; p <0.01). The authors concluded that both implants have excellent long-term survivorship and that while cemented components have lower rates of loosening this should be weighed against the risks of proximal humeral bone loss at the time of revision of a cemented component.[10]

In a review of 2588 shoulder arthroplasties, Singh et al. reported no significant difference in need for all-cause revision between cemented and uncemented fixation (hazard ratio [HR] = 0.62; 95% CI: 0.38–1.02; p = 0.06). While initial univariate analysis suggested decreased revision rates for cemented implants, this difference was not present after multivariate analysis was done to adjust for confounding variables such as gender, age, method of fixation, and diagnosis. In a multivariable analysis, only male gender (HR = 1.72, 95% CI: 1.28–2.31; p <0.001) and

diagnosis of rotator cuff disease (HR = 3.99; 95% CI: 1.91–8.36; p <0.001) and tumor/avascular necrosis (HR = 2.65; 95% CI: 1.40–5.02; p = 0.003) were associated with significantly higher risk of revision surgery.[11]

In a review of 1584 shoulder arthroplasties, Cil et al. reported no significant difference in survivorship (HR = 0.79; 95% CI: 0.22–2.83; p = 0.72) between uncemented and cemented Neer II implants (3M, St. Paul, MN, USA; Kirschner Medical Corporation, Fairlawn, NJ; Biomet, Warsaw, IN, USA). For the Cofield 1 humeral component (Smith & Nephew, Memphis, TN, USA), survivorship was significantly increased for cement fixation relative to fixation without cement (HR = 0.33; 95% CI: 0.13–0.81; p = 0.02). Overall, there was an increased survivorship across all implants for cement fixation compared to a component without cement fixation (HR = 0.31; 95% CI: 0.18–0.76; p = 0.007).[12]

Resolution of clinical scenario

- There is currently insufficient evidence to recommend the routine use of a single method of fixation. The choice between the use of a cemented or uncemented humeral component should be individualized based on patient and diagnostic factors.[9]
- Factors to consider include the patient's age, sex, diagnosis, expectations, functional level, and proximal humeral bone quality.

Question 3: In patients undergoing anatomic TSA with a cemented glenoid and/or humeral component, is there a difference in infection rates with the use of antibiotic-impregnated cement compared to plain cement?

Rationale

The use of antibiotics in cement has the potential to decrease the risk of periprosthetic infections. However, the addition of antibiotics to cement can potentially affect the mechanical properties of the cement and negatively impact fixation strength. In addition, the routine use of antibiotics in this setting may increase the risk of developing antibiotic-resistant bacteria.

Clinical comment

Periprosthetic infection in the setting of a TSA is a devastating complication, with significant morbidity and unsatisfactory patient outcomes after challenging revision procedures.[13-15] It is important to consider interventions that can reduce the incidence of infection and understand their potential risks and benefits.

Available literature and quality of the evidence

- Level III: 1 retrospective cohort study.

Findings

A retrospective review of 501 patients treated with rTSA and mean follow-up of 37 months was performed. The study

demonstrated that in patients receiving cement without antibiotics, rate of periprosthetic infection was 8 of 265 (3%), while none of the 236 patients treated with antibiotic-impregnated cement had a perioperative joint infection ($p < 0.001$). There was no significant difference between the two groups with regards to demographic factors, and the use of antibiotic cement was based upon surgeon preference, rather than patient characteristics. Of the patients with infection, one had a superficial infection while eight had a deep infection diagnosed by positive joint aspiration culture. These infections required additional treatments including suppressive antibiotics, irrigation and debridement, resection arthroplasty, and two-stage exchange arthroplasty.[16]

Resolution of clinical scenario

- To the best of our knowledge, there are no studies that evaluate the use of antibiotic-impregnated cement in anatomic TSA.
- One study reported on the use of antibiotic-impregnated cement in the setting of rTSA humeral stems, which can be extrapolated to our case scenario. This study reported a reduced rate of perioperative deep infection with use of antibiotic-impregnated cement, at short and medium-term follow-up.
- While long-term studies are lacking, there is some evidence that the use of antibiotic impregnated cement may lower the risk of infection when used for humeral stem fixation. Further research in this area is warranted.

Summary of answers

- When comparing cemented and uncemented fixation in TSA, there is limited evidence regarding which method leads to better functional outcomes. While there is one high-quality randomized controlled trial reporting improved functional outcomes with cemented fixation of a specific implant (Bigliani/Flatow Total Shoulder Solution, Zimmer), this may not be applicable to other uncemented implants. We recommend tailoring one's method based on individual patient factors (age, expectations, functional level, and proximal humeral bone quality).
- A number of large retrospective studies have shown conflicting evidence as to whether there is a difference in implant survival with the use of cemented or uncemented humeral implants. Therefore, there is no consensus on whether the use of a cemented versus an uncemented technique affects longevity of the implant.
- There is a single retrospective level III case-control study demonstrating reduced rates of infection in rTSA with antibiotic-impregnated cement, which may be extrapolated to our case scenario. While long-term studies are lacking, there is some evidence that the use of antibiotic-impregnated cement may lower the risk of infection when used for humeral stem fixation. Regarding this question, at the 2018 International Consensus Meeting on Musculoskeletal Infection, the authors concluded that there is insufficient evidence to determine whether antibiotic-impregnated cement should be used during primary or revision shoulder arthroplasty.

Management of Glenoid Bone Loss

Diego Soza MD[1], Montserrat García-Portabella MD[2], Lledó Batalla MD[2] and Josep Massons MD PhD[3]
[1]Orthopaedic Surgery and Traumatology Department, Vall d'Hebron Hospital, Barcelona, Spain
[2]Clínica Corachan, Barcelona, Catalonia, Spain
[3]Vall d'Hebron University Hospital, Barcelona, Catalonia, Spain

Clinical scenario

- A 50-year-old patient presents with chronic shoulder pain; severe osteoarthrosis is evident on plain radiographs.
- Pain and limited range of motion interfere with activities of daily living.
- The patient enquires about arthroplasty options.

Top three questions

1. In patients with glenoid bone loss, does computed tomography (CT), compared to other imaging modalities, perform better diagnostically?
2. In patients with glenohumeral bone loss, does reverse total shoulder arthroplasty (rTSA), compared to other treatment options, result in better outcomes?
3. In patients undergoing rTSA, do any bone graft options, compared to others, result in the best outcomes?

Question 1: In patients with glenoid bone loss, does computed tomography (CT), compared to other imaging modalities, perform better diagnostically?

Rationale

Shoulder arthroplasty is a widely used procedure. In the United States, the frequency of both primaries and revisions are continually increasing.[1,2] As with most orthopedic interventions, preoperative planning is essential to achieving favorable results in shoulder arthroplasty.[3]

Clinical comment

In arthroplasty, restoration of correct alignment is the primary objective. When correction of the glenoid version is not achieved, the risk of posterior humeral head displacement increases, causing asymmetric wear of the polyethylene (PE)[4] and consequent risk of prosthetic loosening.[5–10]

Abnormal glenoid morphologies have been well described. In most cases, glenoid bone loss is multiplanar, requiring correction in more than one plane. However, to simplify surgical pre-planning, it is useful to classify these morphologies by the characteristics of the predominant glenoid loss. Four basic patient profiles, with four corresponding deficit patterns, have been described.[11] The first of these profiles is the osteoarthritic patient with a horizontal defect, as described and classified by Walch et al.[12] The second is the patient with inflammatory arthritis, with a central defect and secondary joint-line medialization, as described by Lévigne and Franceschi.[13] The third is the

patient with cuff-tear arthropathy (CTA) with a vertical-plane defect, as described and classified by Lévigne et al.[14] The fourth profile is the patient who requires revision surgery, with a combined and irregular defect pattern, as described and classified by Williams and Iannotti.[15]

In cases of glenoid bone loss with secondary retroversion or inclination, it can be difficult to achieve correct orientation, increasing the risk of premature loosening.[16] For this reason, careful evaluation of bone stock, glenoid version, and inclination is imperative for achieving proper glenoid component implantation.

Available literature and quality of evidence

Literature addressing investigations into shoulder arthroplasty preoperative planning is widely varied, offering only level III–V evidence. Most papers describe case series or cohort studies. No randomized trials have been reported.

Findings

Plain radiography

Despite the value of the latest imaging technologies, plain x-ray images remain necessary for preoperative planning.[17]

There are several useful projections:

- *Anteroposterior view:* useful in assessing bone quality, osteophytes, and the humeral canal.
- *Axillary view:* useful for studying posterior erosions and subluxations. This view, however, can lead to overestimating retroversion in up to 86% of cases.[18]
- *Y scapula view:* useful for evaluation of anterior or posterior subluxation.

In planning revision surgeries, it can be helpful to have radiographs of both the glenohumeral joint and the entire humerus, in order to appreciate shortening or medialization at the glenohumeral joint level.[19]

Computerized tomography (CT)

The CT is considered the gold standard for the imaging of bone defects. It offers extensive information on both inclination of the glenoid surface and possible bone defects. However, despite the advantages a CT can offer, potential variability has been described regarding measurements obtained by this system, as a function of scapular rotation in the coronal plane.[20]

Seidl et al. described the importance of obtaining images in the scapular plane, to execute an accurate study of the glenoid surface.[11] In an effort to avoid variability, corrective systems have been described, based on the main plane of the scapula. Friedman et al. studied 20 shoulders in 13 patients (10 with osteoarthritis, 10 with inflammatory arthritis). Their study compared these 20 shoulders with 63 controls. They defined the transverse axis of the scapula as a line drawn from the midpoint of the glenoid fossa to the medial end of the scapula.[21]

Three-dimensional computed tomography (3D CT)

Use of 3D CT for preoperative planning has been validated, both in clinical and cadaver studies.[22–25] This system allows deeper study of glenoid morphology, inclination, version, and available bone stock. Preoperative planning using 3D reconstruction has been shown to improve the precision of implant orientation.[3]

Resolution of clinical scenario

- Preoperative planning plays a critical role in shoulder arthroplasty, helping to improve functional outcomes and prosthesis survival.
- The plain radiographic study remains relevant for such planning, allowing collection of a variety of valuable information.
- The CT is reliable and widely used; it allows precise assessment of glenoid version and bone stock. Caution should be exercised with regards to ensuring measurements are made in the scapular plane.
- The 3D CT allows deep study of glenoid morphology, and seems to improve preoperative planning.

Question 2: In patients with glenohumeral bone loss, does reverse total shoulder arthroplasty (rTSA), compared to other treatment options, result in better outcomes?

Rationale

Glenohumeral stability is determined by dynamic compressive forces of the humeral component on the glenoid component. Minor displacements of as little as 2.5° can lead to subluxation of the humeral component.[26] Failure in correction of glenoid version, with a retroversion of >15°, may lead to osteolysis, posterior translation of the humeral head, and eccentric PE wear of the prosthesis.[27]

There are multiple options for managing glenoid retroversion secondary to bone defect, depending on defect location and type. These therapeutic options can be grouped generally as: implantation of an anatomical

prosthesis, implantation of an inverted prosthesis, associating such implants with eccentric reaming, augmented or personalized implants, and resorting to bone grafts. Careful consideration of the potential benefits and disadvantages of each option is essential to arriving at a customized decision for each patient.

Clinical comment

Before addressing rTSA, it is necessary to outline the other treatment alternatives.

Eccentric reaming and implantation of anatomical prosthesis

There is no clear consensus on the optimal management of retroversion in this patient profile. One of the most frequently chosen options for patients with relatively minor retroversion is eccentric reaming. However, the technique has many detractors. Gillespie and colleagues concluded that in the presence of a retroversion of greater than 15° the probability of successful correction was 50%.[28] Subchondral bone reduction can increase the risk of implant loosening, as well as the risk of excessive medialization.[11,29–32] Other authors, however, argue that this is a good option when retroversion is minor. Nyffeler et al. reported favorable results, with a good capsulolabral release and adequate mobilization of the musculotendinous subscapularis unit.[18]

Augmented or customized implants

Augmented or customized implants have been proposed as an alternative to eccentric reaming or bone grafting. Studies to date report controversial results. Sabesan and colleagues report favorable corrections of glenoid retroversion with augmented implants, in cases of less than

16°. When retroversion is greater than 16°, the same authors recommend the use of bone grafts.[30] They concur with the view that it is a difficult and demanding technique. Incorrect implantation can foster a predisposition to micro-movements and consequent loosening.[30,33]

Available literature and quality of evidence

The quality of the literature on appropriate investigations into rTSA for glenoid loss management is widely varied, and offers only level IV–V evidence. The majority of outcome papers are case series or retrospective cohort studies. There are no randomized trials reported.

Findings

The usefulness of rTSA in treatment of osteoarthritis in the context of CTA has been widely described.[34–36] However, this is not the only indication for such an implant. Mizuno et al. studied 27 cases of rTSA for treatment of primary glenohumeral osteoarthritis and biconcave glenoid (Walch type B2). Their study's patient profile included a mean patient age of 74.1 years, and a mean preoperative retroversion of 32°. After 44 months of follow-up, the mean Constant score increased by 45 points. They reported a 15% complication rate, including early loosening of the glenoid component and neurologic problems. There was a 37% incidence of scapular notching; no radiolucent lines were observed.[37]

Similarly, McFarland et al. reported favorable results in their own series, a review of 42 patients with primary osteoarthritis and intact rotator cuffs. The patients presented with a different range of retroversion grades (A2, B2 and C Walch type glenoids), and were treated with rTSA without bone grafting. Objective improvements in pain level and range of motion were observed, as well as

improved subjective scores. One baseplate failure was reported, requiring revision surgery.[38] These favorable results may be explained by the greater degree of constraint afforded by the technique, avoiding posterior subluxation of the humeral head.[39] RTSA can offer more positive fixation and greater constraint than the use of an anatomical prosthesis. However, this procedure is associated with secondary complications. For this reason, it may be more appropriate for older and more sedentary populations, with severe erosions and subluxations.[16,17,39,40]

Resolution of clinical scenario

- The current evidence does not recommend adopting a firm position on the degree of retroversion which must be present to indicate intervention with rTSA.
- Although there is poor evidence, the studies cited recommend that in Walch type B2 cases rTSA may be considered if other relevant factors permit it.

Question 3: In patients undergoing rTSA, do any bone graft options, compared to others, result in the best outcomes?

Rationale

Use of rTSA in a glenoid with bone defects and secondary retroversion can lead to complications such as notching and joint kinematic disturbance, with reduced uptake of deltoid fibers.[41] These defects may be present in up to 10–15% of cases, complicating correct prosthetic implantation.[42] As previously mentioned, there are varied

approaches to glenoid defect management. An alternative to the techniques described previously is *bone grafting* with the objective of filling the defect.

Clinical comments

It can be difficult to avoid prosthetic orientation failure in patients with extensive erosions and glenoid retroversion. Uncorrected superior bone loss can result in scapular impingement, instability, lower-scapular notching, and medial PE wear.[43,44] Inadequate correction of a posterior defect may lead to reduced external rotation, scapular notching, and posteromedial PE wear.[14,45] Bone grafting has been found to be effective as an alternative treatment, to preserve the kinetic and mechanical characteristics of the joint. Indications for grafting include presentation with a version that cannot be corrected by adjusting the version of the different components, insufficient bone stock to support the glenoid component, retroversion >15°, potential penetration of the glenoid vault following version corrections, or a baseplate with less than 80% native bone support.[46–50]

Bone graft options can be classified as structural or nonstructural. Cancellous graft is a nonstructural option; structural grafts include allografts, and hybrids of allograft and autograft.

Donor-site options include the humeral head, the iliac crest, the femoral head, and the femoral neck.[17,34,35,51–53] Use of rTSA and its fixation system could increase the effectiveness of bone grafts in improving bone stock.[42,54,55]

Medium- and long-term results depend on the technique employed. Neer and Morrison found no glenoid loosening or migration at two year follow-up in their 16-patient series.[46] Steinmann et al. reported that 54% of patients had

some degree of radiographic lucency in their 28-patient series, with 5.3 years of follow-up.[47] Hills and Norris reported on 17 shoulders with posterior bone grafts; five presented with glenoid failure. Each of these studies reported high levels of patient satisfaction.[48] Boileau et al. suggested that one cause of these favorable results could be the effect of a fixed and medialized fulcrum.[56] However, the technique has its drawbacks: it is technically demanding, the fixation may fail, and resorption may occur.[49]

Available literature and quality of evidence

Literature addressing investigations into use of bone grafting for glenoid loss management is widely varied, offering only level IV–V evidence. Most outcome papers available are case series or cohort studies. There are no randomized trials reported.

Findings

The literature includes numerous reports on results with this technique. Neyton et al. reported good results in nine rTSA cases, using iliac crest autografts. In all cases the grafts had been integrated at two years, but functional results could have been more favorable.[55]

Lopiz et al. reported the results of a 20-patient study with a mean follow-up of two years. Their mean Constant score improved from 30.7 ± 9.4 to 51.3 ± 13.4, with osseointegration in 95% of the cases. They reported a 20% complication rate: one case of aseptic glenoid component loosening, one surgical wound hematoma, one acromial fracture, and one symptomatic grade 3 scapular notching.[49]

Wagner et al. reported the functional results of 40 bone-graft revision rTSAs at two-year follow-up. Of these

patients, 18% required a second revision surgery.[57] Mahylis et al. reported a retrospective cohort study of 30 patients treated with rTSA, divided into two groups: one with iliac crest autografts, the other with less extensive erosion and no need for structural bone grafts. At two-year follow-up, no statistically significant differences were found in terms of implant position, scapular notching, implant shift, or fixation failure. Likewise, at least partial osseointegration of 93% of the grafts was observed; 40% had some degree of resorption. No differences were found in range of motion or functional scales.[52]

Boileau et al. presented their work with what they described as a *bio-rTSA technique*. This operative technique was designed primarily to lateralize the center of rotation as the main objective, rather than correction of glenoid version. They reported on a retrospective study of results in 54 patients with a two-year follow-up. In these patients, a trapezoidal graft of the humeral head was used to graft B2 and C (Walch), and E2, E3, and E4 defects. Fifteen of the patients had multiplanar deficits. An integration rate of 94% was observed, with 5% glenoid loosening and 25% scapular notching. In this paper, the authors reported the advantages of the humeral head autograft, including low co-morbidities in the donor area, no risk of disease transmission, and low cost as compared with use of allografts and augmented implants.[51]

They presented their treatment system, consisting of use of standard instrumentation to correct up to 15° of the defect with eccentric milling, and the remainder with graft, in patients with simple defects and less than 25° retroversion deficits. For severe (>25°) or multiplanar defects, they performed correction and realignment with bone graft.[51]

Resolution of clinical scenario

- In patients with extensive bone erosion and severe retroversion, achieving proper prosthesis orientation can present challenges. In such patients, bone grafting may provide the structural support necessary to correct the defects.
- The complication rate in rTSA with bone grafting ranges between 9 and 30%, with a resorption rate of up to 40% in surgical patients.
- Although there is poor evidence with short-term follow-up, patients may have functional results as favorable as those in patients operated on with rTSA without bone grafting.

Summary of answers

- Preoperative planning is critical in shoulder arthroplasty.
- 3D CT scan is an excellent resource for precise assessment of glenoid morphology and likely improves preoperative planning.
- rTSA may be considered for Walch Type B2 glenoid, although there is poor evidence on this .
- Bone grafting may provide structural support in those with extensive bone loss and severe retroversion .
- Complication rates can be up to 30% in patients requiring bone grafting, though functional results may not be affected

Reverse Total Shoulder Arthroplasty

Mitchel D. Armstrong MD BMSc FRCSC Bandar M. Assiry MBBS SB-orth and Ryan T. Bicknell MD MSc FRCSC
Division of Orthopaedic Surgery, Department of Surgery, Queen's University, Kingston, ON, Canada

Clinical scenario

- A 75-year-old woman who is living independently is seen with complaints of right shoulder pain and loss of motion.
- She has no history of trauma and the pain has been progressive over the past 2–3 years.
- On examination, she has very limited active movement and crepitus. She is neurovascularly intact.

Relevant anatomy

A rotator cuff tear can be classified as acute (no irreversible muscular fatty atrophy and generally reparable) or chronic (with irreversible muscular fatty atrophy and generally irreparable). Instability of the glenohumeral joint due to a long-standing irreparable rotator cuff tear often occurs in an anterior and superior direction, called *anterosuperior escape*, often leading to a pseudoparalysed shoulder, generally defined as a loss of active forward elevation with maintained passive movement. These abnormalities can eventually lead to arthritic changes at both the glenohumeral and acromiohumeral articulations.

Importance of the problem

Shoulder arthritis can include osteoarthritis, rheumatoid arthritis, post-traumatic arthritis, and cuff tear arthropathy. Each type of arthritis is not infrequently seen in combination with a rotator cuff tear. A conventional anatomic total shoulder arthroplasty (TSA) is used to relieve pain and improve function in arthritic shoulders. The articular surfaces are unconstrained and allow the healthy rotator cuff and extrinsic shoulder muscles to restore shoulder function. In most arthritic shoulders, with or without a rotator cuff tear, the *ball-and-socket* biomechanics of the glenohumeral joint are maintained. However, each type of arthritis may present in combination with rotator cuff dysfunction and loss of the normal biomechanics, often leading to instability and pseudoparalysis. In this situation, the outcome of a traditional shoulder arthroplasty is substantially compromised.[1–3]

The incidence of rotator cuff tear dysfunction in the population of shoulder arthritis patients is difficult to determine, but occurs in a minority of patients. Although shoulder arthritis is much less common than hip or knee arthritis, the incidence and indications for shoulder arthroplasty continue to increase.

Top three questions

1. Among patients with shoulder pain and dysfunction, which indications, compared to others, are most relevant for reverse total shoulder arthroplasty (rTSA)?
2. In patients undergoing rTSA, do some surgical techniques, compared to others, result in better outcomes?

3. In patients undergoing rTSA, what are the clinical outcomes?

Question 1: Among patients with shoulder pain and dysfunction, which indications, compared to others, are most relevant for reverse total shoulder arthroplasty (rTSA)?

Rationale

In general, rTSA is an implant that provides increased stability for a shoulder that has lost, or is at increased risk of losing, its normal ball-and-socket function. This most commonly occurs due to soft tissue (usually rotator cuff) or bony deficiency. However, as experience with this implant increases and with newer research, the indications for rTSA are expanding.

Clinical comment

The traditional indication for rTSA has been rotator cuff tear arthropathy with pseudoparalysis in elderly low demand patients. However, indications have rapidly expanded to now include younger high demand patients, other causes of arthritis, cuff insufficiency, or impending insufficiency, as well as some types of proximal humerus fractures.

Available literature and quality of the evidence

- Level I: 1 randomized control study.[4]
- Level II: 1 nonrandomized control study[5] and 2 economic analyses.[6,7]

- Level III: 1 case-controlled study[8] and 2 retrospective cohorts.[9,10]
- Level IV: 2 systemic reviews[11,12] and 4 case series.[13–16]

Findings

Cuff tear arthropathy

RTSA may be considered when the patient presents with a clinically symptomatic, irreparable rotator cuff tear associated with anterosuperior escape and an irrecoverable pseudoparalysis. However, deltoid function must be preserved and there must be adequate glenoid bone stock to allow secure glenoid component fixation.[17,18]

Rheumatoid arthritis

RTSA in patients with rheumatoid arthritis is considered a reliable treatment option, with similar results to rTSA in rotator cuff arthropathy without a higher complication rate.[11]

Cuff tear arthropathy in younger patients

The use of rTSA for cuff tear arthropathy in patients younger than 65 years of age generates some treatment controversy. However, rTSA is now emerging as a reasonable treatment option for these patients, providing subjective functional improvements, but with higher complication rates and implant longevity concerns.[913–16]

Failed arthroplasty

RTSA is also used as a revision procedure for shoulder arthroplasty associated with instability, this is associated with reasonable survival rates and higher complication rates than other indications. Instability can still remain an issue for one in seven patients.[10]

Proximal humerus fractures

RTSA can be used for the treatment of complex proximal humerus fractures in elderly patients. Patients show better forward flexion and abduction, with lower revision rates when compared with hemiarthroplasty.[4,12,19,20] RTSA has also been shown to be more cost-effective when compared with hemiarthroplasty.[7]

Resolution of clinical scenario

- In patients greater than 70 years of age, rTSA can be considered when rotator cuff dysfunction leads to anterosuperior humeral escape and shoulder pseudoparalysis.
- However, when all other options are exhausted, rTSA may also be considered in patients with rheumatoid arthritis, cuff tear arthropathy in patients less than 65 years of age, failed anatomic TSA, and complex proximal humerus fractures in the elderly.

Question 2: In patients undergoing rTSA, do some surgical techniques, compared to others, result in better outcomes?

Rationale

There has been a dramatic increase in rTSA implant design and surgical techniques over the past 10 years. This has led to debate within the literature regarding many factors, including optimal positioning of the glenosphere and baseplate and humeral stem as well as size and design of the glenosphere. The effects of subscapularis muscle repair also show discordance within the literature.

Clinical comment

rTSA has enjoyed tremendous success considering its relatively short proliferation. This implant design provides a surgical option in difficult situations that previously were inadequately addressed with other surgical options. However, the pain and functional outcomes, survival, and complication rates have been somewhat inconsistent and concerning long term. As a result, authors have searched for implant design and technique methods to optimize the outcomes.

Available literature and quality of the evidence

- Level I: 4 randomized controlled trials.[21–24]
- Level II: 1 prospective case series.[25]
- Level III: 5 retrospective cohort designs, 2 prospective case-control studies, and 2 retrospective case-control studies.[26–34]
- Level IV: 1 systematic review and 3 retrospective case series.[35–38]
- Level V: 4 biomechanical studies.[39–41]

Findings

Humeral component neck-shaft angle

Utilizing a lower neck-shaft angle (135°) on the humeral component leads to a greater impingement free range of motion (ROM) and decreases the rate of scapular notching when compared with a higher angled (155°) design ($p = 0.0081$).[30,39,40] The neck-shaft angle does not appear to affect the rate of postoperative dislocation.[35]

Larger diameter glenosphere

Use of a larger diameter glenosphere (>42 mm) decreases the rate of scapular notching ($p < 0.001$) and improves ROM (forward flexion and external rotation) ($p < 0.05$).[31,33] However, both the size of the glenosphere and the presence of notching does not appear to affect the clinical outcome at short-term follow-up.[22,29,32]

Inferior glenoid component tilt and positioning

Inferior glenoid tilt of >10° does not reduce the rate of scapular notching and does not appear to confer a clinical benefit.[23,30] Inferior glenoid positioning is desirable to decrease the rate of scapular notching and may improve clinical outcome scores.[22,25,41,42]

Glenoid lateralization

No differences in functional outcome scores, ROM, or strength have been identified when comparing bony lateralization (i.e. bony-increased offset rTSA) of the glenosphere with medialized designs.[21,32] Higher rates of scapular notching have been shown in medialized designs ($p = 0.022$); however, clinical outcome scores were not affected.[32,36] In a lateralized glenosphere design without bony-offset augmentation there is a risk of base plate failure secondary to increased shear stress at the baseplate–bone interface.[37] More robust baseplate fixation with the use of multiple peripheral locking screws has been shown to eliminate failure at medium-term follow up.[38]

Subscapularis repair

Repair of the subscapularis has been shown in some series to improve clinical outcome scores ($p < 0.05$).[29] However the differences identified are not likely to be clinically meaningful. Other series have not identified any differences in objective and subjective outcome measures,

ROM, strength, or complication rates.[27,28] Repair of the subscapularis may be desirable in medialized designs to decrease postoperative dislocation rates.[28]

Resolution of clinical scenario

- A lower neck shaft angle leads to lowers rates of scapular notching and greater impingement-free ROM.
- Larger diameter glenospheres are preferable.
- Ideal glenosphere positioning is inferior on the glenoid face.
- Component design offset can be determined by surgeon preference but improvements in ROM can be seen in lateralized offset with an intact teres minor.
- Repair of subscapularis is desirable in medialized designs for decreased dislocation rate; however, in a lateralized design subscapularis repair is the surgeon's preference.

Question 3: In patients undergoing rTSA, what are the clinical outcomes?

Rationale

RTSA has been widely accepted for a variety of indications. Overall, early results have been good but appear to be significantly impacted by the indication for use. Long-term outcome data are uncertain at this time.

Clinical comment

RTSA is generally a last resort in a difficult situation. As such, this implant provides an alternative to many problems that previously did not have a good option. Generally, the

results of rTSA are very good for pain relief and improved motion. However, the results depend on several factors, including the indication, age, gender, and preoperative level of function.

Available literature and quality of the evidence

- Level I: 1 randomized controlled trial.[43]
- Level II: 1 retrospective study[44] and 2 prospective cohort studies.[5,45]
- Level III: 3 retrospective studies.[46–48]
- Level IV: 1 case series,[49] 1 therapeutic study,[17] and 8 meta-analyses.[12,18,50–56]

Findings

Overall

Short- to medium-term results of rTSA show substantial improvements in pain, quality of life, ROM (forward elevation and abduction), functional outcome, and patient satisfaction.[18,46,47,49,50] Overall, absolute constant score improved from a preoperative score of 23 ± 12 to a postoperative score of 63 ± 14.[17]

The largest improvements in ROM are with active forward elevation with postoperative values of 138 ± 26° compared to 81 ± 43° preoperatively.[17,18] The majority of patients will be able to return to their preoperative activity level within six months.[48,51,52] However, patients with a lower preoperative level of function displayed longer recovery times.[44,45]

According to the indication

RTSA for rotator cuff arthropathy is associated with the highest absolute Constant score of 70 ± 11. This is compared to other indications, including revision arthroplasty (55 ± 16), massive cuff tear (63 ± 11), and post-traumatic arthritis (55 ± 20).[17,18]

Long-term results

Long-term studies of rTSA show high functional outcome scores and survival rates. At 10 years, the overall mean absolute constant score is 55 ± 16, which is a significant improvement compared with preoperative values.[17] However, there appears to be a significant functional deterioration between medium- to long-term scores ($p < 0.001$).[17] RTSA for revision arthroplasty and post-traumatic arthritis show lower long-term functional outcome scores when compared to rotator cuff arthropathy. Nonetheless, the 10 year overall implant survival rate is 93%.[17]

Proximal humerus fractures

RTSA for complex proximal humerus fractures in elderly patients have shown improved forward flexion and abduction, but decreased external rotation when compared with hemiarthroplasty.[4,12,19,20] Revision rTSA for failed proximal humerus internal fixation showed improved pain, ROM, and functional outcome scores when compared to preoperative values. However, functional scores were lower than patients who underwent primary rTSA for proximal humerus fractures.[4,20]

Resolution of clinical scenario

- Overall, rTSA results in improved pain and functional outcomes, but these results decrease between medium- and long-term follow-up.

- Results are dependent on the indication, with rotator cuff tear arthropathy showing the best results, and revision arthroplasty the worst.
- rTSA for proximal humerus fractures leads to improved function compared to hemiarthroplasty.

Summary of answers

- In patients greater than 70 years of age, rTSA can be considered in the setting of rotator cuff dysfunction.
- A lower neck-shaft angle leads to lower rates of scapular notching and greater impingement free range of motion.
- rTSA results in improved pain and functional outcomes, but outcomes are less reliable at medium and long-term follow-up.

Glenoid Components in Total Shoulder Arthroplasty

Eric Benson MD[1] George Athwal MD[2] and Kenneth Faber MD[2]
[1]New Hampshire Orthopaedic Center, Nashua, NH, USA
[2]Division of Orthopaedic Surgery, Department of Surgery, Western University, London, ON, Canada

Clinical scenario

- A 72-year-old right-hand-dominant male has been experiencing three years of right shoulder pain. The pain has been insidious in onset and has failed nonoperative treatment.
- Radiographic studies including conventional radiographs and computed tomography (CT) scan show considerable degenerative changes with loss of joint space, marginal osteophytes, subchondral sclerosis, and significant posterior glenoid erosion.

Top three questions

1. In patients with primary osteoarthritis, do keeled or pegged glenoid components correlate with lower revision rates?
2. In patients with primary osteoarthritis, do patient-specific components or intraoperative navigation, compared to traditional techniques, improve accuracy compared to traditional instrumentation?

3. In patients with primary osteoarthritis, do all-polyethylene cemented or metal-backed uncemented glenoid components result in lower failure rates?

Question 1: In patients with primary osteoarthritis, do keeled or pegged glenoid components correlate with lower revision rates?

Rationale

As the number of primary total shoulder arthroplasties continues to increase worldwide, the decision to use a particular style of glenoid component remains an important one in the effort to improve outcomes and prevent future revision surgery. Two glenoid component designs are most commonly used: keeled and pegged.

Clinical comment

One of the most important outcome measures for any joint replacement procedure is the rate of revision-free survivorship. In total shoulder arthroplasty (TSA), a frequent cause for revision in medium- and long-term follow-up is glenoid component failure.[1–4] It is important, then, to identify the best component design as well as clinical markers that can help identify component failure.

Available literature and quality of the evidence

There is a growing body of peer-reviewed literature exploring keeled versus pegged glenoid component design and correlation with implant survivorship and clinical outcomes. The current literature is limited by the variety of glenoid components used, analytic approaches, and outcome reporting. However, there are two level I studies

as well as some level III and IV studies to help us answer this question.

Findings

Level I studies

Two level I studies address radiolucency about the glenoid component in an attempt to use radiographic parameters to establish whether pegged or keeled components perform best. Rahme et al. performed radiostereometric analysis on 26 shoulders comparing results of inline pegged and keeled all-polyethylene components.[5] They found that only one glenoid (keeled) had any radiolucency on immediate postoperative radiographs. Nine of 12 keeled and 8 of 14 pegged glenoids showed radiolucency at two-year follow-up ($p = 0.429$), but that none of these showed Grade 4 or 5 lucency using the Gartsman classification. There was a trend toward glenoids with Grade 2 or 3 radiolucency showing more micro-migration than glenoids with Grade 0 or 1 radiolucency. However, this study was not powered to directly correlate radiolucency to micro-migration.

Edwards et al. report a prospective randomized trial of pegged versus keeled all-polyethylene components including 46 shoulders at 26 months to determine the effect of glenoid component design on immediate and follow-up radiographs.[6] For both immediate and follow-up radiographic evaluation, they selected the presence of at least Grade 2 lucency as their outcome. They concluded that there was no statistically significant difference between pegged and keeled glenoids on immediate postoperative radiographs ($p = 0.128$). They did find statistically significant differences between the two designs at 26 months, with 46% of keeled and 15% of pegged glenoids showing at least Grade 2 radiolucency ($p = 0.044$).

Level III studies

Vavken et al. did a meta-analysis looking at rates of loosening and radiolucency in keeled versus pegged glenoids.[7] They found a small difference between the component styles. The pooled risk ratio for revision was 0.27 (95% confidence interval [CI]: 0.08–0.88) in favor of pegged glenoids.

Throckmorton et al., in a retrospective case-control study, looked at 50 keeled and 50 inline pegged glenoids at approximately four-year follow-up.[8] There was no difference in glenoids that were at risk for loosening based on radiographic evaluation ($p = 0.74$). There was also no difference in clinical outcomes as measured by improvements in pain and range of motion from preoperatively ($p \geq 0.20$).

Level IV studies

Papadonikolakis et al. performed a systematic review of failures of anatomic total shoulder arthroplasties.[3] In this study, they noted limitations of the wide variability of reporting measures, but that overall, there was no detectable difference between pegged and keeled glenoids with respect to component failure. They did note that for asymptomatic radiolucent lines, there was a greater rate for keeled versus pegged glenoids (overall odds ratio = 2.37; $p = 0.01$).

Resolution of clinical scenario

- Based on the current literature, either keeled or pegged glenoid components may be used with equivalent revision rates.
- Keeled glenoids likely have a higher rate of radiolucency that develops over time. However, caution

must be used linking findings of radiolucent lines (RLL) to clinical outcome measures or to revision rates.

Question 2: In patients with primary osteoarthritis, do patient-specific components or intraoperative navigation, compared to traditional techniques, improve accuracy compared to traditional instrumentation?

Rationale

In efforts to improve survivorship of glenoid components, some authors recommend the use of newer patient-specific components or of intraoperative navigation technology. The hope is that, by improving the accuracy of placing the glenoid component, failure rates will improve.

Clinical comment

Glenoid morphology can be difficult to assess and alignment difficult to recreate and optimize in the placement of glenoid components during TSA. Authors hypothesize that use of the new technology will improve the surgeon's ability to accurately place the glenoid component intraoperatively.

Available literature and quality of the evidence

There are few studies looking at patient-specific systems or intraoperative navigation for glenoid placement, but there is one level I and one level II study that investigates the effectiveness over standard techniques for glenoid

placement. Several biomechanical studies also provide information.

Findings

Level I studies

Hendel et al. performed a randomized prospective clinical trial evaluating standard surgical technique compared to the use of patient-specific instrumentation for placement of the glenoid in TSA.[9] They found that patient-specific instrumentation led to improved inclination and mediolateral offset ($p < 0.05$), but there was no statistical difference for version. In glenoids with the most retroversion preoperatively (>16°), the patient-specific instrumentation showed the greatest benefit with only 1.2° deviation from optimal position versus 10° with standard instrumentation. There was also a significant reduction in the incidence of significant malpositioning (>10° of either version and/or inclination from the optimal preoperative plan) from 75 to 27% ($p < 0.01$).

Level II studies

Kircher et al. performed a small prospective randomized clinical trial using intraoperative navigation comparing glenoid positioning with traditional techniques.[10] Correction of preoperative to postoperative glenoid retroversion assessed on CT imaging showed improvement from 15.4° to 3.7° for navigation, and from 14.4° to 10.9° without navigation ($p = 0.021$).

Level III studies

Heylen et al. found that patient-specific instrumentation did not improve glenoid component inclination ($p = 0.093$), but extreme values of glenoid positioning were decreased with

patient-specific guides ($p < 0.001$).[11] They did not assess component version as an outcome in their study.

Biomechanical studies

Nguyen et al. compared computer-assisted navigation to traditional placement of glenoid components in 16 paired cadaveric specimens.[12] Glenoid version with computer assistance was significantly improved at all stages of positioning (initial guide pin insertion, reaming, drilling of the peg holes, and final component implantation) with respect to glenoid version ($p < 0.05$). With navigation, final version was 1.5° compared to 7.4° without navigation ($p < 0.05$). In this study, though inclination was improved with navigation, it did not achieve statistical significance ($p > 0.05$).

Throckmorton et al. showed that, with patient-specific targeting guides, the glenoid was placed in significantly more accurate version ($p = 0.04$) and inclination ($p = 0.01$) with respect to the intended position of the implant.[13] They also showed that significant malposition, defined as being more than 10° off the intended version or more than 4 mm off the intended starting point, was higher for standard compared to patient specific instrumentation. These results applied to low-volume, medium-volume, and high-volume surgeons equally.

Iannotti et al. evaluated the version, inclination, and location of guide pin placement using traditional techniques and patient-specific instrumentation.[14] They found that version improved by 8.2°, inclination improved by 11.4°, and location improved by 1.7 mm. These were each statistically significant ($p < 0.001$).

Resolution of clinical scenario

- Patient-specific instrumentation and intraoperative navigation reduce the likelihood of significant malposition of the glenoid component.
- Patient-specific instrumentation and intraoperative navigation improve component positioning compared to standard component placement techniques.
- Clinical outcomes and improvement in revision rates have not yet been studied or established with either patient-specific instrumentation or intraoperative navigation.

Question 3: In patients with primary osteoarthritis, do all-polyethylene cemented or metal-backed uncemented glenoid components result in lower failure rates?

Rationale

Durable fixation of the glenoid component remains a challenge given the small bone stock of the native glenoid. Revision rates also drive the need to find improved fixation methods to decrease loosening. While there is current interest in so-called hybrid glenoid designs, few studies exist at present to evaluate these implants. Two main categories of implant design have been widely used and studied to date: cemented all-polyethylene components or uncemented metal-backed components.

Clinical comment

The theoretical advantage of the uncemented designs is that the initial stability afforded by screw fixation ultimately allows for durable bone in-growth or bone on-

growth with the hope of more lasting fixation.[15] The theoretical disadvantage of cemented components is that temperatures generated with methyl methacrylate may rise to levels risking bone necrosis leading to higher rates of loosening.[16]

Available literature and quality of the evidence

The available literature investigating metal-backed versus all-polyethylene components is low in quality and is confounded by multiple implant types and outcome measures. Only one level II study exists and it is the only study looking at a direct comparison of results of these two component designs. Multiple level IV case series and one level IV systematic review are available.

Findings

Level II studies

In a prospective, randomized study, Boileau et al. compared 20 shoulders in each of two groups: cemented all-polyethylene keeled glenoids and uncemented metal-backed glenoids.[17] Clinical outcome measures included the Constant score, forward elevation, and external rotation. There was no statistical difference between the two groups at any time point, including at final follow-up for any of these outcome measures. Radiographic lucency was noted in 85% of polyethylene components versus 25% of metal-backed components and this was a significant difference ($p < 0.001$). Progression to radiographic loosening and need for revision surgery did not occur in the polyethylene group, but did occur in four shoulders (20%) of the metal-backed group. This difference in revision surgery rate (0–20%) was statistically significant. Ultimately, despite equivalent clinical results between the two glenoid component types in this short-term follow-up study, the

higher revision rate for metal-backed glenoids led the authors to conclude that use of metal-backed components should be abandoned.

Level III studies

A retrospective cohort by Friedman et al. reviewed 632 primary anatomic TSA cases, 316 of whom received hybrid cage glenoids and 316 age, sex, and follow-up matched controls who received cemented all-polyethylene peg glenoids. They found significantly lower rates of radiolucent glenoid and humeral lines (9/3% vs 37.6/9.1%, $p < 0.01$) and revision rates in metal cage glenoids compared to polyethylene glenoids (2.5% vs 6.9%, $p = 0.0088$).[18]

Level IV studies

Papadonikolakis et al. performed a systematic review including 21 studies on metal-backed and 23 studies on all-polyethylene glenoids.[19] Metal-backed glenoids showed lower rates of radiolucency and of radiographic loosening ($p = 0.0026$ and $p = 0.0005$, respectively). However, there was a much higher revision rate for the metal-backed components of 14% compared to 3.8% ($p < 0.0001$). Revisions in the all-polyethylene group were predominantly for loosening, whereas the metal-backed group revisions were for other reasons ($p < 0.0001$). These data suggest that metal-backed glenoids, then, have a higher rate of revision than all-polyethylene glenoid components.

Boileau et al. assessed 165 patients with metal-backed glenoids at a minimum of two years.[20] Revision-free survival rate at 12 years was only 46% (100% CI: 32–54%). At a mean of 8.5 years, 37% of patients required revision and, of those, 80% showed wear of the polyethylene. They

concluded that this style of implant is not a viable long-term therapeutic option.

Montoya et al. evaluated a metal-backed glenoid at medium-term follow-up of 64 months in 65 shoulders.[21] They noted the Constant score improved from 49 to 89.8 ($p < 0.001$) and there were also significant improvements in flexion, abduction, and external rotation (all $p < 0.001$). There were 9.4% with broken cage screws that loosened and a revision rate of 11.3% during the study. They felt this was too high a revision rate and the implant was removed from the market.

Tammachote et al. followed cemented metal-backed glenoids for a mean of 10.8 years with notable conclusions that the results were not better than comparable results for all-polyethylene cemented components.[22] They showed improvements in pain, abduction, and external rotation (all with $p < 0.001$). However, they showed 83% of components with radiolucency at most recent radiographic follow-up. They felt this was concerning and merited further follow-up.

Clement et al. looked at metal-backed glenoids in a specific patient population of only rheumatoid arthritis patients with 8- to 14-year follow-up.[23] At a mean of 10 years, their glenoid component survivorship was 89%. The Constant score improved postoperatively ($p < 0.001$) from 20.6 to 33.5.

In a later study, Clement et al. looked at the same component design in patients (mean age of 67) with osteoarthritis with 95-month mean follow-up.[24] Here the Constant score improved by 22 points ($p < 0.001$) and the survivorship was 93%.

Fucentese et al. reviewed their results with a soft metal-backed component at 50 months and showed significant

postoperative improvement in mean absolute Constant scores (29.1–65.9, p <0.001), age- and sex-adjusted Constant scores (40.1–87.7, p <0.001), but a high failure rate of 13.6% at this short follow-up.[25] Failures occurred with glenoid component fractures. They concluded that this was too high despite encouraging results with no other cases of observed loosening.

Resolution of clinical scenario

- At this time, the literature is of relatively low quality and mixed in terms of which design has higher revision rates.

Summary of answers

- Based on the current literature, either keeled or pegged glenoid components may be used with equivalent revision rates.
- Keeled glenoids likely have a higher rate of radiolucency that develops over time. However, caution must be used linking findings of RLL to clinical outcome measures or to revision rates.
- Patient-specific instrumentation and intraoperative navigation reduce the likelihood of significant malposition of the glenoid component.
- Patient-specific instrumentation and intraoperative navigation improve component positioning compared to standard component placement techniques.
- Clinical outcomes and improvement in revision rates have not yet been studied or established with either patient-specific instrumentation or intraoperative navigation.

- At this time, the evidence is mixed and of low quality, thus it is unclear which design has lower failure rates.

Periprosthetic Joint Infection in Shoulder Arthroplasty

Peter Lapner MD FRCSC[1], Jay Keener MD[2] and Thomas Duquin MD[3]
[1]Division of Orthopaedic Surgery, Department of Surgery, University of Ottawa, Ottawa, ON, Canada
[2]Department of Orthopaedic Surgery, Washington University, St. Louis, MO, USA
[3]Department of Orthopaedic Surgery, State University of New York at Buffalo, Buffalo, NY, USA

Clinical scenario

- A 55-year-old man with advanced glenohumeral arthrosis has failed nonoperative treatment. He is seeking pain relief and improved function and is considering shoulder arthroplasty.
- Five years following the index anatomic total shoulder arthroplasty, he presents with three months of increasingly severe shoulder pain.
- The pain occurs deep in the joint, is worse with movement, and is not associated with systemic symptoms including fevers, chills, or sweats. Preoperative serum indices reveal an erythrocyte sedimentation rate (ESR) of 6 and a C-reactive protein (CRP) of 4. Plain films and computed tomography (CT) scan reveal significant lucencies around the glenoid component suggestive of loosening. The patient is seeking definitive management and pain relief.

Top three questions

1. Are infection prevention strategies, including modifiable patient factors and perioperative interventions, effective in reducing periprosthetic joint infection (PJI) in patients who undergo shoulder arthroplasty procedures?
2. In patients with possible PJI, do preoperative serum indices, aspiration, or imaging aid in establishing the diagnosis of infection compared with preoperative tissue culture?
3. In patients with shoulder PJI, does a two-stage revision result in lower reinfection rates compared with one-stage revision?

Question 1: Are infection prevention strategies, including modifiable patient factors and perioperative interventions, effective in reducing periprosthetic joint infection (PJI) in patients who undergo shoulder arthroplasty procedures?

Rationale

Infection continues to be a devastating complication following shoulder arthroplasty procedures. Preventative strategies, including optimization of patient modifiable risk factors and perioperative interventions, have varying degrees of success. Optimization of these preventative strategies is essential for reducing infection following shoulder arthroplasty procedures.

Clinical comment

Shoulder arthroplasty continues to show significant growth with the number of procedures performed annually projected to increase by 150% by 2020.[1] The incidence of PJI following shoulder arthroplasty is between 0.4 and 2.9% in the literature.[2,3] Although rare, infection following shoulder arthroplasty results in significant morbidity to the patient and cost to the health care system.[4,5] Risk factors for PJI after shoulder arthroplasty include age, sex, medical co-morbidities, inflammatory arthritis, corticosteroid use, duration of procedure, and blood transfusion. There has been significant attention placed on the development of preventative strategies to reduce the rates of PJI. Identifying effective methods for reduction of infection will result in significant benefit to patients and society. The optimization of patient modifiable risk factors, and the development of effective perioperative interventions that reduce contamination are both important aspects of infection prevention. Developing effective prevention strategies in shoulder arthroplasty is challenging, due to the low incidence of PJI and the prevalence of infection with low virulent organisms.

Available literature and quality of the evidence

There are many studies evaluating different infection prevention strategies in shoulder surgery. Several modifiable patient factors including blood glucose control, obesity, smoking, and substance abuse are commonly thought to influence the risk of PJI in shoulder arthroplasty. Several cohort studies have evaluated the influence of these factors on patient outcomes and complications. There are no level I randomized control studies regarding modifiable risk factors. There is limited evidence that

optimization of patient modifiable risk factors influences the risk of PJI in shoulder arthroplasty.

Findings

Modifiable risk factors

Obesity The best evidence in this area is level II. Richards et al. did not observe any difference in deep infection rate based on body mass index.[6]

Blood glucose control The evidence for glucose control is level III. The influence of diabetes and glycemic control has had mixed results in the literature. In a large retrospective database study of patients who underwent joint replacement surgery, Marchant et al. demonstrated increased risk of wound infection in patients with uncontrolled diabetes (odds ratio = 2.28; 95% confidence interval [CI]: 1.36–3.81; p = 0.002).[7] In a large retrospective study of lower extremity joint arthroplasty at a single institution, Iorio et al. confirmed the increased rate of infection in diabetic patients compared to nondiabetics (3.43% vs 0.87%) but found no association with HbA1c levels.[8] In contrast, a large database study of total knee arthroplasty failed to identify an increased rate of infection in diabetic patients, or in poorly controlled diabetic patients, when compared to patients without diabetes.[9]

Smoking Smoking has been identified as a risk factor for multiple complications following open and arthroscopic shoulder procedures (level III).[10,11] In a retrospective review of 1834 shoulder arthroplasty procedures, Hatta et al. found there was a deep infection rate of 4.7% at 10 years' follow-up for smokers versus 0.6% in nonsmokers(11).[11] In this study smoking cessation was found to decrease the risk of infection but not to the level

of a nonsmoker. The hazard ratio for deep infection decreased from 7.27 in smokers to 4.26 in patients who were classified as former smokers.

Substance abuse Alcohol abuse is a risk factor for complications following total joint arthroplasty.[12] Evidence is level IV. There are no studies specifically regarding alcohol consumption in patients undergoing shoulder arthroplasty. The timing or efficacy of alcohol cessation prior to joint replacement surgery has not been reported in the literature. Despite limited evidence, surgeons should counsel patients regarding alcohol cessation prior to shoulder arthroplasty.

Intravenous drug abuse has been associated with unacceptably high rates of infection following joint replacement surgery. Two small retrospective series have demonstrated infection rates greater than 25%.[13,14]

Perioperative prevention strategies

Skin preparation Evidence for skin preparation is level I based on skin cultures. Saltzman et al. reported decreased rates of superficial skin culture after use of ChloraPrep compared with DuraPrep or povidone-iodine solution.[15] However, all three agents demonstrated limited efficacy against formerly *Propionibacterium acnes* (now known as *Cutibacterium acnes*) with positive cultures in 7–22% of patients after skin preparation.

Preoperative skin preparation In a level I study, the use of chlorhexidine wipes showed significant decrease in the culture rate of coagulase negative staphylococcus prior to skin preparation compared to standard soap and water washing. However, there was no significant decrease in the rate of *P. acnes* cultures.[16] Dizay et al. evaluated the use of

benzoyl peroxide with clindamycin gel application in a level II study and reported reduction of deep cultures at the time of arthroscopic surgery to less than 4%.[17]

Hair removal There are no studies specific to the orthopedic literature regarding clipping versus shaving, but several studies from the general surgical literature support this practice (level I).[18,19] The removal of axillary hair does not have any influence on the bacterial burden of *P. acnes* following skin preparation with chlorhexidine.[20]

Antibiotics The efficacy of antibiotic prophylaxis in joint replacement surgery has been demonstrated with level III evidence.[21] The exact timing of antibiotics has been debated. The current guidelines indicate that administration should be performed with in one hour prior to surgical incision. The available level III evidence indicates increased infection risk if antibiotics are administered >1 hour before, or after skin incision. Conflicting evidence exists regarding the administration between 0–30 minutes and 31–60 minutes prior to incision.[4,22,23]

Local antibiotic administration The only prospective randomized trial in the spine literature (level I) with this technique failed to demonstrate a significant decrease in infection rate compared to standard intravenous antibiotic prophylaxis.[24]

Intraoperative irrigation A prospective randomized control trial of hemiarthroplasty for hip fractures demonstrated a decreased incidence of PJI with the use of pulsatile lavage compared to bulb syringe irrigation.[25]

Betadine lavage A retrospective study (level III) of total knee and hip arthroplasty demonstrated a decrease in the

90-day infection rate with the addition of a dilute betadine lavage at the time of closure (0.97% vs 0.15%).[26]

Resolution of clinical scenario

Antibiotic prophylaxis with a first-generation cephalosporin administered within one hour of the surgical incision has demonstrated efficacy. Topical skin treatments prior to admission and the use of a chlorhexidine-based solution at the time of surgery reduces positive culture rates, but the role of either intervention in reducing PJI is unproven. Local use of antibiotics at the time of routine primary shoulder arthroplasty for the reduction of PJI is not supported. Intraoperative irrigation and betadine lavage use are both supported.

Question 2: In patients with possible PJI, do preoperative serum indices, aspiration, or imaging aid in establishing the diagnosis of infection compared with preoperative tissue culture?

Rationale

P. acnes, a gram-positive anaerobic bacteria, is the most common infecting organism in periprosthetic shoulder infection (PPSI).[27–32] It is very indolent and slow-growing, and does not elicit an inflammatory reaction or clinical features of typical of infection. Establishing the diagnosis of infection with a painful shoulder after arthroplasty is extremely difficult.

Clinical comment

Establishing the diagnosis of infection with a painful shoulder after arthroplasty is extremely difficult and other than arthroscopic tissue biopsy, few reliable preoperative tests exists. This may lead to highly invasive operations in order to treat shoulder infections that may or may not be present. The current lack of a reliable diagnostic tool for infection may lead to delays in diagnosis, additional operations that could have been avoided, or inappropriate surgery in the presence of an undiagnosed infection.

Available literature and quality of the evidence

- CRP – retrospective cohort studies, level III.[30,33,34]
- ESR – prospective and retrospective cohort studies, level II and III.[3033–35]
- White blood cell count (WBC) – prospective cohort study, level II.[35]
- Serum IL-6 – prospective cohort study, level II.[35]
- Synovial fluid IL-6 – prospective cohort studies, level II.[36,37]
- Alpha defensin – prospective cohort study, level II.[38]
- PCR – mechanism-based reasoning, level V.[39,40]
- MALDI-TOF MS – retrospective cohort studies, level III.[41–44]
- Leukocyte esterase – prospective cohort study, level II.[45]
- Synovial fluid culture – case series, level IV.[46]
- Frozen section – retrospective cohort studies, level III.[29,30,34,47,48]
- Tc-labelled leukocyte scan – case series, level IV.[49]

- Preoperative tissue cultures – retrospective cohort study, level III.[50]

Findings

C-reactive protein (CRP)

Evidence for CRP is level III. Piper et al. reported that the CRP level had a sensitivity of 63% and a specificity of 73% with an optimized cut-off of 7 mg/L for shoulder PJI for all organisms.[33] With a more standard threshold value of 10 mg/L, the sensitivity and specificity was 42 and 84%, respectively. In another study of 45 patients undergoing revision shoulder arthroplasty, Grosso et al. found that CRP had a sensitivity of 33% and a specificity of 85% with a cut-off value for a positive CRP of >1 mg/L.[34]

Erythrocyte sedimentation rate (ESR)

Evidence for ESR is level II. ESR frequently occurs in the normal range in the setting of shoulder PJI. The sensitivities and specificities have been reported 21 and 65%, respectively.[35] In a series of 193 revision shoulder arthroplasties, only 17% of patients with positive *P. acnes* cultures had elevated ESR.[30]

White blood cell count

Evidence for WBC is level II. Villacis et al. found a sensitivity and specificity of 7% and 95%, respectively, in a series of patients undergoing revision shoulder arthroplasty with infection.[35]

Serum interleukin-6

Evidence for serum IL-6 is level II. Villacis et al. reported values for sensitivity, specificity, positive and negative predictive values of 14, 95, 67, and 61%, respectively.[35]

Similarly, in a larger study of 69 patients of which 24 had definite or probable infection, Grosso et al. reported values of sensitivity 12%, specificity 93%.[51]

Synovial markers: synovial fluid IL-6

Evidence for synovial fluid IL-6 is level II. IL-6 synovial fluid IL-6 has been the subject two recent studies. Frangiamore et al. reported that IL-6 had sensitivity, specificity, positive and negative likelihood ratios of 87%, 90%, 8.45, and 0.15, respectively.[36] In a subsequent study,[37] IL-6 was used in 75 cases of revision shoulder arthroplasty with a multiplex immunoassay in which IL-6, IL-1 beta, IL-8, and IL-10 showed the best combination of sensitivity and specificity for predicting infection, and a combined cytokine model that consisted of IL-6, tumor necrosis factor-alpha, and IL-2 had superior diagnostic test characteristics that any individual test with sensitivity of 0.80, specificity of 0.93, positive and negative predictive values of 0.87 and 0.89, and positive and negative likelihood ratios of 12.0 and 0.21.

Alpha defensin

Evidence for alpha defensin is level II. Synovial fluid alpha defensin levels were evaluated for diagnostic utility in identifying the presence of shoulder PJI in 30 patients undergoing revision surgery. There were 11 infected cases. The sensitivity, specificity, and positive and negative likelihood ratios were 63%, 95%, 12.1 and 0.38, respectively.[38]

Polymerase chain reaction (PCR)

Evidence for PCR utilization in shoulder infection is level V. This approach[39] has been investigated along with PCR analysis of fluid from sonicated implants[52] for the diagnosis of musculoskeletal infection. Although the approach

appears promising, the main current limitation is the time delay for analysis of samples, along with the potential for false positive results. A study by Holmes et al. demonstrated the potential viability of a rapid-sequence test that has been validated in vitro;[40] further clinical validation is required.

Matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF MS)

MALDI-TOF MS is an inexpensive approach to detecting the presence of *P. acnes* by applying the sample of synovial fluid onto a crystal matrix to assess the fragmented ions by mass spectroscopy.[41] Evidence for MALDI-TOF MS is level III. Walter et al. reported on 61 patients with bone and joint infections. Ninety-eight percent were detected with MALDI-TOF MS, including 20 cases involving *P. acnes*.[41] In a prior study, La Scola et al. were able to isolate 75% of *P. acnes* infections with MALDI-TOF MS, most of which were osteoarticular infections.[42] Coltella et al. found that MALDI-TOF MS had high concordance rates for the detection of other bacterial species but only correctly isolated specimens of *P. acnes* in 16 of 21 (76%) of patients.[43] The authors hypothesized that the relatively poor performance of MALDI-TOF MS in identifying the *Propionibacterium* genus was due to few spectra available in the database and the relatively large number of intra-species genetic variability in *Propionibacterium*. Barreau et al. reported significant improvement in the MALDI-TOF MS technology with successful identification of 350 of 375 *Propionibacterium* species, of which 84% were *P. acnes*.[44]

Leukocyte esterase (LE)

LE can be detected by a test strip and is commonly used for the diagnosis of urinary tract infections. In a level II study,

LE was investigated in patients undergoing primary shoulder arthroplasty (45 patients) and patients undergoing revision shoulder arthroplasty (40 patients).[45] The LE sensitivity was 28.6% sensitive, 63.6% specific, and had a PPV of 28.6% and an NPV of 87.5%.

Joint aspiration

Synovial leukocyte counts Bauer et al. suggested that leukocyte counts of >500 cells/μL is highly suggestive of infection,[53] although the threshold is likely joint or organism specific. The evidence for leukocyte counts in shoulder PJI is level IV; authors have reported that there is rarely enough fluid to complete leukocyte counts[54] and when it possible results are often normal.[48]

Synovial fluid culture Kowalski et al. reported on data from five studies on infection following shoulder arthroplasty.[46] In two-thirds of cases, preoperative aspiration was positive for infection. Patients included in this series had overt signs of infection, however; overt signs of infection are rarely present with *P. acnes* infection and are usually consistent with other more virulent organisms. This evidence is level IV.

Frozen section

Evidence for frozen section is level III. However, only one study has reported on frozen section specific to *P. acnes* PJI.[34] This study recommended using a threshold of 10 or more polymorphonuclear leukocytes per five high-power fields. This new specification carried a sensitivity or 72% and a specificity of 100%, which was considerably higher than the accuracy of this test when the traditional thresholds used in hip and knee infection are applied. In a large retrospective review of 193 revision arthroplasty

cases, 108 patients developed positive cultures, 70% of which consisted of *P. acnes*.[30] There was no association between the presence of inflammation on histopathological examination and the presence of positive *P. acnes* cultures.

Imaging: Tc-labelled leukocyte scan

In a level IV study of Tc-labelled leukocyte scintigraphy for endoprosthetic infections, all infections in the knee, hip, and shoulder were identified.[49] However, only two patients in this series had shoulder endoprosthesis.

Preoperative tissue cultures

In a level III study, preoperative tissue biopsy was obtained by arthroscopic means. Dilisio et al. reported on 19 patients who underwent arthroscopic biopsies prior to revision surgery with 100% sensitivity, specificity, positive predictive value, and negative predictive values compared with open biopsy cultures.[50]

Resolution of clinical scenario

- Serum indices including CRP, ESR, WBC, and serum IL-6 have poor ability to detect the presence of infection in shoulder PJI.
- IL-6 and alpha defensing synovial fluid markers are highly accurate, and synovial fluid IL-6 appears to be more sensitive than alpha defensin.
- There is currently no clinical evidence to suggest that PCR has utility in the diagnosis of shoulder PJI.
- MALDI-TOF MS has potential in the diagnosis of shoulder PPI, but there is currently little evidence to support its use.

- LE has demonstrated poor accuracy in the diagnosis of shoulder PPI.
- Synovial fluid leukocyte counts are typically normal and synovial fluid for aspiration is often absent; current evidence suggests that neither is reliable.
- Studies on frozen section demonstrate that in most cases, there is no evidence of inflammatory response on histologic examination.
- There is little evidence that Tc-labelled leukocyte scanning has utility as a diagnostic modality in shoulder PPI due to paucity of the literature.
- Preoperative tissue cultures obtained by arthroscopy correlate highly with intraoperative cultures.

Question 3: In patients with shoulder PJI, does a two-stage revision result in lower reinfection rates compared with one-stage revision?

Rationale

Successful eradication of shoulder PJI lends itself to considerable morbidity including a lengthy treatment course and the need for multiple surgical procedures. If a one-staged revision has comparable clinical results and infection eradication rates as a two-stage procedure, this treatment approach would be of significant benefit to patients.

Clinical comment

The potential risks of multiple-staged surgical procedures in patients with prosthetic shoulder arthroplasty must be

weighed against the potential benefits of improved infection eradication rates and implant durability. Given the known difficulty of successful eradication of PJI with implant retention, removal of implants followed by surgical debridement and intravenous antibiotics is generally recommended. The potential benefits and success of immediate prosthetic reimplantation at the time of index revision compared to a staged strategy remains unknown.

Available literature and quality of the evidence

Multiple studies exist reporting the clinical results of the management of shoulder PJI for both one- and two-staged procedures. All series are retrospective, consist of nonstandardized treatments and the majority lack control groups. The recommended treatment is inconclusive based on current level III/IV evidence.

Findings

Revision surgery performed in two stages theoretically maximizes the chance of complete infection eradication; however, it is associated with the morbidity of multiple surgeries and the potential for poorer clinical outcomes given the deleterious effects on the bone and soft tissues of the shoulder. Two-staged surgery typically involves placement of an antibiotic Prostalac cement spacer and a course of intravenous antibiotics with eventual reimplantation of the prosthesis.

Two retrospective studies have compared the results of single and two-stage revisions for the treatment of shoulder PJI. In the first (level IV) series, 22 shoulders were treated with removal of the prosthesis, extensive debridement, an intravenous antibiotic course, and either immediate reimplantation (n = 10) or a stage reimplantation (n = 12).[55] The authors noted no recurrence of infection in

either group and no significant difference in final active range of motion, American Shoulder and Elbow Surgeons (ASES) scores, or Visual Analog Scale (VAS) pain scores between groups. Recently, in a level III study, 79 cases of shoulder PJI were treated with either one-stage revision (n = 45), two-stage revision(n = 19) or debridement with incomplete component exchange (n = 15).[56] Revision for infection was significantly less likely in the one-stage revision (4%) compared to the two-stage (21%) and partial revision (27%) shoulders. The authors noted the groups were similar in all characteristics. The rate of noninfectious complications and the improvements in shoulder active range of motion (113–137) and ASES scores (60–68) were similar between groups.

Resolution of clinical scenario

- There is no clear advantage of two-stage compared to one-stage revision arthroplasty for the treatment of shoulder PJI.
- The decision between one and two-staged surgery should consider patient and shoulder related variables including patient medical co-morbidities, the quality of remaining bone stock and associated soft tissues, and the type of infectious organism.

Summary of answers

- Antibiotic prophylaxis with a first-generation cephalosporin, topical skin treatments prior to admission, and the use of a chlorhexidine-based solution at the time of surgery reduces positive culture rates, but the role of either intervention in reducing PJI is unproven. There is weak evidence for the use of local

antibiotics at the time of routine primary shoulder arthroplasty for the reduction of PJI.

- Based on limited level II evidence, synovial fluid IL-6 and alpha defensin appear to be highly accurate in the detection of infection preoperatively compared with arthroscopic tissue biopsy. The main limitation of this approach appears to be a paucity of synovial fluid.
- There is no advantage based on current level III evidence that two-stage revision yields better functional outcomes or improved infection eradication rates than one-stage revision.

Ankle Osteoarthritis

Rosa Busquets MD PhD[1] and Andrea Sallent MD[1]
Foot and Ankle Division, Hospital Vall d'Hebron, Barcelona, Spain

Clinical scenario

- A 54-year-old physically active male presents with painful post-traumatic ankle osteoarthritis. No osteoarthritis is observed in the adjacent hindfoot joints.
- He sustained a bimalleolar fracture more than 20 years ago, which was surgically treated, and has been pain-free up until now.
- Conservative treatment has failed and the patient seeks surgical options.

Top three questions

1. In patients with ankle osteoarthritis, does age predict different outcomes for ankle fusion (AF) versus total ankle replacement (TAR)?
2. For patients with ankle osteoarthritis, what is the best evidence to assess for AF or TAR according to the underlying cause of arthritis?
3. For patients with ankle osteoarthritis who are treated surgically, how do medium- and long-term outcomes compare between AF and TAR?

Question 1: In patients with ankle osteoarthritis, does age predict different outcomes for ankle fusion (AF) versus total ankle replacement (TAR)?

Rationale

AF or TAR should be reserved for cases when joint-preserving procedures have failed or cannot be performed.[1] Traditionally, it has been recommended that young, active, high-demand patients with ankle arthritis may be better candidates for AF than for TAR, which causes minimal limitations and activity restrictions.[2] According to a review, age is a major criterion when considering AF versus TAR.[3]

Clinical comment

Age is probably one of the most important criteria when choosing between AF and TAR, as there is evidence suggesting that age substantially affects the outcomes of TAR.[3] Young patients generally have higher demands in terms of functional outcomes, return to work, return to sports, etc. According to the literature, TAR should mostly be considered in patients over 50 years.

Available literature and quality of the evidence

Several level II and III meta-analyses and reviews, especially national registries are available to answer this question.[4–9] To our knowledge, there is one randomized controlled trial (RCT) currently registered, with results pending.[10]

Findings

Currently, the RCT TARVA (total ankle replacement vs arthrodesis) is to our knowledge the first RCT and has completed the data collecting, although results have not yet been published.[10]

A level II prospective controlled trial comparing outcomes following TAR versus AF found that the arthroplasty group was, on average, six years older than the arthrodesis group.[9] A meta-analysis of comparative studies between TAR and AF found that age at implantation of the compared studies was younger in the AF group; however, no conclusions were drawn regarding age and outcomes.[4] In a level IV systematic review of the literature (therapeutic studies), patients with TAR were older than patients with AF (mean 58 years vs 50 years, respectively).[7]

Spirt et al., in a retrospective review, reported that age was the only significant predictor of failure and reoperation after TAR.[6] The five-year reoperation rate with failure was 80% for all patients and 89% for patients over 54 years. The authors concluded that every one-year increase in age at implantation of the TAR resulted in a 3.5% decrease in failure hazard.[6]

A Swedish report with 780 TARs showed that patients under 60 years had a 1.8 times higher chance of revision compared to older patients; however, the difference was only found to be significant for women.[5] The same Swedish study group associated younger age with osteolysis, loosening, and therefore increased risk of revision surgery. However, other national registries, such as the Finnish and the New Zealand Register, have not found a relationship between age and survival rate.[11,12]

In an epidemiological study of TAR by Seaworth et al.,[13] younger age at implantation was found to be a risk factor for failure (patients <60 years). Similarly, the Swedish

Ankle Arthroplasty Register observed that lower age at surgery implied an increased risk of undergoing revision surgery.[8]

In a recent case series, the authors compared five-year outcomes of TAR according to age or diagnosis.[14] They observed that the age group of patients <60 years had significantly worse mean Foot and Ankle Outcome Score (FAOS) scores both preoperatively and at five years.

Lower age at surgery has also been associated with higher risk of revision in a study of outcomes with long-term follow-up after TAR.[15] However, TAR is occasionally proposed for younger people in cases of rheumatoid arthritis, bilateral ankle osteoarthritis or low activity level.[3]

Resolution of clinical scenario

- Both AF and TAR should be considered only when conservative measures have failed and other joint-preserving options cannot be offered.
- AF remains a good surgical option for end-stage ankle arthritis.
- Younger age should remain a contraindication for TAR; however, rather than considering a specific age group as a limit for AF, the desired activity level and the patient's activity demands should be more important.
- TAR could be considered in younger patients with rheumatoid arthritis or other inflammatory diseases.
- If considering TAR for a younger patient, an explanation of possible future revisions should be addressed.
- TAR in younger patients should also be considered in cases of bilateral ankle arthritis.

Question 2: For patients with ankle osteoarthritis, what is the best evidence to assess for AF or TAR according to the underlying cause of arthritis?

Rationale

The underlying cause of ankle arthritis is considered a major criterion to indicate AF versus TAR, and is closely related to age.[3] As opposed to hip or knee osteoarthritis, a minority of ankle arthritis is primary, and is most frequently secondary to trauma (65–80%) and rheumatoid disease (12–15%).[16]

Clinical comment

In cases of ankle arthritis secondary to trauma, the surgeon may have to deal with deformities in varus or valgus, loss of bone stock, or severe ankylosis.

Higher revision and reoperation rates have been reported for patients with posttraumatic ankle arthritis undergoing a TAR.[17] Satisfaction rates among these patients are lower than in patients with primary or rheumatoid arthritis, likely due to a younger age, higher demand, and previous surgeries.

Available literature and quality of the evidence

No RCTs have been performed regarding diagnosis and TAR or AF. Survivorship studies, level II and III prognostic studies, and comparative studies have been found regarding the subject that matters.[7,14,18–22]

Findings

A systematic review observed that rheumatoid arthritis was the primary indication for TAR (39%), whereas post-traumatic arthritis was the primary indication for the arthrodesis (57%).[7] Arthroplasty clinical outcomes have been shown to be poorer in patients with post-traumatic arthritis than in those with rheumatoid arthritis.[2]

Regarding post-traumatic arthritis, the extent of residual deformities and instabilities that can be corrected with TAR is increasing.[1,3,23,24] However, coronal plane deformity exceeding 10–15° remains a contraindication to TAR as implant failure is correlated with increasing preoperative deformity. In fact, survival rates are less than 50% for patients with significant preoperative varus or valgus deformity and almost 90% for patients with neutral preoperative alignment.[3,19] Realignment hindfoot osteotomies or arthrodesis and supramalleolar osteotomies during TAR are recommended to prevent early TAR failure.[3]

A retrospective single-center study reported on the five-year outcomes of TAR in relation to type of arthritis.[14] Preoperatively, no differences were observed according to the type of arthritis, although patients with rheumatoid arthritis showed a trend toward higher baseline scores. Interestingly, this group was the only group not to experience a significant increase in their scores at five years.

A comparative prospective study comparing TAR after post-traumatic or primary arthritis concluded that clinical and radiographic outcomes were comparable; however, the incidence of complications was higher in the post-traumatic group.[18] This group required more additional surgical procedures than the primary group (i.e. deformity correction, instability).

A level III therapeutic study compared medium- and long-term outcomes of TAR according to preoperative deformity.[22] Results were found comparable between groups postoperatively, as long as a good neutral alignment was achieved. Varus and valgus malalignment up to 20° were included.

A level III prognostic study analyzing TAR outcomes in patients with rheumatoid arthritis and patients with noninflammatory arthritis found similar outcomes between the two groups.[20] The overall pain and disability scores were significantly worse for patients with rheumatoid arthritis before surgery, but were similar following surgery.

Van Heiningen et al. performed a systematic review of observational and noncontrolled clinical trials regarding medium-term outcomes in patients with rheumatoid arthritis following AF or TAR.[21] Authors concluded that, despite the methodological quality of the studies was low, both procedures showed clinical improvement and neither procedure was superior to the other. The failure rate was 11% for TAR and 12% for AF.

Resolution of clinical scenario

- Patients with post-traumatic arthritis and concomitant deformity may be more suitable for AF than TAR.
- In patients with preoperative deformity undergoing arthroplasty, surgical correction should be addressed before or during in order to reduce failure rate.
- TAR has shown good clinical outcomes for patients with rheumatoid arthritis.

Question 3: For patients with ankle osteoarthritis who are treated surgically, how do medium- and long-term outcomes compare between AF and TAR?

Rationale

The available data on outcomes of AF and TAR are mostly based on retrospective, uncontrolled case series from single institutions.

Clinical comment

The lack of knowledge of the medium- and long-term outcomes of AF and TAR limits the ability of physicians to counsel their patients appropriately when they are faced with the decision of whether to undergo one procedure or another.

Available literature and quality of the evidence

No RCT was found. Several level II, III, and IV therapeutic and systematic reviews were gathered for their findings.[5,7,15,25–28]

Findings

A multicenter study (level II therapeutic study) performed in Canada evaluated medium-term results of TAR and AF (mean follow-up 5.5 years).[26] Of the 388 ankles included, 281 had a TAR and 107 an AF, and 7% of the arthrodeses and 17% of the replacements underwent revision surgery. The complication rate was also higher in the replacement group (19 vs 7%, respectively).

The systematic review by Haddad et al. described medium- and long-term outcomes of TAR and AF, including a total of 852 TAR and 1262 AF.[7] The five-year implant survival rate was 78 and 77% at 10 years. The revision rate was slightly higher for the arthrodesis group (9 vs 7%).

Regarding AF, periarticular degeneration is one of the most important downsides. Long-term studies of ankle arthrodesis have suggested accelerated periarticular joint degeneration; however, no definite causation has been proved.[25,27] The pathophysiology may be similar to adjacent-segment disease seen in the spine.

Coester et al. performed a 22-year follow-up in AF.[25] Authors observed a consistently more severe osteoarthritis in the adjacent hindfoot and midfoot joints. Significant differences between the two sides were found regarding overall activity limitation, pain, and disability.

The Swedish Ankle Register reported on 780 cases of TAR along 10 years of follow-up.[5] Twenty-two percent of patients had been revised and the estimated overall five-year survival rate was 0.81 (95% confidence interval [CI]: 0.79–0.83) and the 10-year survival rate was 0.69 (95% CI: 0.67–0.71). Clough et al. found TAR implant survival at 15.8 years was 76%.[28]

In a therapeutic level IV study with 77 TARs, long-term follow-up (11–15 years) of the Scandinavian total ankle replacement (STAR) was analyzed.[15] While the medium- to short-term results for the same sample of patients was encouraging, authors found that long-term survivorship of the same cohort was considerably inferior. Thirty-eight percent had a revision of at least one component, and implant survival at 10 years was 70.7% and 45.6% at 14 years.

Resolution of clinical scenario

- There is a lack of RCTs in order to draw clearer conclusions.
- Ankle arthrodesis is associated with periarticular joint degeneration in a long-term follow-up; however, the clinical relevance is not clear.
- TARs have good clinical outcomes but higher revision rates. Younger patients undergoing a TAR should be advised that chances are they will have a revision surgery.

Summary of answers

- Age must be taken into account when considering AF (generally younger patients) or TAR.
- AF should be recommended for patients with post-traumatic arthritis, especially when deformity is associated. Patients with rheumatoid arthritis should be considered for TAR.
- Currently, evidence regarding AF vs TAR is limited, and further RCTs should be performed to draw clearer conclusions.

Osteoarthritis of the 1st Metatarsophalangeal Joint

Seper Ekhtiari MD MSc[1] and Waleed Kishta MD PhD[1]
Division of Orthopaedic Surgery, Department of Surgery, McMaster University, Hamilton, ON, Canada

Clinical scenario

- You see a 45-year-old female patient in your office with a painful 1st metatarsophalangeal (MTP) joint. She is quite symptomatic, and after examination and radiographs, you confirm the diagnosis of 1st MTP arthritis.
- The patient is an active duty military service member who continues to be physically active both at work and recreationally. She would like to continue to be active for many years to come.
- You consider which nonoperative treatment you can offer to this patient, and if any are particularly more effective than others.
- You also think ahead to what will happen if the patient fails nonoperative management. You wonder which type of surgery would be the best option for her to continue her current lifestyle.

Top three questions

1. In patients with 1st MTP joint osteoarthritis (OA), do any nonoperative treatment modalities result in better

functional outcomes compared to other nonoperative treatment modalities?

2. In patients undergoing surgery for 1st MTP OA, does arthroplasty result in better functional outcomes compared to arthrodesis?
3. In patients undergoing surgery for 1st MTP OA, do some procedures offer faster or higher rates of return to activity compared to other procedures?

Question 1: In patients with 1st MTP joint osteoarthritis (OA), do any nonoperative treatment modalities result in better functional outcomes compared to other nonoperative treatment modalities?

Rationale

Nonoperative management is the first-line treatment for most joints affected by OA, including the 1st MTP joint. It is important to understand which nonoperative treatment modality, if any, is most effective.

Clinical comment

Success rates of over 50% have been reported previously in the literature for nonoperative management of 1st MTP OA, also known as *hallux rigidus*.[1] Many different nonoperative treatments exist, including nonsteroidal anti-inflammatory drugs (NSAIDs), intra-articular injections, orthotics, and shoe modifications.[2] Given that none of these treatments will reverse or cure the disease, it is important to understand what the typical and best-case scenarios are for

each of these modalities. This will help clinicians to have honest and value-based discussions with their patients about nonoperative management.

Available literature and quality of the evidence

A single systematic review of levels I–IV evidence (level IV) summarizes the vast majority of evidence on nonoperative treatment of 1st MTP OA. King et al. reviewed 11 studies on this topic, including one randomized controlled trial (RCT), two level II studies, and one level IV study.[3] The review included a total of 1600 patients. The modalities included in this review were intra-articular injections, manipulation and physical therapy, and orthotics and footwear modifications. There is no clinical evidence for the use of oral NSAIDs in 1st MTP OA; in fact, a recent review on this topic extrapolated from hip and knee OA evidence.[4]

Findings

The systematic review by King et al. found that, overall, the evidence was consistent in supporting the efficacy of physical therapy and footwear modification/orthoses, but more mixed when it came to intra-articular injection in terms of treating 1st MTP OA.[3]

In terms of modification in footwear, insoles, and orthotics, there was only level III and IV evidence available. Success of orthoses was found to be 55% in a large study of 772 patients.[1] Similarly, 63% of patients in a longitudinal case series with over 14 years of follow-up reported that they were satisfied with footwear modification as a first-line therapy and would make the same decision again given the opportunity.[5] Overall, King et al. made a Grade C recommendation (poor level evidence with consistent findings) for the use of orthotics or footwear modifications in the treatment of 1st MTP OA.[3]

Physical therapy is another mainstay in the treatment of most forms of OA. King et al. found two studies looking at the treatment of 1st MTP OA with physical therapy and/or manipulation.[3] A downgraded RCT (level II) which used birthdates to randomize patients to physical therapy or control groups found that the intervention group had significantly better range of motion (42.7° ± 7.8° vs 14.4° ± 8.0°, p <0.001), flexor hallucis longus strength (3.5 ± 1.0 kg vs 0.7 ± 0.4 kg, p <0.001), and pain reduction (6.4 ± 1.3 vs 2.6 ± 1.1 kg, p <0.001).[6] A small retrospective case series (level IV) found that duration of pain relief after manipulation was dependent on radiographic OA grade according to the Karasick and Wapner classification (Grades 1–3, 1 being least severe). Patients with Grade 1 OA had symptom relief for a median of six months, compared to only three months for Grade 2 and no relief for Grade 3.[7] Overall, King et al. also assigned a Grade C recommendation (poor level evidence with consistent findings) for physical therapy/manipulation.[3]

There were six studies looking at various types of injectable therapies for 1st MTP OA. King et al. found that the higher-quality evidence available for injection therapy (levels II and III) suggested either no benefit for injection, or a benefit that lasted three months or less.[3] In their meta-analysis of hyaluronic acid injection studies specifically, they did find that the standardized mean difference (SMD) showed a benefit for both rest pain (SMD = −0.52; 95% confidence interval [CI]: −0.77 to −0.28) and walking pain (SMD = −0.44; 95% CI: −0.83 to −0.05) with low heterogeneity (I^2 = 10.2%). Interestingly, despite the results of this meta-analysis, King et al. made a Grade B recommendation (fair evidence with consistent findings) *against* injection as an effective treatment for hallux rigidus.[3]

Resolution of clinical scenario

- Overall, there is scarce, low-quality evidence for nonoperative treatment of 1st MTP OA.
- Based on consistent findings among level II–IV evidence, physical therapy, footwear modification, and orthoses *are* effective in providing symptom relief in the treatment of 1st MTP OA. In addition, these therapies may be more effective in patients with milder disease.
- Evidence for injection therapy in 1st MTP OA is mixed, with some moderate-quality evidence suggesting no benefit, especially beyond three months. Lower-quality evidence suggests there may be a benefit, particularly when it comes to hyaluronic acid injection.

Question 2: In patients undergoing surgery for 1st MTP OA, does arthroplasty result in better functional outcomes compared to arthrodesis?

Rationale

Many different surgical options exist for the treatment of 1st MTP OA. Broadly, these can be categorized into joint preservation surgery (e.g. cheilectomy, Valenti procedure), arthroplasty (e.g. hemiarthroplasty, implant arthroplasty, interposition arthroplasty), and arthrodesis. Traditionally, arthrodesis and arthroplasty have been the primary treatment options for end-stage 1st MTP OA that is not responsive to nonoperative or joint preservation treatments.

Clinical comment

Similar to wrist and ankle OA, 1st MTP OA that is not suitable for nonoperative or joint preservation surgeries may be amenable to either arthrodesis or arthroplasty.[8,9] Given that arthrodesis can actually provide reasonable function in these joints, and that arthroplasty options are not as well developed as those for knee or hip OA, it is important to understand the evidence behind these various surgical options in order to help patients and surgeons make the most appropriate decision on a case-by-case basis.

Available literature and quality of the evidence

There are four systematic review and meta-analyses (levels III–IV) that summarize the evidence on arthroplasty versus arthrodesis for 1st MTP OA. Patel et al., in their systematic review and meta-analysis of 15 studies (340 patients), compared interposition arthroplasty to arthrodesis (level IV).[10] A systematic review by Stevens et al. analyzed 33 studies, including a meta-analysis of 12 studies looking at total joint arthroplasty versus arthrodesis (level IV).[11] Finally, there was a systematic review and meta-analysis of 11 studies (level IV) and a retrospective cohort study (level III) of 102 patients who had undergone surgery for 1st MTP OA.[12]

Findings

In their systematic review and meta-analysis (level IV) on interposition arthroplasty compared to arthrodesis, Patel et al. included 15 studies, with a total of 340 patients (369 feet). The patients had a mean age of 57.4 with a mean follow-up of 38.1 months. All studies were either level III or level IV evidence. The American Orthopaedic Foot & Ankle Society (AOFAS) score was the most commonly used (14

studies). Mean AOFAS score increased from a pooled preoperative mean of 41.4 (range: 25–63.9) to 83.2 (71.6–93.6) postoperatively. As expected, range of motion was also quite good postoperatively, with increases in dorsiflexion from 21.3° to 42.0°. Among patients asked about satisfaction, 87% were happy and would choose the same surgery again given the opportunity. Importantly, all patients who failed interposition arthroplasty and were converted to arthrodesis had good or excellent results.[10] Thus, the authors felt that interposition arthroplasty provided a comparable alternative to arthrodesis, while not "burning any bridges" with a view to future arthrodesis.

In the most comprehensive review to date on this topic, Stevens et al. completed a systematic review of 33 studies, which included 1160 patients (1296 feet) undergoing arthrodesis or total joint replacement for 1st MTP OA (level IV).[11] Overall, they found that while both interventions improved patient-reported outcomes compared to preoperative status. The results of 12 studies were pooled in a meta-analysis looking at the AOFAS-HMI (American Orthopaedic Foot & Ankle Society hallux metatarsophalangeal interphalangeal) and Visual Analog Scale (VAS) pain scores. This analysis revealed that the treatment effect of arthrodesis was significantly greater than arthroplasty for both AOFAS-HMI (43.8 vs 37.7 points, $p < 0.0001$) and VAS pain scores (6.6 vs 4.7, $p < 0.0001$). The authors concluded that this represented a significant advantage in favor of arthrodesis.[11] It should be noted, however, that the minimal clinically important difference (MCID) for the AOFAS-HMI has been reported at ranging from 7.9 to 30.2,[13] and for the VAS in hallux surgery ranging from 1.8 to 5.2.[14] Thus, only the VAS treatment effect would fall within the MCID, and even then, it would be at the lower end of this range.

In their systematic review and meta-analysis of 11 studies (level IV), Stibolt et al. reviewed a total of 323 patients (350 feet) undergoing hemiarthroplasty, who were being compared with either controls, arthrodesis, or total joint arthroplasty.[15] All studies reported improvement in AOFAS scores regardless of surgical technique. In their meta-analysis, they found a greater treatment effect for hemiarthroplasty versus total joint arthroplasty (mean difference −51.5 vs −40.6, respectively). In contrast, range of motion was comparable for the two groups (24.5 for hemiarthroplasty vs 24.8 for total joint arthroplasty), as were VAS pain scores (6.1 for hemiarthroplasty and 6.3 for total joint arthroplasty). Finally, Beekhuizen et al. performed a retrospective cohort (level III) directly comparing hemiarthroplasty with arthrodesis in 78 patients with a mean follow-up of 8.3 years (range 5–11.8).[12] They found that patients undergoing hemiarthroplasty had significantly better AOFAS-HMI scores (72.8 ± 14.5 vs 89.7 ± 6.6, $p = 0.005$), and pain scores (30.9 ± 9.7 vs 37.4 ± 4.4, $p < 0.001$) than arthrodesis patients. Furthermore, on satisfaction and likelihood to recommend surgery scales (lower score = better), hemiarthroplasty patients did better than arthrodesis (satisfaction: 2.5 ± 1.2 vs 1.3 ± 0.6, $p < 0.001$; recommendation: 1.7 ± 0.8 vs 1.0 ± 0.2, $p < 0.001$).

Resolution of clinical scenario

- Overall, despite the fact that arthrodesis has long been the gold standard operative treatment for end-stage 1st MTP OA, numerous arthroplasty options exist including interposition arthroplasty, implant arthroplasty, and hemiarthroplasty.
- All arthroplasty options are successful in achieving improvements in pain, patient-reported outcomes, and patient satisfaction (level III–IV).

- On direct comparison, hemiarthroplasty appears superior to arthrodesis with long-term follow-up (level III). In contrast, arthrodesis appears inferior to total joint arthroplasty (level IV) and comparable to interposition arthroplasty (level IV).

Question 3: In patients undergoing surgery for 1st MTP OA, do some procedures offer faster or higher rates of return to activity compared to other procedures?

Rationale

OA of the 1st MTP joint can affect patients at a wide range of ages and activity levels. In patients who are active or hoping to return to an active lifestyle, it is important to understand which surgical options provide the greatest likelihood of a timely return to activity.

Clinical comment

Surgical procedures for 1st MTP OA are most often performed for middle-aged patients, and thus rarely considered in the realm of sports surgery. Nonetheless, as a major weightbearing joint of the forefoot, the 1st MTP can play an important role in patients being able to meet their various workplace and recreational activities. As with any arthritic joint, it is important to consider and discuss realistic postoperative expectations and timelines with patients.

Available literature and quality of the evidence

Two retrospective case series (level IV) and one retrospective cohort (level III) study reported on the rates and timelines for return to work and sport in patients undergoing surgery for 1st MTP OA. The retrospective cohort study, discussed above, is a study of patients undergoing hemiarthroplasty versus arthrodesis (level III).[12] The other two studies are retrospective case series with a total of 160 patients.[16,17]

Findings

In the previously discussed study, Beekhuizen et al. found that all patients undergoing hemiarthroplasty or arthrodesis returned to work (level III), with no significant difference in time to return between the two procedures (6.2 ± 6.2 weeks vs 4.3 ± 2.4 weeks, $p = 0.202$).[12] Interestingly, they found that hemiarthroplasty allowed for significantly faster return to sport than arthrodesis (6.7 ± 4.6 weeks vs 11.7 ± 5.1 weeks, $p = 0.002$), though there was no significant difference in rate of return (63% vs 54%, $p > 0.05$).[12]

Da Cunha et al. assessed return to sport in young patients (mean age 49.7, range 23–55) undergoing 1st MTP arthrodesis (level IV).[16] They found that, postoperatively, patients returned to 45% of their preoperative activities within six months, and reached maximal level of participation in 88.6% of activities. Ninety-six percent of patients were satisfied with their postoperative level of return to sport.[16] Jones and Sweet specifically compared return to work outcomes in active duty military service members undergoing three different procedures (cheilectomy, decompressive osteotomy, and arthrodesis) (level IV).[17] They found the highest rate of return to duty with decompressive osteotomy (94.4%) as compared to cheilectomy (80.8%) and arthrodesis (78.8%). Return to

activity was fastest for cheilectomy (12.9 weeks), followed by decompressive osteotomy (19.4) and arthrodesis (20.8 weeks). Subjective satisfaction was not significantly different between the three groups.

Resolution of clinical scenario

- There are generally high rates of return to work and sport regardless of the specific procedures performed for 1st MTP OA.
- Arthrodesis allows for reliable and timely return to activity, though decompressive osteotomy may be even better in this regard. The potential need for future surgery and time missed should be taken into account when deciding between the two.

Summary of answers

- Physical therapy, footwear modification, and orthotic use are supported by weak evidence for the first-line treatment of 1st MTP OA. Nonetheless, nonoperative options should always be exhausted first.
- There is no definitive answer as to which surgical procedure provides the best outcomes, though direct comparison does suggest an advantage for hemiarthroplasty over arthrodesis.
- Most patients return to work and/or sport in a timely manner following 1st MTP OA surgery. Decompressive osteotomy may give patients the best possible chance at this goal.

Hallux Valgus

Sebastián Drago Perez MD[1,2] and Cristian Ortiz Mateluna MD[3]
[1]Department of Orthopedic Surgery, Hospital del Trabajador, Santiago, Chile
[2]Faculty of Medicine, Universidad de los Andes, Santiago, Chile
[3]Foot and Ankle Center, Orthopedic Department, Clínica Universidad de los Andes, Santiago, Chile

Clinical scenario

- A 45-year-old woman presents with medial sided forefoot pain.
- This has worsened over the last few years. She is otherwise healthy and practices trail running frequently.
- On examination she has a bunion and some hypermobility of the 1st tarsometatarsal joint, with no metatarsalgia. She doesn't have clawing of her toes.
- On x-rays, she has severe hallux valgus (HV), with HV angle of 48° and intermetatarsal angle of 18°. There is no evidence of 1st tarsometatarsal sag on x-rays.

Top three questions

1. In adult patients with HV, does percutaneous correction result in quicker recovery versus open surgery?

2. In adult patients with HV, does long chevron (LC) osteotomy result in fewer complications versus scarf (SC) osteotomy?
3. In adult patients with severe HV, does modified Lapidus result in better functional outcomes than 1st metatarsophalangeal joint arthrodesis (MTP)?

Question 1: In adult patients with HV, does percutaneous correction result in quicker recovery versus open surgery?

Rationale

Percutaneous surgery for HV is performed through the smallest possible incision, usually punctate incisions. Performing percutaneous surgery requires a combination of tactile sensation, clinical appearance, and fluoroscopic imaging to evaluate the correction achieved.

Clinical comment

The patient could have smaller wounds, and faster recovery, with percutaneous surgery, but given that it is technically more difficult, it is unclear which choice is optimal.

Available literature and quality of evidence

Three randomized controlled trials (RCTs) exist on this topic, comparing percutaneous versus open surgery for HV.

Findings

Radwan et al. randomized 53 patients (64 feet) with mild to moderate HV. Interventions were percutaneous distal

metatarsal osteotomy (modified Bosch osteotomy) (29 feet), and distal chevron osteotomy (31 feet).[1] Operative time was seven minutes shorter in the percutaneous group. There was no difference in time to union, hallux valgus angle (HVA), intermetatarsal angle (IMA), range of motion of the 1st MTP, pain, and American Orthopaedic Foot & Ankle Scores (AOFAS). They did not evaluate recurrence (I).

Kaufmann et al. performed an RCT comparing open chevron (OC) versus percutaneous V-shaped osteotomy (PVO).[2] There were 22 and 25 cases, respectively. There was no difference in pre- and postoperative HVA, IMA, or range of motion between the groups. There was significantly better patient satisfaction in the PVO osteotomy at 12 weeks' postsurgery. At six weeks and nine months, patient satisfaction did not show any significant differences. One patient of each group reported poor satisfaction. Complications in the OC group were two hardware removals and one case of hallux varus that did not need revision surgery. Complications in the PVO group consisted in 12 cases of soft tissue irritation, caused by the Kirschner wire (K-wire) which was removed. Recurrence occurred in three feet of the OC group and one foot of the PVO group; these were mild and did not require revision (level I).

Lam et al. reported an RCT of 51 patients undergoing surgical correction of HV, comparing scarf-akin (SCA) osteotomies versus percutaneous modified chevron-akin (PECA) osteotomy.[3] There were 26 subjects (27 feet) and 25 subjects (33 feet), respectively. Operative time was four minutes shorter in the PECA group, pre- and postoperative IMA and HVA were not significantly different between groups. The AOFAS scores did not show any significant differences between the two groups. In the SCA group,

there were two subjects who developed mild second metatarsalgia postoperatively. This was managed successfully with orthotics, with no revision required. In the PECA group, six required screw removal. This complication was almost completely eliminated when the authors started using the internal oblique view to confirm that the screw was fully engaged in the bone at the time of screw insertion (level I). Two other studies are consistent with these findings.[1,3]

Resolution of the clinical scenario

- There is no demonstrated difference in the rehabilitation time comparing open versus percutaneous surgery for HV correction (level II).
- Radiologic outcomes and functional scores are similar between patients (level I).
- Percutaneous surgery is 4–7 minutes shorter than open surgery (level I).

Question 2: In adult patients with HV, does long chevron (LC) osteotomy result in fewer complications versus scarf (SC) osteotomy ?

Rationale

Chevron and SC are the most performed osteotomies for the treatment of HV. Both have good outcomes, but SC osteotomy can present a complication called *troughing* that occurs as the cortex of the dorsal half of the first metatarsal shaft collapses and wedges into the softer cancellous bone, leading to pronation and lesser metatarsal overload.

Clinical comment

The most common complication in the HV treatment is *recurrence*. Preventing complications is a key goal in the HV surgery.

Available literature and quality of evidence

Multiple RCTs have compared chevron and SC osteotomies attempting to answer this question.

Findings

Elshazly et al. performed an RCT on patients with HV and IMA between 10° and 20°.[4] Twenty-one patients underwent SC osteotomy and 22 patients underwent LC osteotomy. There was one superficial infection and one wound dehiscence in each group. There was one case of recurrence in the LC group due to a technical error of unintended valgus angulation during translation of the capital fragment leading to alteration of the distal metaphyseal articular angle (DMAA). Mean operative time was not significantly different (SC 69 minutes ± 5.59 minutes vs LC 45.8 minutes ± 8.36 minutes, p = 0.86). Pre- and postoperative HVA and IMA between groups did not show any differences. Preoperative IMA was 18.48 ± 4.5 in the SC group and 20.36 ± 3.54 in the LC group (p = 0.14), postoperative IMA was 9.24 ± 2.98 in the SC group and 9.10 ± 2.31 in the LC group (p = 0.86). HVA correction was 24.71 ± 11.96 in the SC group, and 23.64 ± 12.86 for LC group (p = 0.78) (level I).

Mahadevan et al. performed an RCT on 84 patients (109 feet) with HV and IMA between 10° and 21°.[5] They compared 46 patients (60 feet) with LC versus 38 patients (49 feet) with SC osteotomy. One case of hallux varus was identified in each group. There were no recurrences during the study period (one year). Preoperative HVA and IMA

was not significantly different (p = 0.214). Postoperative IMA was better in the LC group (5.8 ± 2.5) versus the SC group (6.9 ± 2.8, p = 0.045). Postoperative HVA was not different between groups. Patient satisfaction was improved in both groups equally (level I).

Deenik et al. performed an RCT in patients with HV, comparing 47 feet undergoing chevron (CH) osteotomy and 49 feet undergoing SC osteotomy.[6–8] In the CH group, two patients developed superficial pin tract infections. Four patients in the SC group developed a grade I complex regional pain syndrome (CRPS), while one patient in the CH group developed CRPS. Three patients in the CH group developed partial osteonecrosis of the metatarsal head, with subchondral cysts but no collapse of the metatarsal head. One of these patients was asymptomatic. After the authors modified the surgical technique of CH, protecting the plantar blood supply, there were no more cases of osteonecrosis. The final follow-up was 14 years, at which point 78% of patients in SC group and 73% of patients in CH group had recurrence of HV (p = 0.48), and only one person in the SC group had revision surgery. Compared with the preoperative measurements, the CH group retained significantly greater IMA correction (p = 0.007) than SC group. AOFAS and Short Form 36 (SF-36) scores were not different between both groups. Patients with severe HV obtained a better HVA correction with CH osteotomy (20 ± 4.6) than patients who received a SC osteotomy (11.8 ± 5.0, p = 0.01). There was no difference in the IMA correction. Operative time was five minutes faster in the CH group (level I).

Ma et al.[9] performed a meta-analysis including four publications,[5,6,8,10] comparing SC and CH. Complication rates did not show a significant difference (p = 0.39). There was no difference in HVA (p = 0.77), IMA (p = 0.97), or

AOFAS scores (p = 0.91). Publication bias for HVA, IMA, AOFAS scores, and complications were determined using Egger's test. The results indicated likelihood of publication bias (level I). There is no significant difference between SC and CH, when comparing complication rates (p = 0.39), postoperative HVA (p = 0.77), postoperative-IMA (p = 0.97) and AOFAS scores (p = 0.91).[9] At 14-year follow-up, recurrence occurs in 78% of patients undergoing SC and 73% of patients undergoing CH (p = 0.48). There is a risk of avascular necrosis when performing CH that can be controlled protecting the plantar blood supply, especially during the plantar cut.[6–8]

Resolution of clinical scenario

- SC and CH have similar complication rates (level I).
- SC and CH have similar outcomes comparing postoperative HVA and IMA (level I).
- Surgeon's preference and expertise should be considered in choosing between SC and CH (level V).

Question 3: In adult patients with severe HV, does modified Lapidus result in better functional outcomes than 1st metatarsophalangeal joint arthrodesis (MTP)?

Rationale

- Lapidus and 1st MTP arthrodesis are the procedures of choice in the treatment of severe HV.[11]

- Severe HV in adults is a challenging problem because they usually require an arthrodesis.

Clinical comment

Clear understanding of the functional outcomes is a key factor to consider which procedure to offer in patients with severe HV.

Available literature and quality of the evidence

There are no comparative studies between 1st MTP arthrodesis and Lapidus. Lapidus has been prospectively evaluated as part of a RCT comparing Lapidus versus a distal osteotomy. There is a retrospective evaluation of young patients that has shown acceptable results. On the other hand, 1st MTP arthrodesis for HV has been evaluated in three case series with acceptable results.

Findings

MacMahon et al. performed a retrospective case series of 48 patients with HV that underwent modified Lapidus procedure, with a mean age of 37.3 years old (range 14.1–49.3 years).[12] Mean follow-up was 2.8 years (range 1.0–6.1 years). Preoperatively, 40% (84/212) of the total physical activities were high impact and postoperatively 38% (80/209) were high impact. Seventy-nine percent of the patients returned to their preoperative physical activity level. Compared to preoperatively, among the 97 patient-specific sports and physical activities, patients rated 29% as less difficult, 52% as the same, and 19% as more difficult. They rated participation levels as improved in 40%, the same in 41%, and more impaired in 19%. Eighty-ne percent of patients were satisfied with their surgery regarding to return to physical activities (level IV).

Faber et al. reported an RCT comparing Hohmann procedure versus Lapidus procedure for HV.[13] Fifty-one feet had Lapidus procedure that was fixed with two 3.5 mm cortical lag screws. Mean follow-up was 111 months (87–137). Mean age was 41 years (16–63). Mean AOFAS score improved from 57.1 preoperatively, to 88.2 postoperatively at wo years, and was 78 at 10 years. In the Lapidus group 83% of the procedures were considered satisfactory by the patients, 4% were uncertain, and 13% were considered unsatisfactory. The mean pain score on the VAS (Visual Analogue Scale) improved. Complications in the Lapidus group were: 4% superficial infections; 4% CRPS cases; 12% non-union with 2% requiring revision; 10% presented recurrence, 2%, an acute recurrence, required revision; 6% cases of hallux varus with no re-operations; 4% transfer metatarsalgia, with no re-operations (level II).

Coughlin et al. performed a retrospective report of 16 patients (21 feet) with severe HV that underwent 1st MTP arthrodesis.[14] They used a mini fragment plate and trans-articular K-wire or screw. Their mean age was 71 years old (range 60–82 years). Average follow-up was 8.2 years. Patient satisfaction was excellent in 80% of feet, and good in 20%. No foot was rated as fair or poor. After surgery, 12 patients (10 feet) were able to wear conventional or fashionable shoes, while six patients (nine feet) required shoe inserts or comfort wear. No patients required custom shoes or bracing. All of the patients maintained equal or increased level of activity compared to preoperatively. The average AOFAS was 84 out of 90 points. Patients were advised that it is difficult to tolerate heel heights greater than 1.5 inches. Complications were: 14% nonunion, 29% superficial infection, and 10% hardware removal (level IV).

Tourné et al. reported a retrospective study of 32 patients (40 feet) with HV with a mean age of 67 years old (range

57–78 years).[15] Preoperative HVA was 43° (range 26–68°). Preoperative IMA was 15° (range 7–25). They treated them with 1st MTP arthrodesis using crossed screws and quarter-inch tubular screwed plate. Sixty-eight percent of the patients were very satisfied, 27% were satisfied, and 5% were unsatisfied. Normal gait regardless of surface was seen in 35 cases (86%), three cases (7%) had restrictions on uneven surfaces, and 7% had difficulties on flat surfaces. Complications were: inflammatory scar, deep venous thrombophlebitis. There were no nonunions (level IV).

Ellington et al. performed a retrospective evaluation of 145 patients (155 feet) that underwent 1st MTP arthrodesis.[16] They used a nonlocking plate with trans-articular screw. Fifty-four percent of the patients presented with HV, and 12.1% of patients underwent revision surgery. Mean age was 61.4 years (range 24.5–79.8 years). Mean follow-up was 61 weeks (range 27–127 years). Technique included dome-shaped reamer preparation, followed by fixation with trans-articular screw and nonlocking plate. Eighty-three percent of patients reported good to excellent results. Postoperative AOFAS score was 79.7 (out of 90). Complications were as follows: 12% nonunions, 11% superficial infections, 4% deep infection, others 4% (level IV).

Resolution of clinical scenario

- Lapidus (level II) and 1st MTP arthrodesis (level IV) lead to 80–90% of patient satisfaction in the treatment of severe HV. Populations included in Lapidus studies are younger (mean 40 years old) than 1st MTP arthrodesis studies (mean 69 years old). These are effective and predictable procedures for the treatment of severe HV.

- Nonunion and complication rates are comparable between these two procedures (level IV).

Summary of answers

- There is no difference in the rehabilitation time comparing open versus percutaneous surgery for HV correction (level I).
- Percutaneous surgery is 4–7 minutes shorter than open surgery for HV (level I).
- SC and CH have similar outcomes and complication rates (level I), surgeon's preference and expertise should be considered in choosing between SC and CH (level V).
- Lapidus in young adult patients (level II) and 1st MTP arthrodesis in older patients (level IV) have similar outcomes for severe HV.

Cavovarus Foot

Sebastián Drago Perez MD[1,2] and Cristian Ortiz Mateluna MD[3]
[1]Department of Orthopedic Surgery, Hospital del Trabajador, Santiago, Chile
[2]Faculty of Medicine, Universidad de los Andes, Santiago, Chile
[3]Foot and Ankle Center, Orthopedic Department, Clínica Universidad de los Andes, Santiago, Chile

Clinical scenario

- A 35-year-old man presents with ankle instability and overload of the lateral border of his foot.
- This has worsened over the last few years. He is otherwise fit and well. His father had a similar problem, with a similar foot shape.
- On examination he has bilateral high arches and varus heels with callosities under the lateral borders of his feet. He has some clawing of the toes.

Top three questions

1. In patients with cavovarus foot and Charcot-Marie-Tooth (CMT), does physiotherapy result in better functional scores compared to no physiotherapy?
2. In patients undergoing peroneus longus (PL) to peroneus brevis (PB) tendon transfer, does running locked suture result in improved construct strength compared to vertical mattress sutures?

3. In patients undergoing lateralizing calcaneal osteotomy, does prophylactic tarsal tunnel release result in less neurologic deficit compared to no tarsal tunnel release?

Question 1: In patients with cavovarus foot and Charcot-Marie-Tooth (CMT), does physiotherapy result in better functional scores compared to no physiotherapy?

Rationale

Lateral ligament instability, foot drop, and/or Achilles tendon tightness can be manifestations of CMT disorders which conventionally are referred for physiotherapy.

Clinical comment

Physiotherapy is a simple intervention that may be useful to improve the function of CMT patients.

Available literature and quality of evidence

- Two randomized controlled trials (RCTs) and two cohort studies exist to answer this question.

Findings

Lindeman et al. found in their RCT that a strengthening program directed to proximal musculature improves strength and functional performance in patients with CMT.[1,2] This study completed 24 weeks of follow-up (level I).

Rose et al., also in an RCT, reported an improvement of dorsiflexion range with serial night casting over four weeks.[3] Following those four weeks, the patients performed gentle stretching exercises and maintained the dorsiflexion range obtained. This study was conducted in CMT patients (level I).

El Mhandi et al., in a cohort study, showed that a 24-week interval-training stationary bike program performed three times per week was well tolerated by all patients.[4] In addition, it was significantly beneficial to their subjective perception of pain/fatigue; improved the functional capacity of these CMT patients; and although there was no reduced fatigability when tested in isometric mode, all patients increased their dynamic strength and physiological capacities (level II).

Chetlin et al., in a retrospective analysis of an RCT, found that a progressive resistance training program improved strength and activities of daily living in patients with CMT.[5] This study is important because it shows that patients with CMT can improve significantly with a simple, cost-effective, and home-based program (level II).

Resolution of the clinical scenario

- Periodic rehabilitation exercises directed to strength[1,2] (level I), stretching[3] (level I), and aerobic capacity[5] (level II) improve strength and activities of daily living.
- Physiotherapy is a mainstay in CMT treatment (level I).[6]
- A period of physiotherapy or home exercises supervised by physiotherapist is recommended (level I). They may be directed to proximal musculature strengthening, stretching, and aerobic capacity.

Question 2: In patients undergoing peroneus longus (PL) to peroneus brevis (PB) tendon transfer, does running locked suture result in improved construct strength compared to vertical mattress sutures?

Rationale

Most authors recommend using PL to PB tendon transfer in the surgical treatment of cavovarus foot to correct forefoot pronation, reduce the first ray plantarflexion and reinforce the weak eversion of the hindfoot.[7,8] The PL to PB transfer usually requires side-to-side tenorrhaphy, as this is stronger than Pulvertaft weave technique.[9]

Clinical comment

Early active mobilization of tendon repairs promotes better joint motion and limits adhesion of neighboring structures, thus a strong repair is needed.

Available literature and quality of the evidence

- The only evidence available consists in a cadaveric model. Wagner et al. performed a biomechanical evaluation of various suture configurations in side-to-side tenorrhaphy (level V).[10]

Findings

Wagner et al. evaluated the resistance to cyclic forces and monotonic loading.[10] The construct consisted of different side-to-side suture configurations on porcine flexor

digitorum tendons harvested from the forefeet. They tested four vertical mattress sutures, running locked sutures, four figure-of-eight sutures on each side of the tenorrhaphy, and four pulley sutures.

No tenorrhaphy failed during the cyclic loading. Nevertheless, during the monotonic loading, vertical mattress suture failed at a lower load than all the others. Running locked suture, four figure-of-eight sutures on each side of the tenorrhaphy and four pulley sutures are stronger than four vertical mattress sutures on monotonic load. They provide a larger safety margin that provides assurance to surgeons who advocate immediate loading or motion at the repair site**.**

Resolution of clinical scenario

- Side-to-side tenorrhaphy is stronger than Pulvertaft weave tenorrhaphy.[9]
- Running locked suture, four figure-of-eight sutures on each side of the tenorrhaphy and four pulley sutures are recommended over four vertical mattress, for side-to-side tenorrhaphy.[10]

Question 3: In patients undergoing lateralizing calcaneal osteotomy, does prophylactic tarsal tunnel release result in less neurologic deficit compared to no tarsal tunnel release?

Rationale

- In cadaveric research, tarsal tunnel volume diminishes after lateralizing calcaneal osteotomy, despite the amount of translation or the osteotomy placement in the calcaneus.[11,12]
- Neurologic deficit after lateralizing calcaneal osteotomy has been reported in up to 33.8% of patients. The mechanism can include direct surgical trauma, traction, and perioperative compression.[13]

Clinical comment

Lateralizing osteotomy is one of the most frequently used osteotomies in the treatment of cavovarus foot.[7,8]

Available literature and quality of the evidence

- No RCTs exist on this topic. The available evidence ranges from levels III to V.

Findings

VanValkenburg et al. performed a retrospective cohort study of 80 feet in 72 patients with cavovarus foot deformity, with average follow-up of 19 months.[13] They found a 33.8% rate of tibial nerve injury. Major injury was defined as encompassing two or more nerve branches. This occurred in 16.2% of cases. Minor injury, defined as injury to only one nerve branch, occurred in 17.5% of cases. The rate of injury when the tarsal tunnel was released prior to the calcaneal osteotomy (21.4%) was comparable to that of those without a release (29.8%, $p = 0.531$). However, the rate of injury when the release was performed after the osteotomy (77.8%) was significantly greater compared with those without a release (29.8%, $p = 0.006$). None of the neurologic deficits found after tarsal tunnel release was

observed to be a major injury, whereas 48.1% of nerve injuries overall were classified as major (level III).

Jaffe et al. reported a case series of 24 feet in 24 patients that underwent cavovarus foot reconstruction with lateralizing calcaneal osteotomy through the medial approach.[14] They performed tarsal tunnel release in only one patient because of previous symptoms. None of the patients developed neurologic deficit in the tibial nerve distribution after surgery (level IV).

Krause et al. reported a case report of two cases, mother and son, with CMT type 2.[15] Both underwent lateralizing calcaneal osteotomy. Both presented with acute tarsal tunnel syndrome in the immediate period after surgery. Both were advised for surgical tarsal tunnel release. The mother accepted the surgery, and the sensory deficit fully recovered by 12 weeks following this procedure. The son did not accept the procedure, and the disturbance had not resolved at 18 months postoperatively (level V).

Stødle et al. reported a case series of 18 feet in 15 patients with cavovarus foot, treated with lateralizing calcaneal osteotomy as a single procedure or in conjunction with other procedures.[16] Seventeen percent of patients presented with tibial nerve deficit at final follow-up of 51 months. They identified four patients with CMT, of whom two presented with deficits in the tibial nerve distribution of the foot at the final follow-up (level IV).

Bruce et al. performed lateralizing and medializing calcaneal osteotomies in eight cadaveric specimens. They measured the tarsal tunnel volume using magnetic resonance imaging (MRI).[11] The tarsal tunnel volume was reduced significantly after lateralizing calcaneal osteotomy. Medializing calcaneal osteotomy did not reduce tarsal tunnel volume (level V).

Resolution of clinical scenario

- Tarsal tunnel release is recommended before conducting a lateralizing calcaneal osteotomy through lateral approach (level III). This order is specifically important in CMT patients, who are at increased risk of tibial nerve damage during the procedure (level IV).
- Medial approach, with no tarsal tunnel release, is an alternative to diminish neurologic risk during lateralizing calcaneal osteotomy (level IV).
- Prophylactic tarsal tunnel release is recommended before performing a lateralizing calcaneal osteotomy (level III).

Summary of answers

- A period of physiotherapy or home exercises supervised by physiotherapist is recommended for CMT patients (level I).
- Running locked suture, four figure-of-eight sutures on each side of the tenorrhaphy and four pulley sutures are recommended over four vertical mattress, for side-to-side tenorrhaphy (level V).
- Tarsal tunnel release is recommended before conducting a lateralizing calcaneal osteotomy through lateral approach (level III).
- This order is specifically important in CMT patients, who are at increased risk of tibial nerve damage during the procedure (level IV).

[2]University of Zurich, Universitätsspital Zurich, Research Laboratory, Division of Surgery and Harald Tscherne Laboratory, Zurich, Switzerland
[3]Aachen University Medical Center, Department of Orthopaedic Trauma, Aachen, Germany

Clinical scenario

- After a severe accident you see a multiply injured 45-year-old male patient in the trauma bay.
- The patient is in critical condition: hypotensive, tachycardic, temperature 34.6 °C, lactate 3.8 mmol/L, INR 2.5, pH 7.28; hemopneumothorax with lung contusion and rib fractures, minor traumatic brain injury.
- The patient has severe major fractures that need stabilization: pelvic-ring fracture, femoral shaft fracture, Gustilo–Anderson Grade 3 open ankle fracture.

Top three questions

1. In patients with multiple injuries in a borderline or unstable condition, what parameters best describe a patient in danger for complications?
2. In patients with multiple injuries in a borderline or unstable condition, which fracture is associated with the most complications?
3. In patients with multiple injuries after placement of an external fixation on long-bone fractures, does early or late conversion to intramedullary nailing lead to increased infections?

Question 1: In patients with multiple injuries in a borderline or unstable condition, what parameters best describe a patient in danger for complications?

Rationale

One of the most difficult tasks for a treating physician is to decide about clearance for surgery – and what type, depending on the patient`s condition. Previous studies have shown that early definitive surgery is beneficial in most patients, but lengthy operations, or overzealous blood loss, may trigger complications.

Clinical comment

Around the turn of the century, *damage control orthopedics* (DCO) was introduced to the care of the severely injured patient (level II and III).[1,2] This implies the application of an external fixator to stabilize major fractures of the extremities, or the pelvis, whenever the patient's condition is critical (*borderline* or worse). This technique is in contrast to *early total care*, where the fracture is stabilized definitively in one surgical session. The most relevant advantage of DCO is the substantial decrease of mortality[3] (level III) resulting from minimal invasive surgery minimizing the *second hit*, a theory that indicates the surgery to be a second traumatic hit that might overwhelm the inflammatory response and lead to sepsis, multiple organ failure, and death[4] (level III). However, DCO implies further surgical interventions to perform the definitive fixation and prolonged hospitalization with their associated increased risks of complications and adverse events.

Table 70.1 Defining the condition of a multiple injured patient[3]

	Parameter	Stable (Grade 1)	Borderline (Grade 2)	Unstable (Grade 3)	In Extremis (Grade 4)
Shock	systolic Blood pressure (mmHg)	100 or more	80-100	60-90	<50-60
	Blood units received within 2h after admission	0-2	2-8	5-15	>15
	Lactate (mmol/l)	norm	<2.5	>2.5	severe acidosis
	Base deficit	norm	no data	no data	> -18 - (-6)

Recommended Surgical Strategy		ETC	stabilized In doubt: DCO	DCO	DCO

norm = normal range

AIS = Abbreviated injury Scale

TTS = Thoracic Trauma Score

DCO = Damage control orthopedic

ETC = Early Total Care

Available literature and quality of the evidence

Several studies have been performed to evaluate which is the best parameter – or combination – to describe patients at risk. For two decades, the triad of death, using indicators of shock, acidosis, and coagulopathy has been used to assess trauma patients (level III).[5] One of the earliest classification method that is still in use in routine clinical practice is the Injury Severity Score (ISS), that merely describes injury severity and distribution without giving recommendations on treatment strategy (level III).[6] Rotondo et al. described pathological values of acid–base, temperature, and coagulation as the *triad of death* that should be treated as early as possible (level III).[5] Nahm et al. proposed the stratification of patients depending on only three laboratory values (all from the acid–base group) into low- and high-risk patients; they postulated definitive surgery to be safe in low-risk patients (level III).[7] A further scoring system includes the injury severity and stratifies the patient's condition based on the mortality rate (level III).[8] Based on published evidence, the clinical grading scale categorizes the severely injured patient based on parameters of shock, coagulation, temperature, and soft tissue injuries, and recommends appropriate treatment strategies based on the patient's condition (level II).[9]

Findings

Overall, no level I evidence exists that clearly presents recommendations on what parameter, or which combinations of parameter, are to be used in defining the condition of the severely injured patient. Studies investigating this topic draw their conclusions mainly based on retrospective data analysis[8,10,11] and one on the combination of a profound literature review and expert opinion.[2] However, what most of these findings have in common are the evaluation of parameters from the same physiologic systems: shock and hemorrhage, acid–base, coagulation, temperature, and injury severity.

Resolution of clinical scenario

The current literature suggests that this patient is to be graded as *borderline* based on the pathological parameters of shock, acid–base, coagulation, temperature, and injury severity (Table 70.1).

This patient should be treated according to damage control principles until the relevant parameters are physiologic range and the patient is stabilized.

Question 2: In patients with multiple injuries in a borderline or unstable condition, which fracture is associated with the most complications?

Rationale

Initial emergency intervention is based on the principle: stop the bleeding and treat first what kills first. In the presence of multiple fractures, the treating team has to decide which one is associated with the biggest impact on the patient's physiology. These fractures should be addressed first.

Clinical comment

The treatment strategy of severely injured patients with multiple fractures includes planning the definitive treatment of fractures as soon as the patient's condition is stable enough. However, a major issue is the sequence of fracture fixation. Fractures that are associated with the most complications should be addressed earlier. These complications might be stratified into early complications, such as bleeding; medium-term complications, such as infection; pulmonary embolism; and late

complications, such as pneumonia, sepsis, or multiple organ failure (all level III).[4,12,13] Each fracture comes with its own set of possible complications; the clinical challenge is to prevent complications with early appropriate treatment without compromising the patient's overall condition.

Available literature and quality of the evidence

Historically, major fractures have been categorized to represent mainly the long bones (level 2).[14] Moreover, pelvic ring injuries were thought to have a major impact, and both entities have been closely examined recently. Fractures of pelvic ring and fractures of the femur are associated with major bleeding in the acute phase (level II).[15] Severe femoral fractures have been identified to be associated with an increased risk for pre-hospital hemorrhagic shock, higher resuscitation requirements, multiple organ failure, and longer in-hospital and intensive care stay (level III).[16] Moreover, pelvic ring fractures appear to benefit from emergency fixation with associated hemorrhage control (level III).[17] The soft tissue injury associated with a major extremity fracture seems to represent a crucial issue (level III).[18] Open fractures substantially increase the risk of infections (level I) and should be addressed accordingly.[19–21] Over the last decade, there has been only one clinical study that looked at the complications specifically in multiple injured patients in the ICU (level III).[22] The aim of the study was to compare the risk of local complications in patients after DCO for femoral shaft fractures. They showed that even the rate of superficial infection is higher in the DCO group (18.7% vs 1.9%, $p < 0.05$), the rates of deep surgical site infection were comparable in those groups (DCO 1.2% vs early total care [ETC] 1.1%). That led to the conclusion of comparable relevant infection rates, open fractures with severe local tissue damage to be an independent risk factor for infections, and an increase of contamination rate in external fixators when the fixator was placed for longer than two weeks.[22]

A recently published meta-analysis confirmed that in isolated femur fractures there are improved outcomes and fewer embolic events after early stabilization of the femoral shaft compared to delayed management. (level I).[23] Pooling data of one RCT and four retrospective studies, no statistically significant association between timing of intramedullary nailing (IMN) and odds of pulmonary embolism (odds ratio [OR] = 0.71; 95% confidence interval [CI]: 0.21–2.39). However, early IMN is associated with a statistically significant reduction of the odds of deep vein thrombosis (OR = 0.39; 95% CI: 0.21–0.71). Further,

early IMN reduces the odds for decubitus ulcer significantly (OR = 0.17; 95% CI 0.08–0.36).[23]

Even though they described little confidence in the effect estimate, this conclusion is drawn by several other studies as well.[24,25]

Findings

Pelvic fractures and femoral shaft fractures are associated with increased blood loss and hemorrhage and should be treated expeditiously. The most common fractures associated with complications are open fractures (Gustilo–Anderson 2 and above).

Resolution of clinical scenarios

Treatment of thoracic trauma and stabilization of the pelvis and the femoral shaft to facilitate breathing and stop the bleeding.

Level I evidence suggests high risk of infection in open fractures; treatment should include irrigation, surgical debridement, and antibiotic treatment.

Question 3: In patients with multiple injuries after placement of an external fixation on long-bone fractures, does early or late conversion to intramedullary nailing lead to increased infections?

Rationale

The external fixator usually is used during DCO as a temporary, minimal-invasive technique to stabilize a fracture. The timepoint at which the external fixator should be replaced with the definitive fixation is controversial.

Clinical comment

Multiply injured patients are being treated with external fixation and other measures of DCO. Afterward, their physiologic systems are stabilized and treated in the intensive care unit, until definitive surgery of the fractures can be performed.

A prolonged treatment with an external fixator is associated with several complications and should only be used for definitive treatment in

selected cases. However, it still remains difficult to define the best timepoint on when to replace the external fixator.

Available literature and quality of the evidence

Reasons for temporary fracture fixation with external fixators are very individual. In severely injured patients, the aim is to minimize the load of the first surgery in order not to overwhelm the inflammatory system (level III).[26] A systematic review summarized infection rates and the investigated a possible association of conversion time with complications in femoral and tibial shaft fractures.[27] They summarized 185 acute open fractures of the femur (six level IV studies) and 268 fractures of the tibia (seven level IV, one level I studies). With regards to sequential femoral nailing following external fixation of femoral fractures they found a plausible infection rate average of 3.6% (95% CI: 1.8–7.4%). With regards to sequential nailing of tibial fractures after external fixation, they found infection rates of 9% (95%: CI: 7–12%). They also found that length of external fixation ≤28 days reduces the risk of infection by 83% (95% CI: 62–93%). Additionally, interval time in external fixation <14 days resulted in a significant reduction in the infections rates than longer times.[27]

The soft tissue status around the fracture presents as a limiting factor. This has led several groups to the development of a staged protocol in the treatment of fractures with substantial soft tissue damage (level II).[28,29]

These recommendations were published in order to avoid infectious complications at the time of conversion (level II).[29] Also, there are reports about the use of external fixation for definitive fracture care, without conversion to internal fixation (level III)[30] and has been proposed as an safe alternative to intramedullary nailing (level II).[31]

Findings

Evidence is sparse on defining the most appropriate timepoint on when to convert to an internal fixation from an external fixation. However, studies agree on two limiting parameters: the status of the surrounding soft tissue and the patient's general condition.

Resolution of clinical scenario

The timepoint of conversion is defined by the patient's condition and the soft tissue status.

The patient's condition should be remeasured regularly to show treatment effects.

Summary of answers

- Currently, parameters of shock, coagulation, temperature, acid–base, and injury severity most accurately describe the condition of the severely injured patient.
- Each fracture has its unique complications based on injury severity, concomitant injuries to surrounding tissue, or open and closed fractures.
- Early fracture treatment in severely injured patients should stop hemodynamic relevant bleeding, and decrease mid-term and long-term complications.
- The timepoint of conversion from external to internal fixation should occur as early as the patient's condition and soft tissues allow, as longer times in external fixation (>14 days) have been shown to increase infection rates.
- A staged protocol in the treatment of fractures with substantial soft tissue damage has been recommended by several authors.

Open Fractures

Michael D. Hunter MD[1], Mark D. Hasenauer MD[2], Atul F. Kamath MD[3] and Kyle J. Jeray MD[1]
[1]Greenville Hospital System, Greenville, SC, USA
[2]Department of Orthopaedic Surgery, University of Pennsylvania, Philadelphia, PA, USA
[3]Cleveland Clinic, Cleveland, OH, USA

Clinical scenario

- A 32-year-old female unrestrained driver versus a tree.
- Nonorthopedic injuries include multiple rib fractures, left pneumothorax, and a subarachnoid hemorrhage. The patient was intubated in the trauma bay due to respiratory compromise.
- Orthopedic injuries include a left open comminuted tibial shaft fracture with associated fibula fracture. The patient has a 2+ dorsalis pedis pulse; however, motor and sensory exam are difficult to evaluate secondary to patient intubation.

Top three questions

1. In trauma patients with open fractures, does early antibiotic administration result in lower infection rates as compared to delayed antibiotic administration?
2. In polytrauma patients with open fractures, does timely irrigation and debridement result in decreased complications and infection rates as compared to delayed irrigation and debridement?

3. In patients with open fractures, does irrigation with normal saline versus an additive solution, and high pressure versus low pressure, result in lower infection/complication rates?

Question 1: In trauma patients with open fractures, does early antibiotic administration result in lower infection rates as compared to delayed antibiotic administration?

Rationale

Proper early management of open fractures in the trauma bay is essential to afford patients the best orthopedic outcome. This includes application of splints and bedside irrigation, as well as administration of proper medications and appropriate resuscitation techniques.

Clinical comment

Early administration of antibiotics and resuscitation efforts can help reduce complications.

Available literature and quality of the evidence

- Level I: 10
- Level II: 16
- Level III: 11.

Findings

Open fractures are initially managed in the trauma bay with local irrigation, splinting, and administration of antibiotics. Tetanus is administered as indicated as well. As

experiments have suggested, antiseptics (such as povidone iodine) may be toxic to the host cells;[1,2] therefore, gauze dressings moistened with normal saline may be the safest, least destructive choice for short-term coverage.

The administration of systemic antibiotics for open fractures has been the standard of care since 1974.[3] A Cochrane review by Gosselin et al. showed that antibiotics given for open fractures reduce the infection risk by 59%.[4] The current antibiotic recommendations stem from the original Gustilo and Anderson articles.[5,6] Several studies agree that the single-most-important factor in reducing infection is early administration of the appropriate antibiotics.[2–4,7–9] A 2015 journal article showed that antibiotics given >66 min after arrival in type III fractures were associated with increased infection rates (odds ratio [OR] = 3.78; 95% confidence interval [CI]: 1.16–12.31; p] = 0.03).[10] Contrary to this, a prospective cohort study showed that timing of antibiotic of administration may be less important than Gustilo type for developing deep infection in open fractures.[11] In current protocols, a first-generation cephalosporin (usually cefazolin) is given for type I and II fractures, while an aminoglycoside (usually gentamicin) is often added for type III fractures or fractures with gross contamination based upon the work of Patzakis et al.[7] Penicillin is also recommended for highly contaminated wounds or in areas with poor vascularity.

Some exceptions to early systemic antibiotic therapy do exist, but these studies are primarily focused on hand fractures. For example, a systematic review and a randomized placebo-controlled trial found that prophylactic antibiotics did not add to the prevention of infection in conjunction with routine treatment of open distal phalanx fractures with irrigation and debridement.[8,12] Although these studies suggest that antibiotics may not be

necessary, phalanx fractures are in highly vascular areas, lend to easier bedside irrigation/debridement, and are typically low-energy injuries.

Few articles give length of dosing recommendations for antibiotic therapy, although most surgeons agree that antibiotics should be continued for at least 24 hours after the final irrigation and debridement, similar to antibiotic prophylaxis recommendations for elective surgery.[9]

Resolution of clinical scenario

- Early administration of intravenous (IV) antibiotics is the most important factor for initial management of open fractures; however, subsequent evidence indicates that Gustilo type may be the most important predictor of future infection.
- In our clinical scenario, treatment with a first- or second-generation cephalosporin is recommended with the addition of an aminoglycoside for type III open fractures.

Question 2: In polytrauma patients with open fractures, does timely irrigation and debridement result in decreased complications and infection rates as compared to delayed irrigation and debridement?

Rationale

The importance of this question lies in determining the optimal time from when patients arrive at the hospital to

when a formal irrigation and debridement should be conducted.

Clinical comment

Polytrauma patients are nonelective surgeries; however, operating within the *six-hour rule* for irrigation and debridement should be balanced with the patient's overall physiologic status, operating room availability, and reasonable demands on the surgeon.

Available literature and quality of the evidence

- Level I: 0
- Level II: 9
- Level III: 8.

Findings

Based on the Gustilo/Anderson articles, open fractures have been considered emergent cases that need to undergo operative debridement within six hours of injury. However, only one study supports the idea of debridement of open fractures within six hours of injury; Kindsfater and Jonassen reviewed open tibial fractures and found a significant increase in infection rate in fractures that were delayed greater than five hours. One in fifteen open fractures (7%) became infected if debrided in <5 hours versus 12/32 open fractures (38%) debrided >5 hours after injury ($p < 0.03$).[13]

On the contrary, many studies question the need for urgent irrigation and debridement (I and D) within six hours and some have even suggested no debridement is necessary for isolated type 1 open injuries in the pediatric population.[14] Pollack concluded in a review article that within the modern era of antibiotics timing to I and D is not an

independent predictor of postinjury infection.[15] Later in the Lower Extremity Assessment Program (LEAP) study, he showed that there was no difference in outcomes when debridement occurred within the first 24 hours.[16] In 2012, a systematic review showed no difference in time to operation and infection risk regardless of subtype. Overall infection rates ranged from 4 to 63%, with an OR of late compared to early debridement of 0.91 (95% CI: 0.70 to 1.18).[17] Weber, in 2014, also released a cohort study of 736 patients which showed no difference in time to surgery on infection risk of open fractures.[11] Dr. Srour and the University of Southern California examined 315 patients and again saw no difference in early or late infections when the index procedure was performed <6 hours after injury or between 6 and 24 hours.[18] Lastly, a 2016 systematic review showed there was no difference in infection risk with debridements done before or after six hours. Meta-analysis showed no statistical difference between groups with regards to overall infection rates (risk ratio [RR]] = 1.32; 95% CI: 0.54–3.23; p] = 0.55), deep infection rates (RR] = 0.99; 95% CI: 0.48–2.07; p] = 0.98), and nonunion rates (RR] = 1.49; 95% CI: 0.64–3.49; p] = 0.36).[19]

In summary, many recent studies have examined early initial debridement (<6 hours) versus debridement (6–24 hours), and the consensus has revealed no difference in infection rates. Initial debridement when the patient has been medically optimized, and preferably within 24 hours, has been the current thought process at most level I trauma centers.

Resolution of clinical scenario

- In this specific scenario, a patient should be stabilized from a medical standpoint prior to proceeding for

irrigation and debridement as this can be safely done within 24 hours of admission.

- All cortical bone with no soft tissue should be removed at the time of the initial debridement in this patient to minimize sources of infection.
- Gustilo type appears to correlate more closely with infection risk as opposed to the urgency of which initial debridement is performed.

Question 3: In patients with open fractures, does irrigation with normal saline versus an additive solution, and high pressure versus low pressure, result in lower infection/complication rates?

Rationale

Many options exist with irrigation. Whether or not to use additives, high pressure versus low pressure versus gravity flow, and amount of fluid are all questions that orthopedic surgeons will face in managing open fractures in an effort to improve surgical outcomes and minimize infection risk.

Clinical comment

The choice for irrigation solution, additional additives, volume, and method of delivery (pressure) until recently has been unclear. These choices can affect the cost of the procedure and can have potentially harmful effects to the patient. The safest and most cost-effective irrigation solution and delivery system should be used to yield the best outcome for the patient.

Available literature and quality of the evidence

- Level I: 2
- Level II: 4
- Level III: 3.

Findings

No clear consensus until recently existed for the choice of irrigation solution or method of administration during the initial or subsequent procedures. A previous international survey found 70.5% of respondents favored normal saline as an irrigation solution, 71% of surgeons used low pressure systems, and only 1.3% of the surgeons routinely used a soap additive.[20] Experimental data suggest some toxicity to the host cells from antiseptic solutions. Other concerns for solutions other than normal saline include allergic reactions, additional cost, promotion of resistance, and unproven efficacy.

Volume of irrigation

The volume of solution used to irrigate a wound after adequate debridement is rooted in tradition, with one animal study showing increased bacterial removal with increased volume of irrigation but the correlation plateaued for normal saline alone.[21,22] The traditionally accepted minimum volume is 3 L for type I, 6 L for type II, and 9 L for type III injuries.

Irrigation additives

The efficacy of antiseptic additives in eliminating bacterial loads must be weighed against the potentially toxic side effects to normal host cells in the wound bed. For example, although povidone iodine solution has demonstrated

efficacy in reducing infection in surgical wounds,[23] undiluted povidone iodine is toxic to bone cells.[1] Furthermore, there is continued concern over local antibiotic resistance[24] and anaphylactic reactions.[25,26] Animal models have shown that irrigation with an antibiotic reduces the rate of infection compared with the use of saline solution alone.[27]

Anglen reported the results of a prospective, randomized, controlled trial of 398 lower extremity open fractures comparing castile soap with bacitracin solution.[28] Despite equivalent infection and bone-healing rates, bacitracin was more problematic in terms of wound-healing issues (9.5% vs 4%; p] = 0.03). Soap solutions have been shown to be more effective than normal saline in removing bacteria from stainless-steel screws, while antibiotic solutions showed no advantage (p >0.05).[27] This clinical benefit has been challenged by the conclusion of the FLOW study which examined 2447 patients with open fractures and compared re-operation rates in castile soap irrigation versus normal saline. The re-operation rate with use of castile soap was 182/1229 (14.8%) as opposed to normal saline 141/1218 (11.6%) (p] = 0.01), indicating castile soap may not be as safe or effective as was once thought.[29]

Other potential additives not systematically studied in well-controlled trials include hydrogen peroxide, hexachlorophene, sodium hypochlorite, benzalkonium chloride, and various alcohol-containing solutions.[4]

Method of irrigation delivery

Multiple studies have promoted the superior mechanical properties of high-pressure irrigation, while many others have addressed the more tissue-friendly approach of low-pressure methods. While high-pressure lavage systems may be more effective in reducing bacterial cell counts and

protective biofilm barriers,[30,31] macro- and microscopic damage to both host soft tissues and bone occurs[32–34] and may result in deeper seeding of bacterial colonies.[35,36] These data are limited by lack of human *in vivo* testing of lavage systems. In general, the bulk of experimental evidence suggests an inverse relationship between efficacy of removal of contamination and potential tissue damage with the various methods of wound irrigation.

The FLOW study also evaluated re-operation rate at one year in patients with open fractures with regard to high-pressure irrigation, low-pressure irrigation, and very low-pressure irrigation (gravity flow). Re-operation occurred in 109/826 patients (13.2%) in the high-pressure group, 103/809 (12.7%) in the low-pressure group, and 111/812 (13.7%) in the very low-pressure group. Hazard ratios were conducted in high versus low pressure (0.92; 95% CI: 0.70–1.2; p] = 0.53), high versus very low pressure (1.02; 95% CI: 0.78–1.33; p] = 0.89), and low versus very low pressure (0.93; 95% CI: 0.71–1.23; p] = 0.62). Their conclusion showed no difference in re-operation rates between the three groups. This study further confirms the trend toward use of very low-pressure irrigation for open fractures as a safe and effective approach. While the pendulum has swung toward lower-pressure lavage systems, newer innovations, such as the Versajet™ (Smith and Nephew, Inc., London, UK), claim to provide controlled surgical debridement of tissues. However, there is no high-grade evidence that these newer systems have resulted in improved outcomes and may be reserved for specific situations of severely ground-in contamination as opposed to a thorough surgical debridement and gravity flow irrigation used for most open fractures.

Resolution of clinical scenario

- The FLOW study on human subjects showed that irrigation with normal saline led to lower re-operation rates compared to castile soap in the management of open fractures.
- In our clinical scenario, it is completely acceptable to irrigate the wound thoroughly with gravity flow normal saline, as higher pressure and additives have shown no increased benefit.
- There is no convincing evidence for, or against, using alternative technologies to perform irrigation and debridement of open fractures.

Summary of answers

Initial open fracture management

- Prompt IV antibiotics should be given to patients with open fractures.
- Tetanus toxoid should be administered based on immunization history.
- Initial wound management should consist of placing a sterile normal saline moistened dressing and temporary stabilization of fractures.

Timing to operative intervention

- Timing of operative intervention should be done as soon as possible based on the overall patient's physiologic status.
- The timing of irrigation and debridement, although not as important as early antibiotic delivery, should occur within 24 hours to optimize the outcomes.

Open fracture irrigation management

- Normal saline is the irrigation of choice for most open fractures.
- Additives, including soap, have shown no benefit and have potential risks to the host resulting in increased re-operation rates.
- Very low-pressure irrigation (gravity flow) has shown to be equivalent to higher-pressure irrigation; therefore, current recommendations are for very low-pressure irrigation.

The Mangled Extremity

Tiffany Huynh MD[1] and Ted V. Tufescu MD FRCSC[1]
University of Manitoba, Winnipeg, MB, Canada

Clinical scenario

- A motorcyclist collides with a car at high speed. He is brought to the Emergency Department with a severe open injury to his leg.
- He has been experiencing financial difficulties and would like to return to work (RTW) as soon as possible. With this goal in mind, he asks whether amputation or limb salvage would be the best option for him.
- He looks at his mangled leg and wonders about the long-term consequences of his injury.

Top three questions

1. In patients with a mangled extremity injury, does limb salvage necessitate greater resource investment than amputation?
2. In patients with a mangled extremity injury, what patient factors influence the success of therapy and the rate of RTW?
3. In patients with a mangled extremity injury, is limb salvage associated with better long-term outcomes when compared to amputation?

Question 1: In patients with a mangled extremity injury, does limb salvage necessitate greater resource investment than amputation?

Rationale

Limb salvage and amputation impose different stressors on a patient's financial and emotional well-being. An understanding of the investment required in each intervention enables the clinician to better counsel patients.

Clinical comment

Salvage may require multiple, costly procedures, and may result in failure rates as high as 40%.[1–5] More than half of patients develop mental health conditions after a failed limb salvage and many would not opt for it again.[2–6] However, at time of injury, 92% prefer an attempt at salvage.[3] Appreciating the financial and psychological costs of limb salvage compared with amputation may assist patients with decision-making.

Available literature and quality of the evidence

The most current relevant literature consists of:

- Level II: 2 cost-analysis studies based on prospectively collected data.[7,8]
- Level III: 3 retrospective chart reviews.[3,9,10]

Findings

Financial cost of limb salvage and amputation

Georgiadis reported a lower acute hospitalization charge (US$65,624) for amputation than for salvage ($109,044) (p <0.006)(level III).[4] Hertel reported equal mean annual hospital cost, based on four years, for amputation (15 112 CHF and salvage (17 365 CHF) (level III).[9] MacKenzie reported equal long-term hospital costs for amputation ($78 221) and salvage ($81 091) (level II).[8] Hertel reported higher total cost, including pension and loss of wage benefits for amputation (64 000 CHF) compared to salvage (33 000 CHF) (p <0.01).[9] When considering lifetime prosthesis-related costs, MacKenzie reported that amputation is three times more costly ($509 275) than salvage ($163,282).[8] Chung calculated cost as amount of money paid for a single extra quality-adjusted life years (QALYs). Assuming the patient has 40 years of life remaining, the average cost is $91 105 for amputation and $81 316 for salvage at two years after injury (level II).[7] The remaining lifetime cost is again higher for amputation ($350 465) than for salvage ($133 704).[7]

Duration of hospitalization for limb salvage and amputation

Georgiadis reported a shorter acute hospitalization for amputation (48 days) than salvage (71 days) (p <0.05).[4] Dagum reported equal stays for amputation (28 days) and salvage (25 days) (level III).[3] Georgiadis reported shorter readmission for amputation (5 days) than for salvage (18 days).[4] Hutchins reported equal total hospital stays, including readmission, for amputation (14 weeks) and for salvage (14.8 weeks) (level III).[10] Additionally, it is important to account for the time spent in rehabilitation centers. Hutchins reported that total acute and rehabilitation admission times were equal for amputation (101 days) and for salvage (129 days).[10] Shorter outpatient

rehabilitation time was required for amputation (12 months) than for salvage (30 months), although this was self-reported by patients ($p < 0.009$).[10]

Resolution of clinical scenario

Level II and III evidence suggests that the cost of limb salvage is:

- Less than amputation, when considering lost wages, pension, lifetime prosthesis-related charges, and QALYs.
- Equal to amputation in regard to in-hospital charges, duration of hospitalization, and duration of inpatient rehabilitation in most studies.
- More than amputation in regard to duration of outpatient rehabilitation.

Question 2: In patients with a mangled extremity injury, what patient factors influence the success of therapy and the rate of RTW?

Rationale

A severe extremity injury is a life-altering event that affects quality of life and function. An important aspect of treatment includes managing patient expectations regarding recovery and ability to RTW.

Clinical comment

Patient factors are often overshadowed by the urgency of the situation, but current opinion suggests that certain factors, such as education level and presence of social

support, can influence success of therapy.[1] It is important to appreciate predictors of outcome and ability to RTW, as they may guide necessary counseling.

Available literature and quality of the evidence

The most current relevant literature consists of:

- Level II: 3 studies from the LEAP (Lower Extremity Assessment Project) group, which retrospectively analyzed a large body of prospectively collected data.[1,11,12]
- Level III: 2 retrospective chart reviews.[3,10]

Findings

Predictors of poor outcome

The LEAP studies measured outcome with the Sickness Impact Profile (SIP) (level II).[1,11] The following patient characteristics predicted poor outcome at two years: less than high school education ($p < 0.05$), household income below the poverty level ($p < 0.1$), non-Caucasian ethnicity, lack of insurance, poor social support network, low level of self-efficacy (confidence in one's ability to resume chief life activities), smoking, and involvement with the legal system for injury compensation ($p < 0.01$).[1] The following predicted poor outcome at seven years: low education level, older age, female gender, non-Caucasian ethnicity, household income below poverty line, smoking, low self-efficacy, poor self-reported health status before injury, and involvement with the legal system for injury compensation ($p < 0.05$).[11] In a small study, Dagum reported that patient involvement with legal action was not associated to Short Form 36 (SF-36) mental component scores or Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC) pain

scores (level III).[3] Success of salvage and amputation was equally influenced.

Predictors of return to work (RTW)

Hutchins reported older age to be inversely related to RTW (level III).[10] The LEAP study found the following predictors of RTW: age less than 55, Caucasian ethnicity, high school or college education, nonsmoking status, as well as average to high self-efficacy and motivation (high job involvement and being in a preinjury job for one or more years) ($p < 0.05$) (level II).[12] Involvement with the legal system for compensation predicted lower RTW ($p < 0.01$).[12]

Resolution of clinical scenario

- Level II evidence suggests the following patient characteristics predict poor outcome and difficulty with RTW: lack of education, older age, non-Caucasian ethnicity, poverty, smoking, involvement in disability-compensation litigation, and low self-efficacy.
- Level III evidence had similar findings.

Question 3: In patients with a mangled extremity injury, is limb salvage associated with better long-term outcomes when compared to amputation?

Rationale

A severely injured extremity has life-altering consequences and, as such, the degree of long-term disability associated

with each intervention may be the most important factor to consider.

Clinical comment

Before proceeding with definitive management, patients and physicians must be aware of the outcomes of both limb salvage and amputation. Although there are multiple factors to consider in decision-making, the degree of long-term disability associated with each treatment may be the most significant.

Available literature and quality of the evidence

The most current relevant literature consists of:

- Level II: 3 studies from the LEAP group, which assessed outcome based on prospectively collected data.[1,11,13]
- Level III: 3 retrospective chart reviews.[3,4,14]

Findings

Outcome

The LEAP studies measured outcome with the SIP based on prospectively collected data. At two years after injury, the SIP was the same for salvage and amputation; 42% of all patients had a SIP greater than 10, indicating severe disability (level II).[1] RTW was 49% after salvage and 53% after amputation ($p = 0.48$).[1]At seven years, 49.4% of all patients had a SIP greater than 10 (level II).[11] Rehospitalization was more likely in patients after salvage than for amputation (47.6 vs 33.3%, $p = 0.002$).[1] Through-the-knee amputees had a worse outcome ($p < 0.05$).[11] Most other retrospective studies support these findings,[2–5] with minor exceptions.[3,4] Dagum reported better SF-36 physical

function scores after successful salvage ($p < 0.007$) (level III).[3] Georgiadis reported longer time to weightbearing, and more interference of health on work and recreation after salvage (level III).[4] Melcer reported that in military patients the incidence of mental health disorders was similar after amputation and salvage (level III).[14]

Complications

The most common complication after salvage is nonunion (31.5%), usually diagnosed at six months (level II).[13] The most common complication after amputation is wound infection (34.2%), which usually occurs at three months.[13,14] Salvage patients have more complications ($p < 0.001$), longer time to complication, and require more interventions.[13]

Resolution of clinical scenario

- Level II evidence demonstrates that outcomes after salvage and amputation are equal and do not improve from two to seven years after injury.
- Level II evidence suggests that limb salvage is associated with higher risk of complications and requires more interventions after the index operation.
- Level III evidence suggests similar incidence of mental health disorders with both interventions.

Summary of answers

- Limb salvage costs less than amputation, when considering lost wages, pension, lifetime prosthesis-related charges, and QALYs.

- Salvage and amputation are equal in regard to in-hospital charges, duration of hospitalization, and duration of inpatient rehabilitation in most studies. The duration of outpatient rehabilitation is longer after salvage.
- Patient characteristics predicting poor outcome and difficulty with return to work are as follows: lack of education, older age, non-Caucasian ethnicity, poverty, smoking, involvement in disability-compensation litigation, and low self-efficacy.
- Outcomes after salvage and amputation are equal, and the outcome does not improve from two to seven years after injury.
- Limb salvage patients have a higher risk of complications.

Acute Compartment Syndrome

Aurelia Bihari PhD[1]Christopher Del Balso MBBS MSc FRCSC[1] and Abdel-Rahman Lawend MD PhD FRCSC[1]
Division of Orthopaedic Surgery, Department of Surgery, University Hospital, London Health Sciences Centre, Western University, London, ON, Canada

Clinical scenario

- A 34-year-old healthy male pedestrian, struck by a motor vehicle, sustaining an open comminuted fracture of right tibia (Gustilo grade IIIA).
- Patient receives antibiotics (cephalosporin, aminoglycoside); right tibia treated with intramedullary nail fixation following irrigation and debridement.
- Several hours later, patient complains of pain (with progressive increase in analgesic requirements), pain on passive stretch, progressive hypoesthesia, and paresthesia.
- Clinical examination reveals swollen, palpably tense anterior, and lateral compartments; acute compartment syndrome (CS) confirmed by intracompartmental pressure (ICP) measurement.

Top three questions

1. In patients with CS, do open fractures pose greater risk of missed diagnosis and delayed fasciotomy compared to closed fractures?

2. In patients with CS, are patients who undergo compartment pressure monitoring diagnosed faster than patients undergoing clinical assessment?
3. In patients with anterior CS of the leg, does a one-incision fasciotomy of the anterior compartment achieve better decompression and fewer complications compared to the full two-incision/four-compartment release?

Question 1: In patients with CS, do open fractures pose greater risk of missed diagnosis and delayed fasciotomy compared to closed fractures?

Rationale

Acute CS is caused by elevated pressure within a closed osteofascial compartment. CS can develop in response to a multitude of traumatic injuries and medical comorbidities: fractures, burns, exercise, crush injuries, and ischemia-reperfusion injury;[1] less common causes may include bleeding disorders,[2] diabetes, administration of statins,[3,4] infection,[5] hypothyroidism,[6] lithotomy position,[7] snake bites,[8] arterial rupture,[9] and blast injuries.[10]

Clinical comment

A high index of suspicion for CS is required for all fractures, in particular those within the forearm and leg, regardless of whether the fracture(s) are closed or open. Serial examination is the key to diagnosis and avoidance of a missed CS.

Available literature and quality of the evidence

- Level I: 2 randomized controlled trials (RCTs)
- Level III: 1 retrospective cohort.

Findings

McQueen, Gaston et al. (level I evidence) evaluated the occurrence of acute CS; they reported that CS can occur in every muscle compartment of the upper extremity, lower extremity, and trunk; leg (80% of all cases) and forearm are most frequently involved.[1] Age and sex play a role in the likelihood of CS development: male patients under 35 years of age are prone to developing CS more often.[1]

CS is most commonly due to closed long-bone fractures (75% of cases),[11,12] in which the fascia is maintained. Comminuted fractures increase the risk further.[12] In adults, the most common cause of CS is tibial fracture (approximately 1–10%),[11,13] followed by the fractures of forearm bones (distal radius). In children, supracondylar humerus fractures are the most common cause.[14]

Open fractures can result in CS development if a sufficient portion of the deep fascia or skin remains intact (level III evidence).[15] In both volar plating of distal radius fractures and intramedullary nailing of tibial fractures, ICP has been found to peak during the procedure, followed by a decrease postoperatively over 24 hours,[16] and 36 hours,[17] respectively.

Trauma patients without fracture may be at significantly greater risk of delayed CS diagnosis and fasciotomy (level I evidence)[2]: 20% of patients without fracture had muscle necrosis that required debridement, versus debridement being necessary in 8% of patients with fractures.

CS appears to be less frequent in nontraumatic cases. It may be caused by ischemia-reperfusion injury, thrombosis, and bleeding disorders, among a variety of other conditions. Sustained external pressure on an extremity can precipitate CS.[18,19] This can occur in an unconscious patient (i.e. drug overdose, poor surgical position technique). CS is less frequent in nontraumatic cases, and is usually caused by a sustained external pressure on an extremity.[18,19]

Resolution of clinical scenario

- Watchfulness is necessary in all types of fractures (particularly in open fractures and fractures of the leg and forearm). Rapid progressive worsening signs and presence of multiple findings indicate CS development.
- The suspicion of CS should be confirmed by measurement of ICP; the presence of unequivocal signs requires emergency decompression via fasciotomy as the case of our patient in our clinical scenario.

Question 2: In patients with CS, are patients who undergo compartment pressure monitoring diagnosed faster than patients undergoing clinical assessment?

Rationale

Diagnosis of acute CS is challenging, as there is no true diagnostic test; instead, the surgeon must rely on the clinical examination and observation of CS signs and symptoms.[20] Although the timing of the appearance of

specific signs and symptoms varies, they all tend to appear in stepwise fashion.

Clinical comment

Clues indicating a developing CS include the rapid progression of symptoms over a few hours, as well as the presence of multiple findings that are consistent with impending CS. Thus, all patients at risk of CS should be serially evaluated; special attention must be paid to any tense and painful muscle compartment. If acute CS is suspected on the basis of risk factors and clinical findings, ICP measurements should be obtained without delay.[21]

ICP measurements are of particular use in intubated, sedated, and/or obtunded patients. CS remains a clinical diagnosis; history and repeated physical exams are critical to timely diagnosis. A low threshold for fasciotomy should be maintained when clinical signs are present. Obtaining ICP measurements should not delay a patient being brought to the operating room.

Available literature and quality of the evidence

- Level II: 2 studies.

Findings

Level II evidence indicates that the first symptoms of acute CS are disproportionate pain relative to the injury and pain on passive muscle stretch (PPS),[22,23] often coupled with a progressive increase in analgesia requirements.[24] Both pain out of proportion to what is expected of the injury (based on the physical examination) and PPS are the most sensitive clinical findings (19%) and are often the *only* observation that precedes ischemic dysfunction in the nerves and muscles of the affected compartment.[22,23] While

the specificity of both pain measures is high (97%), the sensitivity is very poor (19%); thus, absence of pain may be a useful measure in *ruling out* acute CS.[22]

Approximately one hour after the onset of ischemia, the patient may experience the first sensory changes (level II evidence).[23] As a clinical measure of acute CS, paranesthesia has a sensitivity of 13% and a specificity of 98%.[22] Unfortunately, paresis and/or paralysis of the muscles of the involved compartment are considered signs of a late acute CS; at this stage, the patient is less likely to respond to fasciotomy.[22,25]

The lack of a pulse rarely occurs in CS patients; alternatively, the presence of a pulse does not exclude CS.[26] While congestion of the digits and prolonged capillary refill time may also indicate acute CS, these should not be relied upon, as they may be affected by many different external factors (e.g. shock, dehydration, decreased peripheral perfusion).[26]

Although controversial, level II evidence suggests that the role of ICP measurement in acute CS remains a valuable tool for providing objective criteria for the diagnosis,[27] decreasing the delay to fasciotomy (and thus the long-term complications).[28] In order to capture the peak ICP value, measurements should be taken at the level of the fracture, as well as at sites up to 5 cm proximal and distal to injury.[29]

The indications for ICP measurement include unconscious patients;[30–32] difficult-to-assess patients (e.g. young children, patients with psychiatric problems, or those under the influence of narcotics);[33] patients with equivocal signs and symptoms,[30] especially when accompanied by nerve injury;[33,34] and patients with multiple injuries.[32]

There is no clear protocol for a specific pressure threshold at which fasciotomy should be carried out. Normal tissue pressure within a compartment is 0–8 mmHg.[33] The threshold ICP for decompression is variable in the literature (i.e. 30–45 mmHg). Differential pressure (ΔP) may be a better indicator of tissue ischemia.[33] Level II evidence suggests that the threshold ΔP be 30 mmHg, based on the retrospective observation that this value lead to no apparent missed cases of acute CS.[27] The advantages of a differential pressure threshold include better utility in hypotensive trauma patients and a lower overall fasciotomy rate, compared to an absolute pressure threshold.[27,35]

Clinical findings associated with CS tend to correlate with the degree to which tissue pressure within the affected compartment approaches systemic blood pressure. It has been demonstrated that the capillary blood flow becomes compromised at ΔP of 25–30 mmHg of mean arterial pressure,[36] leading to the development of pain. Once the tissue pressure approaches diastolic pressure, tissue ischemia will occur.[37,38]

Resolution of clinical scenario

- Pain (including pain on passive stretch of muscles) is the earliest and most common finding in all CS cases.
- A suspected CS diagnosis should be confirmed by measuring ICP; ΔP of less than 30 mmHg indicates the need for emergency surgical decompression.

Question 3: In patients with anterior CS of the leg, does a one-incision fasciotomy of the anterior compartment achieve better decompression and fewer complications compared to the full two-incision/four-compartment release?

Rationale

Goals of management in acute CS are to minimize permanent injury of the affected limb by restoring microcirculation to the muscle and nerve, and therefore avoid the sequelae of ischemic contracture. As such, the current gold standard therapy for confirmed acute CS is fasciotomy, where the skin and underlying fascia are incised in order to relieve the limb ischemia generated by the elevated ICP, provided the diagnosis of CS is made within the recommended surgical window of 6–8 hours.[27,35,39] The consequences of delaying fasciotomy are severe; therefore, nonoperative measures are restricted to an adjunctive role supplemental to fasciotomy.

Clinical comment

While the acute CS may be localized to one compartment, it is always safer to release all compartments at the same time. CS may evolve with the passage of time from the inciting event, injury, or surgical intervention, to ultimately affect all compartments. Sufficient extensile skin incision is crucial to complete decompressive fasciotomy of superficial, intermediate, and deep compartments. There is

no role for minimally invasive or percutaneous fasciotomies in the trauma setting.

Available literature and quality of the evidence

- Level III: 1 study
- Level IV: 2 studies
- Level V: 3 studies.

Findings

Three techniques for fasciotomy are most commonly used in the leg: two-incision fasciotomy, one-incision perifibular fasciotomy, and fibulectomy; these have been shown to be sufficiently effective at decreasing ICP. The two-incision technique performed on cadaver specimen (level IV evidence) allows for adequate visualization of all compartments, assessment of muscle viability, and sufficient surgical control to avoid neurovascular structures.[40] A four-compartment release with fibulectomy performed through one lateral incision[41] (level IV evidence) takes advantage of the fascial anatomy, as all fascial membranes insert onto the fibula. This method is technically challenging, places the peroneal vessels at risk, and sacrifices the fibula. Both the two- and one-incision techniques are sufficiently effective at decreasing ICP;[40,42] the one-incision four-compartment fasciotomy without fibulectomy can be useful in cases where soft tissue trauma or contamination is of concern, including situations in which only a single vessel perfuses the leg, or when flap coverage may be necessary.

Level III evidence suggests open fasciotomies (performed by two-incision, one-incision, and fibulectomy techniques) for compartment decompression maximize postischemic tissue viability,[43] although they slightly increase the risk of

minor wound morbidity (superficial wound complications arose in 2 out of 19 patients).

Subcutaneous fasciotomy techniques have been described using cadaver specimens (level IV evidence), in which the fascia is incised blindly with dissecting scissors through a small skin incision.[44,45] Advantages include technical ease and cosmesis; however, access is limited to the deep posterior compartment and the neurovascular bundle (31% of specimen). In acute CS, the skin is an important boundary of all compartments that must be released to achieve the greatest decrease in ICP. While small incision fasciotomy and endoscopically assisted fasciotomy may have a role in chronic exertional CS, cadaver specimen studies have demonstrated that these techniques achieved adequate decompression in only 82% of cases,[46] suggesting that the recurrence of limb-threatening ischemia may occur despite fascial release when the skin is left intact.[45–48]

Resolution of clinical scenario

- In this clinical scenario, to avoid the potential for recurrence of CS, two-incision/four-compartment fasciotomy should be the preferred decompression method of choice in this acute leg CS.
- Level IV evidence suggests that small incision and endoscopically assisted fasciotomies do not provide sufficient decompression and should not be used in *acute* CS.

Summary of answers

- Open fractures can result in CS development if a sufficient portion of the deep fascia or skin remains

intact. Adequate suspicion must be maintained for all fractures (simple *and* compound).

- Compartment pressure monitoring is a valuable tool in confirming a diagnosis of acute CS. The threshold for decompression is a ΔP of 25–30 mmHg of mean arterial pressure.
- Two-incision/four-compartment fasciotomy is the safest choice in the leg for the release of ICP, allowing for adequate visualization of all compartments, assessment of muscle viability, and sufficient surgical control to avoid neurovascular structures.

Noninvasive Technologies for Fracture Repair

Natsumi Saka MD[1], Yoshinobu Watanabe MD PhD[1] and Takashi Matsushita MD DSc[1,2,3]
[1]Department of Orthopaedic Surgery, Tokyo University School of Medicine, Tokyo, Japan
[2]Fukushima Medical University, Fukushima, Japan
[3]Southern TOHOKU General Hospital, Koriyama, Japan

Clinical scenario

- You see a 32-year-old male who has sustained a comminuted open tibial shaft fracture as a result of a motor vehicle accident two months after the internal fixation.
- Radiographs show no sign of callus formation. There is no clinical, biochemical or radiographic evidence of infection. He has mild tenderness at the fracture site.
- Previously, he worked as a construction worker and wishes to return to his previous work as soon as possible. He does not wish to undergo secondary surgical intervention.

Top three questions

1. In patients with acute tibial fractures, does low-intensity pulsed ultrasound (LIPUS) accelerate fracture healing and improve health-related quality of life (QOL) of the patient compared to no treatment to accelerate fracture healing?

2. In patients with chronic tibial nonunion, does LIPUS promote fracture healing of nonunion and improve health-related QOL of the patient compared to no treatment to accelerate fracture healing?
3. In patients with acute tibial fractures, does pulsed electromagnetic field (PEMF) treatment and extracorporeal shockwave therapy (ESWT) accelerate fracture healing and improve health-related QOL of the patient compared to no treatment to accelerate fracture healing?

Question 1: In patients with acute tibial fractures, does low-intensity pulsed ultrasound (LIPUS) accelerate fracture healing and improve health-related quality of life (QOL) of the patient compared to no treatment to accelerate fracture healing?

Rationale

Length of time to fracture healing is of paramount importance to avoid prolonged periods of pain and disability. In vitro and in vivo studies have revealed that LIPUS increases cell proliferation, protein synthesis, membrane permeability, integrin expression, and cytosolic Ca^{2+} levels, which indicates bone repair response.[1] Several clinical studies support the use of LIPUS and it has been widely used to accelerate fracture healing in acute fractures and to prevent nonunion.[2–5] Clinical effectiveness of LIPUS on fracture healing and QOL of the patient has to be clarified.

Clinical comment

Approximately, 5% of fractures go on to nonunion.[6] Due to limited soft tissue coverage, the risk of developing nonunion is higher in tibia compared to other bones. In addition, the risk of nonunion is increased with increasing Gustilo–Anderson grades.[7]

Available literature and quality of the evidence

There are three randomized controlled trials (RCTs) of acute tibial fractures and two meta-analyses including other bones that are available to answer this question (all level I).[2–4,8–10] Earlier RCTs showed an effectiveness of LIPUS on radiographic union, but limitations of those studies are small sample size, risk of bias, inconsistent results, and lack of evaluation of patient-based outcome measures. Previous meta-analysis by Griffin et al. was based on those RCTs.[4] An RCT in 2016 which evaluated the functional outcome of patients who had sustained acute tibial fracture and subsequent meta-analysis has cast doubt on the effectiveness of LIPUS in acute fractures.[9,10]

Heckman et al. (level I) conducted an RCT in simple closed or Gustilo I open tibial fracture treated by cast.[2] Patients in the LIPUS group healed significantly faster both on radiographs and overall healing compared to the control group (86 ± 5.8 days vs 114 ± 10.4 days, $p = 0.01$, 96 ± 4.9 days vs 154 ± 13.7 days, $p = 0.0001$, respectively). The weakness of this study is that there is a 31% loss to follow-up. Leung et al. (level I) investigated the effect of LIPUS on fracture healing for open and/or severely comminuted tibial shaft fractures fixed by intramedullary nail or external fixator.[3] They concluded that the LIPUS-treated group showed statistically significantly better healing as demonstrated by all assessments. The downside of this study was high risk of bias such as selection bias and

detection bias. However, in the study of fresh tibial fractures treated with reamed and statically locked intramedullary nail by Emami et al. (level I), the average healing time was 155 ± 22 days (median 113 days) for the active treatment group and 125 ± 11 days (median 112 days) for the placebo group ($p = 0.76$).[8] It was concluded that LIPUS treatment did not shorten healing time. None of these studies measured the functional outcome and pain score of the patients. Based on the inconsistency and lack of patient-based outcomes in the result and high risk of bias, Busse et al. (level I) reevaluated the effectiveness of LIPUS compared with sham treatment in acute tibial fractures by randomized trial with a parallel group design of 501 patients.[9] According to their study, postoperative use of LIPUS after tibial fracture fixation did not accelerate radiographic healing as well as functional outcome. There was also no difference in time to radiographic healing (hazard ratio [HR] = 1.07; 95% confidence interval [CI]: 0.86–1.34; $p = 0.55$) and there was no improvement of functional outcome such as 36-item Short Form Health Survey (SF-36), time to return to work without limitations, time to return to household activities without limitations, time to full weight bearings, time to return to ≥80% of function before injury, and time to return to leisure activities without limitations. The risks of unplanned secondary procedures related to bone healing, infection, and nonunion were similar. Subsequent meta-analysis by Schandelmaier et al. (level I), including studies in fractures in other sites, stated that, from studies with a higher quality of evidence, LIPUS does not accelerate radiographic fracture healing, does not affect the risk of subsequent operation related to fracture healing, and does not affect outcomes important to patients.[10]

Findings

Overall, the RCT by Busse et al., which is larger and less biased compared to other RCTs, demonstrated that in the acute phase of tibial fractures LIPUS failed to show the acceleration of radiographic fracture healing and failed to show the prevention of nonunion. The same study suggests that LIPUS does not improve the functional outcome, such as SF-36 and the period going back to the work.

Resolution of clinical scenario

In this acute phase of fracture, there is high-quality evidence to support that the patient would not be benefit from LIPUS treatment in terms of accelerating radiographic union, preventing nonunion, and improvement of functional outcome.

Question 2: In patients with chronic tibial nonunion, does LIPUS promote fracture healing of nonunion and improve health-related QOL of the patient compared to no treatment to accelerate fracture healing?

Rationale

LIPUS has been used in chronic nonunion as well. Compared to secondary surgery for nonunion, LIPUS treatment is less invasive. However, there is also a failure of union after the use of LIPUS in the treatment of chronic nonunion.[11] Effectiveness of LIPUS in avoiding surgical treatment in chronic nonunion has to be clarified.

Clinical comment

In the event of established nonunion, patients normally require a secondary surgery for treatment. It is important for patients to know whether they can avoid the secondary surgery if they use LIPUS. If LIPUS is effective for established nonunion, it is less invasive for patients. In addition, it is more cost-effective, considering the cost of secondary surgery.

Available literature and quality of the evidence

Schofer et al. conducted an RCT (level I) in delayed unions of tibia and concluded that mean improvement in bone mineral density was 1.34 (90% CI: 1.14–1.57) times greater for LIPUS-treated subjects compared to sham subjects ($p = 0.002$).[12] A mean reduction in bone gap area also favored LIPUS treatment ($p = 0.014$). However, in this study there is no statistical difference of the healing rate between two groups: 65% (33 out of 51) of LIPUS and 46% (23 out of 50) of placebo treatment ($p = 0.07$).

Most of the studies related to the use of LIPUS in chronic nonunion are retrospective cohort studies, and those studies as well as RCT by Schofer et al. were summarized as meta-analysis by Leighton et al. (level 1).[13] By this meta-analysis, overall pooled estimate of effect size for healing was 82% (95% CI: 77–87, $I^2 = 71$) for any anatomical site. Subgroup analysis of the tibial nonunion with 354 patients showed 86% of healing rate (95% CI: 79–93) but with considerable heterogeneity($I^2 = 81$). Hypertrophic nonunion had more favorable results compared to atrophic nonunion (odds ratio [OR] = 2.11; 95% CI: 1.26–3.54, $I^2 = 6$). There is no study which compares LIPUS treatment and surgical intervention for nonunion.

Findings

Although one RCT showed the improvement of bone mineral density, this study failed to show the difference of healing rate between the LIPUS treatment group and the placebo treatment group.

Meta-analysis showed an 86% healing rate in chronic tibial nonunion using LIPUS. However, there was a high heterogeneity between studies. It is difficult to test the efficacy of LIPUS for nonunion by RCT. There is no study which evaluated the functional outcome in the use of LIPUS for chronic nonunion.

Resolution of clinical scenario

It is difficult to prove the efficacy of LIPUS over surgical treatment for chronic nonunion. However, given the reported union rate, LIPUS may be useful for treating nonunion, especially in patients who want to avoid secondary surgery.

Question 3: In patients with acute tibial fractures, does pulsed electromagnetic field treatment (PEMF) and extracorporeal shockwave therapy (ESWT) accelerate fracture healing and improve health-related QOL of the patient compared to no treatment to accelerate fracture healing?

Rationale

PEMF and ESWT are other types of bone stimulators. Electric and electromagnetic fields regulate the expression

of genes in connective tissue cells for extracellular matrix proteins, which results in an increase in cartilage and bone.[14] Shockwaves have been shown to produce oxygen radicals, which are supposed to play a key role in translating the mechanical energies of the shockwaves into biological effects.[15] Clinical effectiveness to support the use of PEMF and ESWT on bone union has to be determined.

Clinical comment

Although LIPUS is the most widely used method to accelerate fracture healing, it is important to evaluate the efficacy of other methods such as PEMF and ESWT to the patients.

Available literature and quality of the evidence

PEMF There is only one randomized trial (level I) testing the efficacy of PEMF treatment in acute tibial fractures. Adie et al. conducted a multicenter double-blind randomized trial with 259 acute tibial fracture patients and demonstrated that PEMF does not reduce the secondary intervention for nonunion. In their study, 16 out of 106 in the treatment group and 15 out of 112 in the placebo group needed surgical intervention because of delayed union or nonunion (risk ratio [RR]: 1.02; 95% CI: 0.95–1.14; p = 0.72).[16] They also tested the functional outcomes using the SF-36 and Lower Extremity Functional Scale scores at 12 months and found no difference between groups.

Aleem et al. conducted a meta-analysis (level I) to assess the efficacy of electrical stimulator for bone healing.[17] They included other bones and trials treating spinal fusion. In the subgroup analysis focused on fresh fractures, there was no difference of radiographic nonunion at last reported follow-up to 12 months (RR: 0.83; 95% CI: 0.51–1.35).

ESWT Wang et al. tested the efficacy of ESWT on acute fracture of the tibia and femur in 59 fractures by quasi-randomized trial (level I).[18] The rate of nonunion was 11% (3 out of 27) in the study group versus 20% (6 out of 30) in the control group ($p < 0.001$). Significantly better rates of fracture healing were noted in the study group than in the control group at 3, 6, and 12 months ($p < 0.001$). In addition, the Visual Analog Scale (VAS) score was better in the study group at 3, 6, and 12 months ($p < 0.001$). However, this study was quasi-randomized and the mode of the treatment was selected according to the days of the week, therefore increasing the risk of selection bias.

Findings

Level I studies showed that PEMF did not reduce the risk of nonunion rate of acute tibial fracture and did not improve the functional outcome of the patients. ESWT seems to reduce the nonunion rate of acute fractures of the tibia and femur and improve the VAS score. However, RCTs with better quality are needed.

Resolution of clinical scenario

ESWT but not PEMF might be beneficial to the patient in accelerating union of acute tibial fracture.

Summary of answers

- In acute tibial fractures, LIPUS does not improve the functional recovery of the patients, does not accelerate radiographic union of acute fractures, and does not change the risk of secondary surgery related to fracture healing.
- In chronic nonunion, patients might be able to avoid secondary surgery with LIPUS treatment.

- PEMF does not change the functional outcome of the patients.
- PEMF is unlikely to reduce the risk of radiographic nonunion in acute fractures or reduce the pain caused by fractures.
- ESWT seems promising to reduce the nonunion rate of acute fractures of the tibia and femur and improve the VAS score.

[4]Division of Orthopaedic Surgery, Department of Surgery, University of Calgary, Calgary, AB, Canada

Clinical scenario

- A 54-year-old female presents with a fractured tibial plateau following a low energy injury at home.
- The patient's X-rays indicate a split depression injury laterally, with an associated medial condylar injury with a posterior medial split.

Top three questions

1. In periarticular fractures with joint depression, can calcium phosphate bone substitutes enhance the standard fixation when compared with autogenous bone grafting and fixation or fixation alone?
2. In patients with a fracture requiring bone graft augmentation, does the use of calcium phosphate

cement instead of autogenous iliac crest bone graft result in fewer complications?

3. In osteoporotic fractures, does calcium phosphate augmentation improve fixation of implants when compared with no augmentation of fixation?

Rationale

Periarticular fractures are common injuries that result from indirect coronal and/or direct axial compressive forces. As the patient ages, the fracture pattern is usually a split depression type without associated ligamentous injury. Surgical guidelines advocate anatomic reduction, re-establishment of the long bone alignment, subchondral bone grafting to support the articular cartilage, and stable internal fixation.[1]

Clinical comment

Metaphyseal fractures are among the most difficult fractures to treat. Depressed articular fragments can crush the underlying weak subchondral cancellous bone, leaving a void when the articular segments are reduced surgically. Potential long-term problems including pain, post-traumatic arthritis secondary to apoptosis of the chondrocyte, and limitation of motion and function might occur if joint surface subsidence cannot be prevented or at least limited.

Available literature and quality of the evidence

Russell et al. compared the treatment of subarticular bone defects in tibial plateau fractures with conventional autogenous iliac bone graft (AIBG) to bioabsorbable calcium phosphate paste (alpha-BSM, Etex Corporation) in a randomized controlled trial (RCT).[1] All fractures united in both groups within the same time periods.

There was an unexpected statistically significant (p = 0.009, Fisher's exact two-tailed test) higher rate of articular subsidence in the AIBG group compared to the alpha-BSM group. Subsidence of equal to or greater than 2 mm on the anteroposterior radiographs was found in 31% of patients in the AIBG group compared to 8% in the alpha-BSM group in the final evaluation. This provided level I evidence that bioabsorbable calcium phosphate material, such as alpha-BSM, appeared to be a better choice for the treatment of subarticular defects than AIBG in tibial plateau fractures.

Johal et al. performed a similar RCT on os calcis fractures comparing open reduction and internal fixation (ORIF) plus alpha-BSM to ORIF alone in the treatment of calcaneal bone voids encountered after operative treatment of displaced intra-articular fractures of the calcaneous.[2] There was no difference between the groups in the degree of collapse of Bohler's angle at six weeks and three months when compared to initial postoperative values. However, at six months the mean collapse of the alpha-BSM and ORIF group was 5.6° (standard deviation [SD] 4.5) and ORIF alone was 9.1° (SD 5.8). This was statistically significant (p <0.01).

Findings

Level I evidence suggests that the addition of calcium phosphate to internal fixation in periarticular fractures is more supportive than fixation alone or fixation with autologous bone graft. Although the radiographic outcomes were better with calcium phosphate, these studies were not powered to detect differences in patient-reported outcome scores.

Resolution of clinical scenario

- For ORIF of tibial plateau fractures, calcium phosphate reduces articular subsidence better than autogenous iliac crest bone graft.
- For ORIF of os calcis fractures, calcium phosphate reduces articular subsidence better than fixation alone.

Question 2: In patients with a fracture requiring bone graft augmentation, does the use of calcium phosphate cement instead of autogenous iliac crest bone graft result in fewer complications?

Rationale

Autogenous bone graft, typically from the iliac crest, has been stated in the past to be the gold standard of bone grafting. However, it is associated with donor site morbidity including chronic pain and wound complications.[3–9] Calcium phosphate cement has increased compression strength and improved custom-filling of bone defects. However, any alternative graft material should have a better risk/benefit profile than the current standard.

Clinical comment

Alternative grafting materials for filling fracture voids include allograft and synthetic bone materials. While using allograft avoids the donor site morbidity associated with autograft, it also can lead to complications including potential disease transmission, host–donor incompatibility, and possibly lower union rates.[10–12] Therefore, synthetic bone materials, such as calcium phosphate bone cement, appear to be an attractive alternative. They perform better

acutely and over the first year and lack the disadvantage of bone site morbidity or the potential for infection and disease transmission associated with allograft.

Available literature and quality of the evidence

There are several narrative review articles that address the use of bone grafting in fractures and trauma situations.[3–16] In addition, Bajammal et al. have completed a meta-analysis (level I evidence) of studies comparing calcium phosphate bone cement to bone graft.[17] The meta-analysis included 14 RCTs. The studies had documented outcomes that included pain, maintenance of fracture reduction, infection, and functional outcomes.

Findings

The meta-analysis found there was a lower prevalence of pain at the fracture site in the calcium phosphate group (n = 455 patients) (relative risk = 0.57; 95% confidence interval [CI]: 0.33–0.99]; relative risk reduction = 43%; 95% CI: 1–67%; p = 0.04; heterogeneity tests, p = 0.39, I^2 = 0%). They were not able to pool the functional outcomes across the studies; however, the results of individual studies suggested improved functional outcomes in association with the use of calcium phosphate cement.

There was no significant difference in the prevalence of infection between the calcium phosphate bone cement group and the control group (relative risk = 0.74; 95% CI: 0.19–2.87], p = 0.66; heterogeneity, p = 0.03, I^2 = 59%); however, the use of calcium phosphate significantly reduced the risk of infection in patients with distal radial fractures (relative risk = 0.15; 95% CI: 0.15–0.42; p <0.0001; relative risk reduction = 85%; 95% CI: 58–85%).

Calcium phosphate reduced the risk of loss of reduction compared with autogenous bone graft by 68% (n = 166,

relative risk = 0.32; 95% CI: 0.14–0.70; p <0.001; relative risk reduction = 68%; 95% CI: 30–86%]; number needed to treat, 6; heterogeneity, p = 0.87, I^2 = 0%) and in patients with tibial plateau fractures specifically, the benefits were similar (relative risk = 0.3; 95% CI: 0.13–0.72], p = 0.007; relative risk reduction = 70%; CI: 28–87%; number needed to treat, 6; heterogeneity, p = 0.64, I^2 = 0).

The cost of autogenous bone graft harvesting was investigated in a study by St John et al.[18] The direct and indirect costs involved in harvesting iliac crest were gathered from a cross-section of hospitals in the United States via a questionnaire completed by both finance and surgical personnel. The study concluded the mean cost of autologous bone graft is estimated to be $4154, assuming a hospital stay extended by one day. In comparison, 10 cc of alpha-BSM, a common amount used in Russell's trial,[1] has an average cost of $1270. Additional cost savings include no additional tray instrumentation and a reduction in operating time and postoperative complications.

Resolution of clinical scenario

- Anterior iliac crest bone grafting (AICBG) often results in donor site pain and morbidity.
- Calcium phosphate cement is associated with less pain.
- Calcium phosphate cement decreases the risk of losing fracture reduction.
- Calcium phosphate cement lowers the infection rate in distal radius fractures.
- Some studies have reported better functional outcomes with calcium phosphate cement.
- Inclusive healthcare costs are actually less with calcium phosphate than iliac crest autograft if it saves

the patient a day or more in hospital.

Question 3: In osteoporotic fractures, does calcium phosphate augmentation improve fixation of implants when compared with no augmentation of fixation?

Rationale

Osteoporotic cancellous bone has high porosity and low mechanical strength. Calcium phosphate can be manufactured into various forms, including ceramics, powders, and cements. These can also be manufactured with varying porosity structures and therefore variable compressive strengths from 4 MPa to 60 MPa. In addition, calcium phosphate cements may be molded or injected to custom-fill defects.

Clinical comment

Osteoporotic fractures remain difficult to treat. Calcium phosphate bone substitute material (BSM) can be used to provide a scaffold for new bone ingrowth and also augment fracture hardware, such as bone screws. With the advances in minimally invasive surgical stabilization of fractures, the need for less invasive delivery systems for bone graft substitutes has driven new research into the fluid dynamics of self-setting bone graft substitutes to allow percutaneous application without the previous necessity of large dissections to open the fracture cavities.[19] The previous generations of calcium phosphate synthetic BSM were nonintrusive nonnewtonian fluids that were not amenable to conventional needle injection techniques. The addition of viscosity modifiers such as carboxymethylcellulose and

surfactants/biodegradable oils to calcium phosphate cements changes their flow characteristics to allow controlled flow and good trabecular intrusion.[19] N-Force Blue (Zimmer Biomet, Warsaw, IN) and IN3 (Innoterre, Radebeul, Germany) have received regulatory clearances and marketed in the United States and Europe, respectively, permitting controlled augmentation of the osteopenic bone around implants. An example of this augmentation is a new development of a fenestrated screw or intraosseous implant optimized for hydraulic flow of calcium phosphate cement to fill the defective cancellous bone architecture but also to permit augmentation of the overlying cortex at the implant insertion site. This technique serves to reinforce the structural stability of the implant along its length and not just at one location. The N-Force Fixation System (Zimmer Biomet, Warsaw, IN) was the first FDA-cleared fracture implant with this ability and has been available in Europe and the United States. Cortical replacement by synthetic bone substitutes in diaphyseal fractures is not yet possible, but three-dimensional printing developments may yield such materials in the near future.

Available literature and quality of the evidence

Literature is available for calcium phosphates use in osteoporotic fractures of the proximal humerus, distal radius, vertebra, hip, and tibial plateau. Unfortunately, much of the literature reports retrospective studies or case series (level III–IV).[20–23]

Some level I evidence is available for osteoporotic distal radius fractures,[24] hip fractures,[25] and tibial plateau fractures.[26]

Findings

Cassidy et al. performed a randomized trial of distal radius fractures treated with closed reduction and casting or external fixation versus the same augmented with calcium phosphate cement.[24] They found early benefits such as increased grip strength and range of motion in the augmented group but by one year there were no clinical differences between groups.

Lindner et al. performed a systematic review of the role of bone substitutes in the treatment of osteoporotic hip fractures.[25] They only identified two randomized trials each related to the use of calcium phosphate in displaced femoral neck fractures and unstable intertrochanteric fractures. In femoral neck fractures they recommend against the use of calcium phosphate augmentation due to a trend toward more reoperations in the augment group with no long-term advantages. For intertrochanteric fractures they found a modest reduction in pain and a slight improvement in quality of life, but follow-up was only six months.

Goff et al. reviewed the use of bone graft substitutes in tibial plateau fractures.[26] Overall, results favored the use of bone graft substitutes. Osteoporotic fractures were included in the trials reviewed, but none of the trials was on solely osteoporotic fractures.

Robinson et al. reported good functional outcome with calcium phosphate as an augment in a series of severely impacted valgus fractures of the proximal humerus.[22] Ryu et al. found that early benefits, such as decreased pain and disability scores after using injectable calcium phosphate in balloon kyphoplasty for osteoporotic vertebral fractures, decreased within six months as vertebral height loss decreased and kyphotic angle increased.[27]

Resolution of clinical scenario

- There is not enough evidence to recommend the routine use of calcium phosphate to augment osteoporotic fractures.
- Short-term results of calcium phosphate use in intertrochanteric fractures favor the use of calcium phosphate, but long-term evidence is not available.
- Results with femoral neck fractures have not been favorable to date but low numbers and no long-term follow-up are limitations with this literature.

Summary of answers

- Calcium phosphate provides stronger support to subchondral bone than autogenous bone graft or fixation alone.
- Calcium phosphate decreases the risk of losing fracture reduction.
- Calcium phosphate results in less pain than AICBG.
- Calcium phosphate lowers the infection rate in distal radius fractures.
- There is not enough evidence to recommend the routine use of calcium phosphate as an augment to osteoporotic fractures but as an addition to a good construct it may add support.

Clinical scenario

- A 28-year-old snowboarder crashed into a tree and was dazed at the scene, had labored respirations, and carried off via stretcher and airlifted to a level I trauma center.
- A trauma work-up revealed a Glasgow Coma Score of 13 in a mildly disoriented male who complained of severe shoulder, chest, and back pain.
- History revealed that he was a right-handed warehouse stockman who was otherwise healthy. Physical exam revealed left-sided facial lacerations and an abrasion over a tender mass at the acromion. He had a strong grip, intact sensation of C5–T1, but an inability to forward elevate or externally rotate the shoulder.

Radiography

A chest X-ray revealed four consecutive left-sided rib fractures and a pneumothorax, prompting dedicated shoulder X-rays. A fracture of the scapula in the region of the glenoid neck in addition to a displaced acromioclavicular (AC) joint was diagnosed. Moderate displacement at the lateral scapula border, and a glenopolar angle (GPA) of 63° as seen on the anteroposterior (AP) view, with an angular deformity of 21° measured on the scapula Y X-ray, prompted a computed tomography (CT) scan.

On three-dimensional (3D) CT, the patient had 20° of angulation, 150% translation and 0.5 cm of displacement of the lateral border. Fracture lines propagated into the spinoglenoid notch, and out the scapular spine, and vertebral border. A two-dimensional (2D) CT revealed no intra-articular involvement, however there was significant displacement at the base of the coracoid, and a retroverted glenoid neck of 11°.

Top three questions

1. For patients with a scapula fracture, does CT, compared to plain X-rays, provide an advantage in terms of diagnosis and management?
2. In patients with scapula fractures, does operative management, compared to nonoperative management, result in better outcomes?
3. In patients with scapula fracture, do rehabilitation protocols differ for those who have undergone surgery compared to those managed nonoperatively?

Question 1: For patients with a scapula fracture, does CT, compared to plain X-rays, provide an advantage in terms of diagnosis and management?

Rationale

Scapula fractures account for approximately 1% of all fractures, about the same percent as calcaneus fractures and exceeding that of the talus fractures. Therefore, this injury is quite relevant; particularly for trauma centers, where such injuries are filtered with regularity.

Clinical comment

A history should render the patient's job description and recreational activities. The shoulder can compensate adequately for lower functioning individuals; therefore, not every displaced scapula fracture requires surgery. A physical exam should include whether abrasions exist over the shoulder, palpation of the AC and sternoclavicular joints, and a neurovascular exam of the extremity. When the patient can be upright, they must be examined disrobed to appreciate shoulder drooping, which is bothersome in severe cases.

Available literature and quality of the evidence

There are level IV and level V studies available to answer this question.

Findings

Shoulder X-rays yield the detail necessary to determine whether or not there is displacement of a fracture. If on the

radiographs, there is displacement of a fracture greater than one centimeter, a 3D CT should be obtained to specifically measure displacement and angulation. In nondisplaced fractures in which nonoperative treatment has been selected, weekly follow-up films over two weeks should be obtained due to the risk of displacement (level IV).[1]

Oftentimes, scapula fractures are delayed in referral or workup, either because of missed injury, or treatment of other bodily injuries, or the time it takes to refer to an appropriate medical center (level IV).[2] In cases when such delay is greater than two weeks, an EMG and nerve conduction study should be performed due to a high association with nerve injuries (level V).[3] This information is helpful for preop planning and prognostication. A 2D CT scan is useful when there is intra-articular involvement to determine step, gap, and number of fragments.

Resolution of clinical scenario

- Medialization, angulation, GPA, and intra-articular step-off should be measured. Medialization is often misunderstood, and represents the displacement at the fractured lateral border, or the position of the proximal relative to the distal main fragments.
- *Angulation* refers to the angle measured between the lateral borders on the scapula Y view.
- GPA measures the inferior rotation of the glenoid (on its proximal fragment) relative to the body as measured off an AP image.
- A 3D CT scan is vital for accuracy since this modality allows for the perfect rotation of the images to get an accurate *AP and Y view*.

Question 2: In patients with scapula fractures, does operative management, compared to nonoperative management, result in better outcomes?

Rationale

There are multiple opinions on the degree of displacement or angular deformity which warrant open reduction and internal fixation (ORIF). It is important to understand when to operate on patients with scapula fractures.

Clinical comment

It is important to understand which fractures require surgical treatment. For those which do require operative management, it is also important to understand which surgical approach is optimal.

Available literature and quality of the evidence

There are level IV and V studies available to answer this question.

Findings

Though nonoperative treatment of double lesions of the superior shoulder suspensory complex have been shown to eventuate in good or excellent outcomes, it is likely that such series reflected minimally displaced injuries since almost no malunions were reported (all level IV) (Table 76.1).[4–7] Nonoperative series to date have not stratified data based on measured displacement, and rigorous outcomes assessment of strength, motion, and function are lacking in those series (all level IV) (Table 76.1).[4–8]

Furthermore, other authors have reported patients with malunion which eventuated in poor outcomes, indicating that not all malunions are benign (all level IV).[9–11] One study demonstrated increased pain and dysfunction and/or decreased motion in almost half of patients who were malunited.[7]

These have included displaced articular injuries between 4 and 10 mm (all level IV),[2,19–21] fractures with lateral border displacement (*medialization*) of 10–20 mm (all level IV),[2,11,19,22] angular deformity of 25–45°,[2,11,19,22] and a GPA of <20°.[9,10] Some authors feel that excessive translation and version of the proximal relative to the distal fragment should be considered a relative indication for surgery (level IV and V, respectively).[1,23] Though there is no “high level” evidence to date, deductive reasoning would lead us to believe that some degree of displacement and angular deformity will yield an adverse clinical result. If function and form are interdependent then malunion results in compensation, and by definition compensation has some physiologic cost. Experts differ as to what amount and type of displacement warrants intervention, but there is growing consensus, given the positive surgical results on record, that operative correction of displaced scapula fractures is beneficial for a subset of patients.

Table 76.1 Current evidence in floating shoulder fractures.

Author	**Level of Evidence # of Patients # Followed/Total (% Follow-up)**	**Summary**
Therapy		
Herscovici D, et al. (1992)	IV 2 Nonop/7 Op/2 LTF 9/11 (82%)	The authors reviewed 9 patients having double lesion injuries and recommended the use of anteroposterior radiographs of the clavicle and scapula, and trans-scapular views. Internal fixation of the clavicle should be performed as soon as possible to prevent malunion of the scapular-neck fracture.
Leung KS and Lam TP (1993)	IV 15 Operative 15/15 (100%)	The authors found that operative treatement for ipsilateral fractures of the scapular neck and the clavicle is safe and that functional recovery is predictably good with most patients regaining normal function of the shoulder soon after injury. With fixation of both fractures, postoperative rehabilitation is greatly facilitated.

Author	**Level of Evidence # of Patients # Followed/Total (% Follow-up)**	**Summary**
Rikli D, et al. (1995)	IV 12 Operative 12/12 (100%)	The authors found that in an unstable shoulder girdle, the therapeutic goal can be reached with ORIF of the clavicle alone. The fracture of the scapular neck is usually reduced indirectly and sufficiently stable for functional aftertreatment. ORIF of the scapula is therefore, only necessary in displaced intra-articular fractures.
Oh CW, et al. (2002)	IV 3 Nonop/10 Op 13/13 (100%)	The authors found that surgical treatment for double disruption of the SSSC is a good option, allowing for early rehabilitation and giving good functional results.
Prognosis		

Author	Level of Evidence # of Patients # Followed/Total (% Follow-up)	Summary
Ramos L, et al. (1997)	IV 16 Nonoperative 13/16 (81%)	The authors found that after a mean follow-up of 7.5 years, the functional results were good or excellent in 92% of the cases and propose that successful nonoperative treatment was due to intense physical therapy, and to the fact that most clavicular and scapular fractures do not require formal reduction for healing, and vicious callus are well tolerated by most patients.
Edwards SG, et al. (2000)	IV 36 Nonoperative 20/36 (56%)	The authors concluded that many floating shoulder injuries are not as unstable as was previously thought and do not require operative fixation. None of the functional assessments utilized identified poor outcomes and thus, it is difficult to identify factors that might predict which fractures will do well with nonoperative treatment and which will have a better result with surgery.

Author	Level of Evidence # of Patients # Followed/Total (% Follow-up)	Summary
Egol KA, et al (2001)	IV 12 Nonop/7 Op/4 LTF 19/23 (83%)	The authors concluded that good results may be seen both with and without operative treatment, and therefore do not universally recommend operative treatment for double disruption of the superior suspensory complex. Treatment must be individualized for each patient.
Van Noort A, et al. (2001)	IV 31 Nonop/4 Op/11 LTF 35/46 (76%)	The authors conclude that ipsilateral fractures of the neck of the scapula and of the clavicle is not inherently unstable and, in the absence of caudal dislocation of the glenoid, conservative treatment gives a good functional outcome.

Author	Level of Evidence # of Patients # Followed/Total (% Follow-up)	Summary
Hashiguchi H and Ito H (2003)	IV 5 Operative 5/5 (100%)	The authors conclude that for a patient with a floating shoulder, it is important to determine the severity of fracture displacement accurately and the presence or absence of coraclavicular ligament rupture radiographically. On the basis of those factors, an appropriate treatment for both fractures that may lead to a satisfactory clinical outcome can be determined.
Labler L, et al. (2004)	IV 8 Nonop/9 Op 17/17 (100%)	The authors concluded that nondisplaced or less displaced floating shoulders are expected to give good results after nonoperative treatment and recommend operative treatment in cases of displacement of scapular neck fracture of more than 25mm and/or reduction of the glenopolar angle less than 30 degrees as an indirect sign for ruptured associated ligaments.

Fractures of the scapula neck and body should be addressed through a posterior approach. There have been a number of modifications to the posterior Judet approach,[24] which are variations on the theme of invasiveness (level IV and V).[19,25,26] Either the entire rotator cuff (and deltoid) can be mobilized from the vertebral border to the lateral border on the neurovascular pedicle or muscular intervals between the infraspinatus and teres minor can be utilized to spare the muscles of detachment from their origins. Such an interval allows good access to the articular surface (level IV).[26] A straight posterior approach to the glenoid neck can be used for fractures isolated to the posterior glenoid or those lateral to the acromial base. The only glenoid fracture associated with the scapula body, which should be addressed from anterior rather than posterior, are those involving the superior coronal half extending into the superior fossa, usually inferior to the coracoid. Sometimes the coracoid itself is detached at the base in these variants.

Most articular fractures, however, are best accessed through a deltopectoral approach, as the version of the glenoid allows for better visualization from anterior, either through an arthrotomy or through a fracture interval. A transaxillary approach has also been described for inferior glenoid fractures in the frontal plane (level V).[27]

Resolution of clinical scenario

- Displacement and intra-articular disruption are key considerations in terms of deciding on a management plan.
- Most articular fractures, however, are best accessed through a deltopectoral approach.

Question 3: In patients with scapula fracture, do rehabilitation protocols differ for those who have undergone surgery compared to those managed nonoperatively?

Rationale

Eighteen muscles insert on, originate from, or traverse the scapula. This bone provides interplay between the clavicle, humerus, and the thoracic cage, as well as provides the conduit for the suprascapular nerve and protection of the brachial plexus. Thus, appropriate rehab is critical to recovery.

Clinical comment

It is important to mobilize patients as soon as safely possible. However, it is unclear how long this timeline should be for operative versus nonoperative management.

Available literature and quality of the evidence

Only level IV evidence exists to answer this question.

Findings

One of the goals of surgery is to achieve stability, which means that the fixation can withstand physiologic motion. Intraoperatively, the patient should be taken through a range of motion to prove such stability has been accomplished. To our knowledge, different rehabilitation regimens have not been studied or compared after scapula fractures.

The only caveat for physical therapy and rehabilitation in nonoperated scapula fractures is that the patient requires a

period of immobilization due to the instability of the fragments. Not only are they too painful for a few weeks to begin motion, but there is a risk of further displacement if motion ensues too early.[1] This period of immobilization is not benign, as extrinsic adhesions establish, and must be overcome.

Resolution of clinical scenario

- Physical therapy protocols are generally similar for operative and nonoperative management.
- Little evidence exists on this topic.

Summary of answers

- Displacement and intra-articular disruption are key considerations in terms of deciding on a management plan.
- Most articular fractures, however, are best accessed through a deltopectoral approach.
- Physical therapy protocols are generally similar for operative and nonoperative management.
- A 3D CT scan is vital for accuracy since this modality allows for the perfect rotation of the images to get an accurate *AP and Y view*.

77
Sternoclavicular Joint

Annie Weber MD[1] and Raymond A. Pensy MD[1]
University of Maryland Department of Orthopaedic Surgery, University of Maryland Medical System, Baltimore, MD, USA

Clinical scenario

- A 30-year-old male passenger presents status post T-bone motor vehicle collision with right-sided anterior superior chest pain, ecchymosis, and swelling.
- Reports difficulty swallowing, guarded right shoulder range of motion, and tenderness at the right sternoclavicular (SC) joint.
- Computed tomography (CT) scan with three-dimensional (3D) reconstructions show a posterior SC joint dislocation.

Top three questions

1. In patients with posterior SC joint dislocations does CT provide a better understanding of the injury severity when compared to plain radiographs?
2. In patients with an SC joint dislocation undergoing closed reduction, is the shoulder abduction and traction technique more successful and have fewer complications than other closed reduction techniques?
3. In patients with an SC joint dislocation, does open fixation with allograft or autograft result in improved

patient outcomes when compared to open fixation with metal implants?

Question 1: In patients with posterior SC joint dislocations does CT provide a better understanding of the injury severity when compared to plain radiographs?

Rationale

The clinical anatomy and mechanism of injury associated with posterior SC joint dislocations is complex. A thorough understanding is the first step in evaluating the injury and directing treatment.

Clinical comment

Posterior SC joint dislocations are morbid and, in some cases, life threatening.

Available literature and quality of the evidence

- 1 level IV
- 8 level V.

Findings

The SC joint, an inherently unstable diarthrodial synovial joint, requires stabilization by intrinsic and extrinsic structures to maintain congruency.[1–3] In the event of traumatic injury, thorough evaluation of the joint capsule and surrounding structures must be completed to determine joint stability and injury extent.

The articulating surface of the SC joint is oriented in an anterior lateral to posterior medial sloping direction with a relatively flat articular surface in the axial plane (Figure 77.1)[1] Intrinsic and extrinsic stabilizers as well as the surrounding musculature provide added stability.[1,4] The posterior ligamentous complex is crucial for joint stability regardless of dislocation direction.[1,5] When the posterior capsule is disrupted there is an estimated 41% increase in anterior translation and 106% increase in posterior translation of the joint.[5] Only 25% anterior and 0.7% posterior translation of the SC joint occurs with anterior capsule disruption.[5] When all but the capsular ligaments were disrupted, no significant instability was reported.[6] Subclavius adds additional protection by reducing the upward displacement of the clavicle under compressive loads.[2]

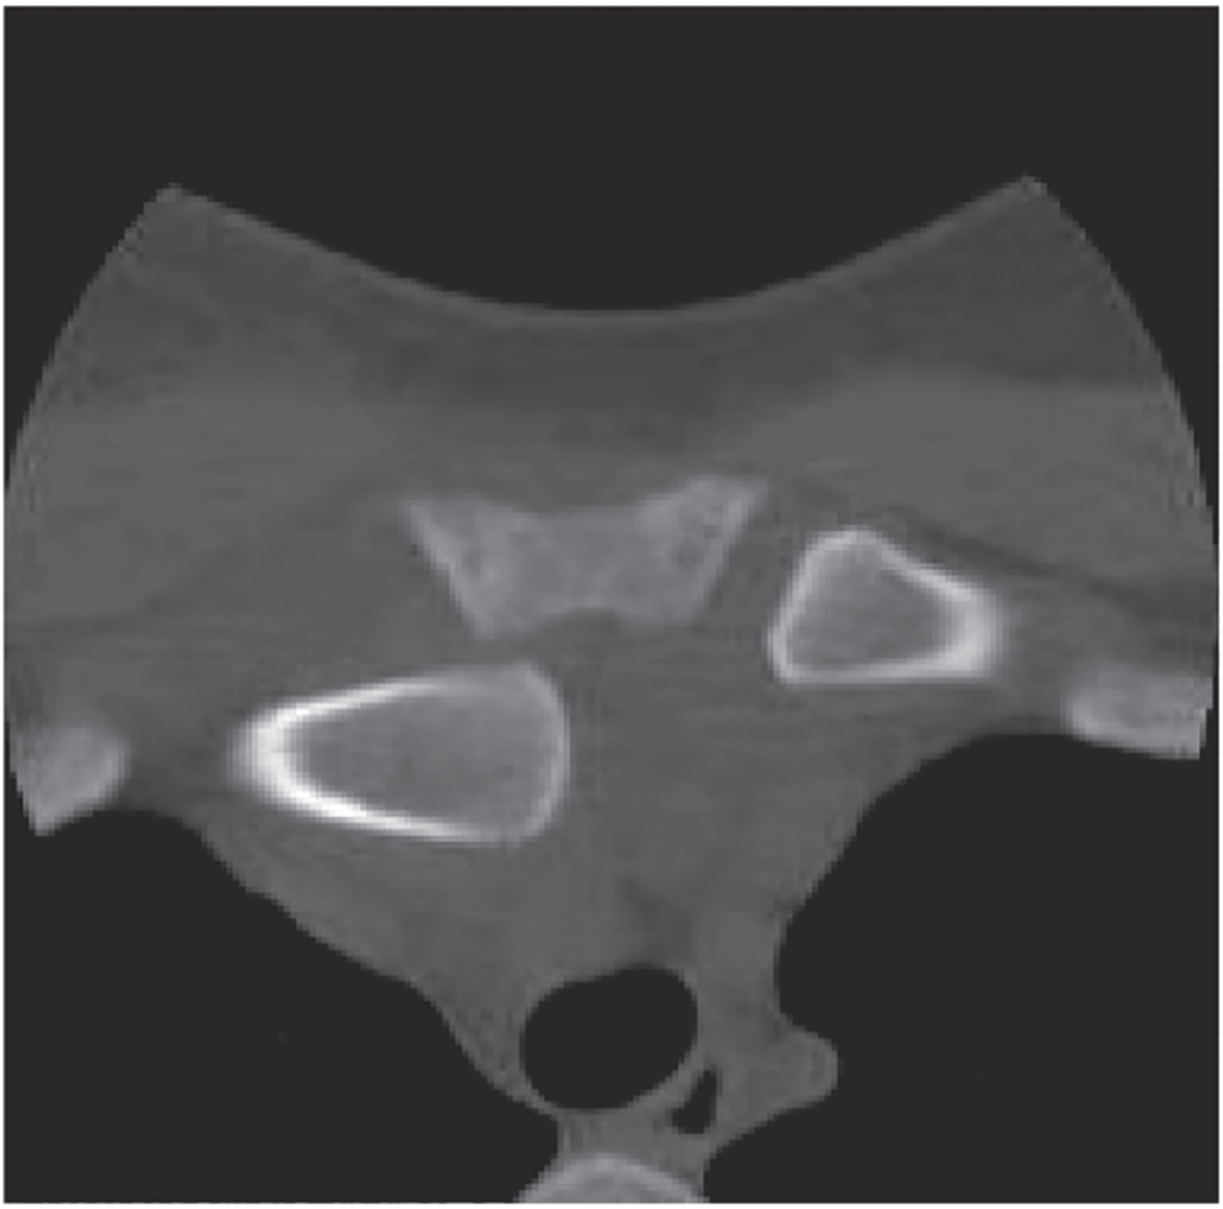

Figure 77.1 CT axial image of a posteriorly dislocated SC joint. Source: Image adapted from Bontempo and Mazzocca.[10]

Traumatic posterior SC joint dislocations occur due to a direct anteromedial force over the medial clavicle or an indirect force onto the posterior lateral shoulder. The amount of initial displacement reflects the magnitude of the applied force and degree of soft tissue injury.[4] Of note, the medial clavicular physis is the last to fuse.[1] Therefore, a

physeal fracture dislocation is more common in individuals under 25 years of age.[1]

Posterior SC joint dislocations are associated with a 3–4% mortality rate secondary to life-threatening neurovascular, tracheal, and esophageal injuries.[7] The brachiocephalic veins lie immediately posterior to the SC joints bilaterally increasing the risk for massive hemorrhage after dislocation or during reduction. Literature review of 60 cases of SC dislocations report a 26% incidence of mediastinal complications.[8] Common compressive symptoms include dysphagia, dyspnea, or vascular/neurologic compromise.[1,7] Urgent reduction of posterior dislocations are recommended.

CT scans should be obtained for any patient with concern of posterior SC dislocation. CT scans provide valuable information on displacement and the integrity of surrounding structures.[4] CT angiograms provide excellent visualization of vascular structures and 3D reconstructions prove beneficial in determining the degree of vertical displacement (Figure 77.2).[4] Chest X-rays or dedicate clavicular films may provide additional information about associated intrathoracic injuries or increase the suspicion for an SC joint dislocation; however, CT scans provide better diagnostic images.[2,9]

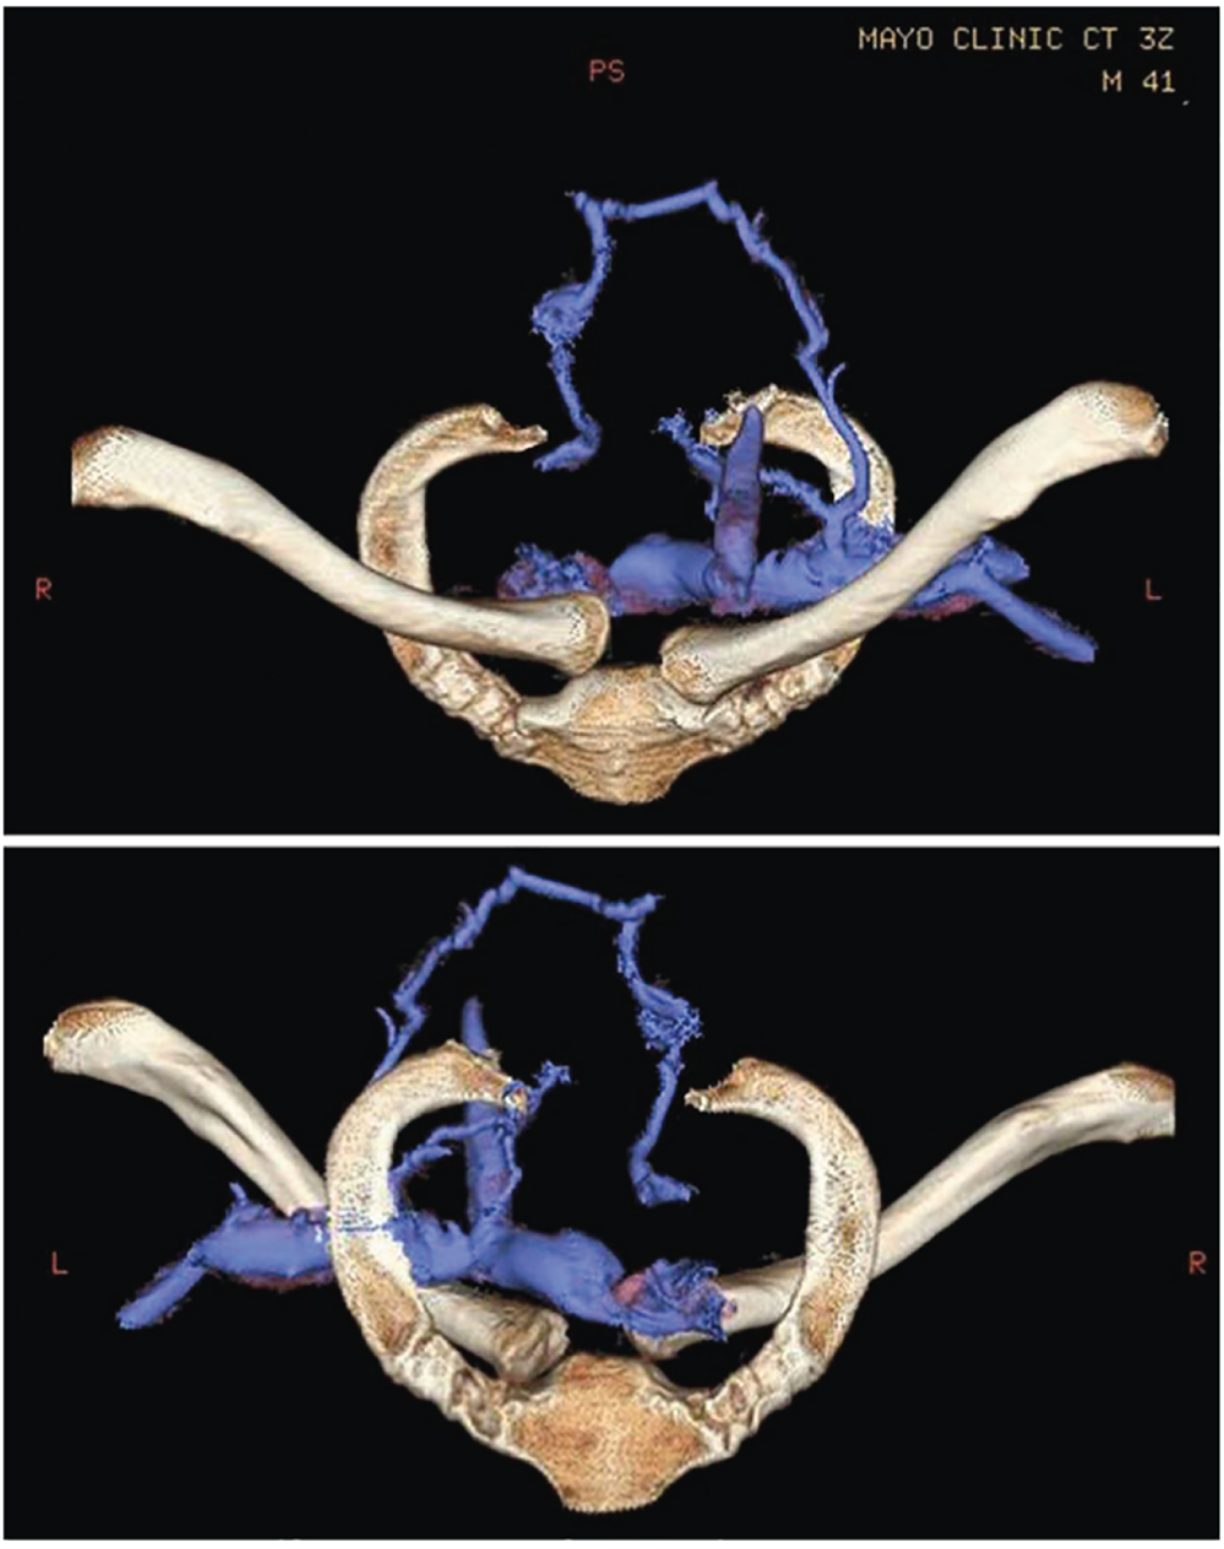

Figure 77.2 3D CT reconstruction of a right posteriorly dislocated SC joint with venous compression. Source: Imaged adapted from: Hoekzema.[11]

Resolution of clinical scenario

- The posterior ligamentous complex is crucial for SC joint stability. Their structural integrity is best appreciated on a CT scan.
- Visualization of posterior structures is best on a CT scan, which can help evaluate potentially life-threatening injuries.
- All suspected SC joint dislocations should be evaluated with CT as the diagnostic sensitivity of plain radiographs are low.

Question 2: In patients with an SC joint dislocation undergoing closed reduction, is the shoulder abduction and traction technique more successful and have fewer complications than other closed reduction techniques?

Rationale

Multiple closed reduction techniques exist for posterior SC joint dislocations. Therefore, knowledge of the unique set of complications and outcomes for each technique is imperative for successful reduction and patient communication.

Clinical comment

Traumatic posterior SC joint dislocations are rare. Missed or unsuccessfully managed dislocations can lead to devastating complications. Correctly identifying patients

who need transfer to a tertiary care center is paramount to successful management.

Available literature and quality of the evidence

- 4 level IV
- 4 level V.

Findings

Unlike anterior dislocations, all posterior SC joint dislocations require reduction.[12] Closed reduction is considered first line management of acute posterior SC joint dislocations without mediastinal compression.[1] Close reductions should be performed under general anesthesia in an operating room; consideration of the posterior vascular structures must be taken; blood products should be available; a cardiothoracic surgeon should be on standby; and most importantly, if attempted closed reduction is unsuccessful, the surgeon must be comfortable performing an open reduction and internal stabilization. If cardiothoracic support or orthopedic expertise is not available, transfer of a stable patient to a tertiary care facility is crucial to provide appropriate treatment. After reduction, CT scans are mandatory to confirm SC joint relocation.[4]

Several closed reduction techniques are reported in the literature, including the shoulder abduction and traction technique, the Buckerfield et al. technique and the Rockwood percutaneous sterile towel clamp assisted technique.[1,13] During the shoulder abduction and traction technique, traction should always precede extension of the arm to prevent the anterior clavicle from binding on the posterior surface of the manubrium.[12] Buckerfield et al. found that the use of an interscapular bolster and caudal

traction applied to an adducted ipsilateral arm achieved reduction of SC joint dislocations in six of seven patients who failed prior reductions.[13] Of note, this study included patients aged 13–26 and did not distinguish between physeal fracture dislocations and pure ligamentous dislocations.

The Rockwood technique utilizes a percutaneously placed towel clamp to apply an anteriorly directed force on the medial clavicle and is typically utilized after failure of a purely closed technique.[14] Significant swelling associated with SC joint dislocations is common and errant clamp placement can cause considerable damage to surrounding structures.[4] The authors do not use this and advise extreme caution with this technique.

Groh et al. reported a closed reduction success rate of ~52% in 21 patients within 10 days of initial injury.[15] Nine reductions were performed with purely closed techniques and two with the aid of a sterile towel clamp.[15] Three of the 11 initially successful reductions re-dislocated.[15] The remaining 13 either had a failed reduction or had symptoms secondary to posterior compression and subsequently underwent successful open reductions.[15] Final evaluation showed good to excellent results in 18 of the 21 patients reviewed.[15] Laffosse et al. reported a purely closed reduction technique success rate of 50% in 10 patients.[16]

Post-reduction protocol should include post-reduction CT scan and immobilization with gradual return to activity. Proposed protocols include figure-of-eight clavicular brace for at least six weeks and active strengthening and range of motion exercises at ~12 weeks.[17]

Resolution of clinical scenario

- Case reports show closed reduction attempts of posterior SC joint dislocations are successful less than 50% of the time regardless of technique.
- The percutaneous towel clamp technique can be utilized after failure of a purely closed reduction attempt.
- The surgeon performing the closed reduction must be able to perform an open reduction or the patient should be transferred.

Question 3: In patients with an SC joint dislocation, does open fixation with allograft or autograft result in improved patient outcomes when compared to open fixation with metal implants?

Rationale

There is no universally accepted open reduction method for posterior SC joint dislocations. A thorough knowledge of successful and unsuccessful techniques, complications, and outcomes is imperative for successful treatment.

Clinical comment

There are a wide variety of internal stabilization methods with the primary goal of recreating joint forces that mimic the native intrinsic and extrinsic stabilizers.

Available literature and quality of the evidence

- 2 level IV

- 7 level V.

Findings

Understanding the morbidity associated with persistent posterior SC dislocations, the authors prefer open reduction of all posterior SC dislocations. As exsanguinating hemorrhage is possible, we recommend all patients be typed and crossed for four units of blood, large bore IV access is established, and cardiovascular surgeons are available for possible vascular control. All patients are consented for open reduction and internal stabilization and risks to damage of posterior structures are discussed.

No gold standard technique for internal stabilization of posterior SC joint dislocations exists. All proposed techniques are technically demanding and should be performed by experienced surgeons. The authors prefer the patient supine with a *horseshoe headrest*. An incision is made over the medial clavicle and manubrium in Langer's lines. A large part of the dissection is typically already completed by the trauma, with the pectoralis major avulsed from the inferior clavicle. A malleable retractor is carefully placed behind the manubrium and clavicle, as a safe stop for the drill. Doubled #5 suture or tendon allograft in a figure-of-eight configuration is passed with looped dental/surgical wire from medial to lateral through two 3.2 mm or 4.5 mm sternal drill holes. The graft is sewn into itself in a Pulvertaft weave anteriorly.[18,19]

Case series and biomechanical studies have been reported on the use of soft tissue allografts for SC joint stabilization. Booth et al. described a technique to reconstruct the costoclavicular ligament in which the distal attachment of the sternocleidomastoid (SCM) along with a strip of local periosteum is passed under the first rib and through a drill

hole located in the medial clavicle. The SCM is then reattached to itself proximally.[20]

Spencer et al. performed a biomechanical study examining the joint stiffness and peak loads to failure of an intramedullary ligament reconstruction versus subclavius tendon reconstruction versus a figure-of-eight semitendinosus graft.[18] The semitendinosus reconstruction restored native joint stiffness better than the other two techniques, especially in the posterior direction (241.4 ± 49.7 N: semitendinosus reconstruction, 85.0 ± 22.8 N: intramedullary ligament reconstruction, 51.5 ± 28.9 N: subclavius tendon reconstruction [$p = 0.004$]).[18] No clinical outcomes could be extrapolated, but it is predicted from the biomechanical data that the semitendinosus reconstruction may produce superior clinical results.

Abiddin et al. reported on a cohort of eight patients with symptomatic SC joint instability stabilized capsular plication and medial clavicular and lateral manubrial suture anchors.[21] The mean follow up was 4.5 years, with no subsequent instability events; seven of eight patients returned to work and only one reported poor results (constant score of 33).[21]

Franck et al. described the Balser plate technique in nine patients after traumatic instability of their SC joint.[22] The goal of this technique is to avoid prolonged postoperative immobilization and allow early physiotherapy.[22] The plate, similar to a hook plate, is placed on the posterior aspect of the manubrium and anterior aspect of the medial clavicle.[22] There were no reported re-dislocations. All plates were removed to avoid migration.[22] Brinker et al. reported on the use of two seventy-five-millimeter 7 mm cannulated screws in a small two-patient cohort with unstable posterior SC joint dislocations.[23] Both patients returned to

the operating room in three months for hardware removal.[23] Both were noted to have a strong neocapsule formation.[23] During recovery, no precautions were taken to limit stress across the SC joint.[23] At 10 months patients had painless full range of motion.[23]

Wallace et al. described a technique using a synthetic braided polyester mesh device to reconstruct the costoclavicular ligament.[1] A histological examination of the tissue created around the mesh in acromioclavicular joint reconstructions was likened to the creation of a fibroblast outer capsule.[1] Overall, this technique has been used for more than 15 years with over 11 000 implanted with very few reported explants or devices failures.[24]

Historically, Kirschner wires (K-wires) were used for stabilization of SC joint dislocations. However, catastrophic failure resulting in a high mortality rate made the use of K-wires contraindicated. Lyons et al. described K-wire stabilization in 21 SC joint dislocations.[25] The results were disastrous with eight deaths due to K-wire migration into major vascular structures and six reports of postsurgical cardiac tamponade requiring cardiac surgery intervention.[25]

Similarly, medial clavicle excisions for posterior SC joint dislocations are looked upon skeptically. Rockwood et al. evaluated 15 patients who underwent ~1.5 cm medial clavicle excision.[26] Outcome were based on a 15-point rating scale that included pain, range-of-motion, strength, reported limitations, and subjective patient outcomes. Each category was assigned a score between 0 and 3. An overall score of ≥13 was an excellent, 10–12 good, 7–9 fair, and <7 poor. The group with intact costoclavicular ligaments reported excellent results. Only three of seven patients in the disrupted costoclavicular ligaments group (equivalent

to patients with traumatic SC joint dislocations) had excellent results and the remaining four patients had fair to poor results. This study suggests resection arthroplasty alone without ligament reconstruction is unsatisfactory.[26]

Resolution of clinical scenario

- Multiple successful open reduction and stabilization techniques reported with no clear answers to which technique is superior.
- K-wires should never be used as a final means to stabilize the SC joint.

Summary of answers

- The SC joint relies on surrounding structures for stability.
- Injury to the posterior structures can be life threatening.
- Closed reduction of posterior SC joint dislocations has a low success rate.
- Readiness to perform an open reduction and stabilization must always be prepared for prior to reduction attempt.
- There are many viable reconstruction options for open reduction and internal stabilization of the SC joint; however, K-wire fixation and joint resection alone should be avoided.

Clavicle Fractures

Chad Myeroff MD and Michael D. McKee MD FRCS(C)
University of Minnesota, Department of Orthopaedic Surgery, Regions Hospital and TRIA Orthopedic Center, St Paul, MN, USA
Department of Orthopaedic Surgery, University of Arizona College of Medicine, Phoenix, AZ, USA

Clinical scenario

- A 30-year-old left-hand-dominant male, laborer, presents with isolated intense pain in his shoulder after falling off his mountain bike.
- On examination, his left shoulder is deformed, appearing shortened and *ptotic*. It is a closed, isolated injury and his left upper extremity is neurovascularly intact (Figure 78.1).

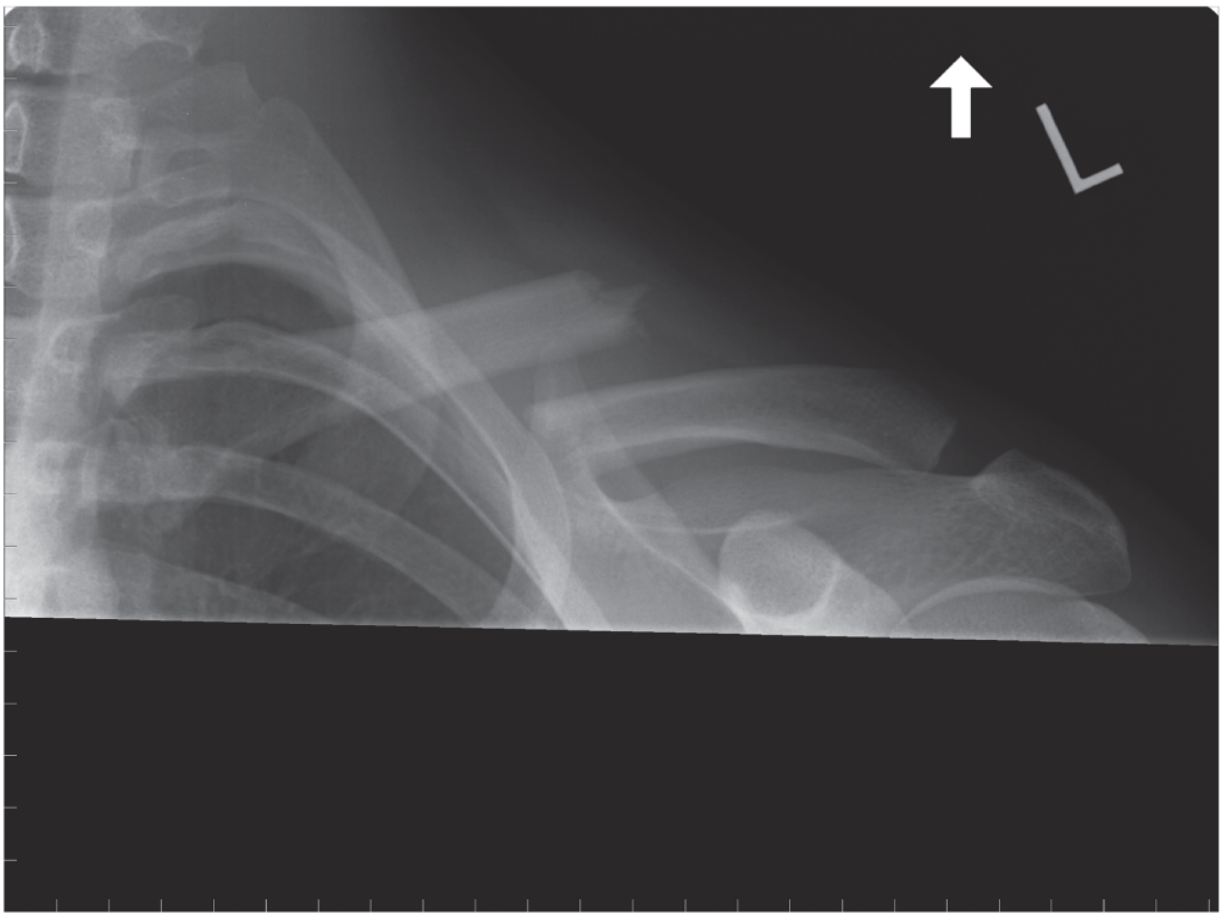

Figure 78.1 Radiograph of a 30-year-old man who fell off his mountain bike and sustained a midshaft clavicle fracture. Displacement and shortening is evident.

Top three questions

1. In patients with clavicle fractures managed nonoperatively, do displaced fractures have worse outcomes than nondisplaced fractures?
2. In patients with displaced clavicle fractures, does open reduction and internal fixation offer improved outcomes compared to nonoperative management?
3. In patients with clavicle fractures managed operatively, does intramedullary nailing result in improved outcomes compared to plating?

Question 1: In patients with clavicle fractures managed nonoperatively, do displaced fractures have worse outcomes than nondisplaced fractures?

Rationale

In order to optimize care, it is important to identify the minority of patients who are at risk for poor outcomes with nonoperative management.

Clinical comment

Nonoperative management is not without risks, so physicians and patients should understand fracture and patient characteristics that negatively affect the outcome in nonoperatively treated fractures.

Available literature and quality of the evidence

After searching the literature, nine studies were utilized to answer this question including: two level I studies and further supported with level II–IV data.

Findings

The majority of patients with a clavicle fracture will heal uneventfully with satisfactory function with nonoperative treatment. However, a minority of patients will have ongoing sequelae from a displaced midshaft clavicle fracture as shown in a recent randomized clinical trial (RCT) reporting 23.1% nonunion with nonoperative management of midshaft displaced fractures.[1] In addition to the unexpected 15% nonunion rate reported by Hill in 1997, a 31% dissatisfaction rate, related to 25% of patients

complaining of deformity and a 29% incidence of thoracic outlet syndrome, was reported. They found initial shortening >2 cm was significantly associated with nonunion and unsatisfactory results ($p < 0.0001$).[2] McKee looked at 30 healed, displaced fractures using patient-based outcomes and strength testing. They showed 27% dissatisfaction, Constant score of 71, and a Disabilities of the Arm, Shoulder, and Hand (DASH) score of 25. There was a trend toward worse DASH scores for shortening >2 cm and there was a statistically significant inverse correlation between abduction endurance strength and shortening.[3] Lazarides found a 25.8% dissatisfaction rate in patients with a healed midshaft clavicle fracture, significantly associated with shortening >18 mm in males and >14 mm in females.[4] This phenomenon has recently been challenged by Goudie, but with an average of only 11 mm shortening and only five patients with >2 cm shortening, this study was underpowered to detect a statistical difference.[5]

In a systematic review, Zlowodzki reported an overall nonunion rate of 5.9% which increased to 15.1% for completely displaced fractures.[6] Robinson's study employing multivariate analysis found increasing fracture displacement, comminution, advancing age, and female gender all to be independent predictors of nonunion in shaft fractures.[7] Nowak also found that displacement, comminution, and older age were predictors for sequelae (pain and deformity) following clavicle fracture.[8] Murray reviewed 941 diaphyseal fractures managed nonoperatively and identified smoking (odds ratio [OR] = 3.76; 95% confidence interval [CI]: 2.39–5.89; $p < 0.001$), displacement (OR = 1.17; 95% CI: 1.13–1.21; $p < 0.001$), and comminution (OR = 1.75; 95% CI: 1.11–2.76;

p = 0.015) to be statistically significant risk factors for nonunion.[9]

Resolution of clinical scenario

- The patient should be counseled that nonoperative management of displaced midshaft clavicle fractures results in a 15% nonunion rate and 25–30% dissatisfaction rate.
  - Major reasons for dissatisfaction: 15% nonunion, 15–20% malunion, 25% deformity, 29% thoracic outlet syndrome.
- This patient should understand this clavicle fracture has no cortical contact and has shortening which are both prognostic for poor outcome (nonunion or symptomatic malunion).
  - Poor prognostic factors include:
    - no cortical contact (displacement)
    - comminution
    - shortening >20 mm
    - smoking status
    - advanced age
    - female gender.

Question 2: In patients with displaced clavicle fractures, does open reduction and internal fixation offer improved outcomes compared to nonoperative management?

Rationale

Multiple high-quality RCTs have suggested potential benefits to primary operative fixation of displaced midshaft clavicle fractures.

Clinical importance

Shared clinical decision-making between patient and provider demand an unbiased, accurate understanding and communication of the literature.

Available literature and quality of the evidence

After searching the literature, 11 studies were utilized to answer this question. Of these, six were level I studies including multiple high-quality RCTs.

Findings

Zlowodzki et al. performed a systematic review of 2144 clavicle fractures. In a subset analysis of only displaced fractures, 460 plated fractures had a nonunion rate of 2.2% versus 15.1% for nonoperatively treated displaced fractures. They reported a nonoperative relative risk (RR) 6.9 (95% CI: 3.4–14.2) for nonunion and an absolute risk reduction (ARR) OF 12.9%, with a number need to treat of 7.8 patients to avoid one nonunion for plating; relative risk reduction (RRR) of 86% (95% CI: 71–93%; $p < 0.001$).[6] In 2007, an RCT comparing plate fixation versus nonoperative treatment for displaced midshaft clavicle fractures demonstrated statistically significant differences including a shorter time to union (16.4 vs 28.4 weeks; $p = 0.001$), improved Constant and DASH scores, as well as improved patient satisfaction ($p = 0.002$) and appearance ($p = 0.001$) in the operative arm.[10] Complications for the operative group were 37% versus 63% for nonoperative treatment. The operative group's complications included hardware

irritation, removal of hardware (ROH), transient brachial plexus irritations, and wound complications (4.8%). The nonoperative group had complications predominated by nonunion (7/49; 14.3%), malunion requiring corrective surgery (9/49; 18.4%), and brachial plexus irritation. The only statistically significant difference in complications were lower nonunion (15% vs 3.2%; p = 0.04) and malunion (22.5% vs 0%; p = 0.001) in the operative group.[10] Smith and Smekal noted similar results following operative fixation of displaced midshaft clavicle fractures in two other RCTs.[11,12]

In 2012, McKee et. al. published a meta-analysis of nonoperative versus operative management for midshaft displaced fractures including six RCTs (412 pts) and showed an overall reduction of non- and malunions from 23 to 1.5% with fixation.[13] Robinson performed an RCT of 178 patients finding a significantly lower nonunion with open reduction and internal fixation (ORIF) (1.2% vs 17%; p = 0.007) with an ARR of 15.8 for ORIF and an number needed to treat (NNT) of 6.2 to prevent one nonunion (RRR = 93%; p = 0.007). The surgical group was more satisfied with the shoulder contour and had better DASH (3.4 vs 6.1; p = 0.04) and Constant scores (92 vs 87.8; p = 0.01) at all time points but this lost significance after exclusion of nonunions.[14] In order to better predict these nonunions and to optimize treatment choice, the same group used a retrospective review of 941 diaphyseal fractures to create a *ready reckoner* table to aid clinical decision-making in real time. Their table uses displacement, comminution, and smoking status to predict risk of nonunion. If the ready reckoner computes the risk for nonunion to be >40%, the fracture is associated with an NNT of 1.7 to prevent a single nonunion with fixation.[9] A meta-analysis in 2017 including 8 RCTs and 12 observational studies (1760 patients) showed lower

nonunion (OR = 0.18; 95% CI: 0.10–0.33; p <0.01) with operative treatment. Looking only at high-quality studies, they found a lower malunion (OR = 0.26; 95% CI: 0.07–0.92), better DASH (mean difference [MD]: −2.04; 95% CI: 23.56–20.52; p = 0.01) and Constant score (MD: 3.23 95% CI: 1.52 to 4.95; p <0.01), and return to work 8.6 days earlier (95% CI: −16.22 to −1.05) with fixation compared to nonoperative treatment.[15] While several studies cite primary fixation being more expensive than nonoperative care.,[14,16] these studies only include direct costs. In a retrospective review comparing 204 operatively and nonoperatively treated displaced fractures, Althausen et al. found ORIF to be $5000 cheaper mostly as a function of less secondary lost wages from earlier return to work (8 vs 35 days).[17] While there is variability of such cost data in the literature, especially in meta-analysis, this internal database study may better capture the total cost of care.

Resolution of clinical scenario

- Literature supports improved function, a lower nonunion and symptomatic malunion rate, improved cosmetic perception, and overall higher satisfaction level with operative versus nonoperative treatment of this displaced, shortened fracture (Figure 78.2).
- Clinical decision-making tools should be used to help understand and communicate the patient's risk for nonunion with nonoperative treatment for this patient.

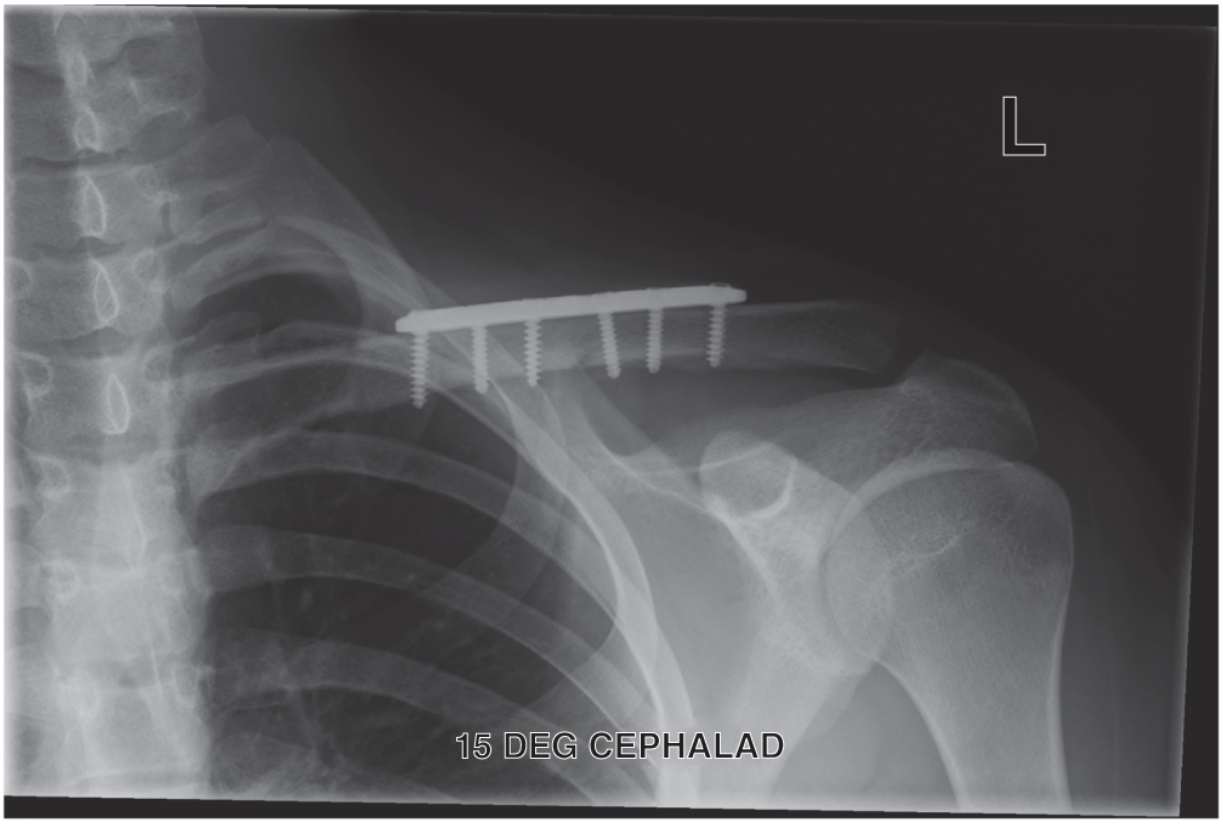

Figure 78.2 The patient in the case scenario elected to have operative treatment. This radiograph was obtained during follow-up and demonstrates fixation with a precontoured clavicle plate.

Question 3: In patients with clavicle fractures managed operatively, does intramedullary nailing result in improved outcomes compared to plating?

Rationale

There are a variety of fixation options available to surgeons, including intramedullary nails or pins (IMN) and

plate fixation. In addition, plates can be placed on the superior or anteroinferior surface.

Clinical comment

Several clavicle fixation options are available. There is debate as to which method is superior and each has unique risks and benefits.

Available literature and quality of the evidence

After searching the literature, 14 studies were utilized to answer this question. Of these, seven were level I studies.

Findings

Compared to the results of plates, there is more variability in the published outcomes for IMN but larger, higher-quality, studies paint a more balanced picture. Ferran performed an RCT comparing IMN versus plate fixation and found no difference in functional scores (Constant score or Oxford score) but with higher hardware removal rate in the IMN group (100% vs 53%).[18] A similar RCT of 120 patients by Hulsmans in 2017 confirmed these same results with no difference in Quick Dash (at all time points except three months) and higher hardware removal rates in the IMN group (RR = 1.65; 95% CI: 1.24–2.19; p <0.001).[19] The same year, Funglesang published an RCT of 123 patients randomized to flexible intramedullary nail versus plate. Operative time was faster for IMN. Plate fixation showed faster functional recovery (DASH p <0.001, and Constant score p <0.001) between 0 and 6 months but no difference at 12 months. Those with comminuted fractures treated with an IMN had the slowest recovery. IMN had a higher hardware removal rate.[20] A systematic review of 20 studies (six RCTs) reported no statistical difference in re-intervention rate (OR = 1.21; 95% CI: 0.71–2.04; p = 0.48),

Constant scores (p = 0.85), nonunion (p = 0.19) or infection (p = 0.13) between plate and IMN. Plate fixation had higher major complication rate while IMN had higher removal of hardware (73% vs 38%). Re-fracture occurred more commonly after plate removal (OR = 3.42; 95% CI: 1.12–10.24; p = 0.03).[21] Hussain published a systematic review and meta-analysis in *Nature* in 2016 comparing IMN versus plate fixation using seven RCTs and three quasirandomized trials showing no statistical difference in long-term function (MD: −0.66; 95% CI: −2.03 to 0.71; I^2 = 62%; p = 0.34). Plating had a statistically significant twofold risk of operative complications (95% CI: 1.38–3.23; I^2 = 53%; p = 0.0006) as well as prolonged operative time by 20 minutes (95% CI: 16.87–23.44; I^2 = 56%; p <0.00001) and a twofold statistically insignificant increase in treatment failure (95% CI: 0.03–5.15; I^2 = 0%; p = 0.07).[22]

Superior plating is accepted to be biomechanically superior to anteroinferior plating.[23] More importantly, both options appear to have adequate efficacy clinically.[24] Serrano looked at the more relevant question of plate irritation in a retrospective review of 252 fixations comparing both plate positions. Superior plates were more likely to undergo secondary intervention (ROH: 5.9% anteroinferior vs 22.3% anterosuperior; OR = 4.6; 95% CI: 1.9–10.9; p <0.001).[25] Using the same economic model as Walton, secondary surgery increased the cost an incremental $5173. They postulated that anteroinferior plating would avoid 17 additional surgeries for every 100 ORIFs and with a cost savings of $87 000.[16,25] Nourian et al. performed a meta-analysis using 34 articles to compare these techniques. They found no difference in functional score, union, malunion, or implant failure; however, superior plate had significantly higher symptomatic hardware (17% vs 8%;

p = 0.005) and significantly higher removal of hardware (11% vs 5%; p = 0.008).[24] In a large national database, Naimark et al. showed a 12.7% ROH rate within two years postoperatively. In a retrospective study of 73 plate fixations as part of the same report, they showed plate removal to be more likely in females (p = 0.009) and with non-precontoured plates (ROH: 25.5% non-precontoured vs 12.5% precontoured; p = 0.27) but the study was underpowered to show a statistical difference.[26] Those who required hardware removal had lower DASH scores, EQ-5D, and lower satisfaction.[26] However, a 2015 Cochrane review found the current evidence comparing clavicle operative treatment methods to be of low or very low quality. This was due to the risk of bias due to flawed methods, or such low numbers that a type I error may be possible. They support surgeon discretion in decision-making of implant choice and location: “There is very limited and low quality evidence available from RCTs regarding the effectiveness of different surgical methods of surgical fixation of fractures and nonunion of the middle third of the clavicle.”[27]

Resolution of clinical scenario

- When choosing between various surgical options, there is level I evidence that plate and IMN fixation are both viable options and offer similar union rates and functional outcome.
- There is level I evidence that plate fixation may offer earlier return to function, especially in comminuted fractures and that IMN fixation is associated with higher removal of hardware rates.
- Removal of hardware is associated with increased cost and inferior outcomes.

Summary of answers

- Nonoperative management of displaced midshaft clavicle fractures results in a 15% nonunion rate and a 25–30% dissatisfaction rate.
- Factors prognostic for poor outcome (nonunion or symptomatic malunion) following nonoperative management of clavicle fractures include: no cortical contact (amount of displacement), comminution, shortening >20 mm, smoking status, advanced age, female gender.
- In patients with a displaced clavicle fracture, there is a functional benefit, lower nonunion rate, improved cosmetic perception, and overall higher satisfaction level with operative versus nonoperative treatment.
- Clinical decision-making tools should be used to help understand and communicate the patient's risk for nonunion with nonoperative treatment for this patient.
- Plate and IMN fixation are both viable options and offer similar union rates and functional outcome.
- Plate fixation may offer earlier return to function, especially in comminuted fractures.
- Precontoured plates lower the rate of hardware removal.
- IMN fixation is associated with a higher removal of hardware rates.
- Removal of hardware is associated with increased cost and inferior outcomes.

Acromioclavicular Joint

Chad Myeroff MD[1] and Michael D. McKee MD FRCS (C)[2]
[1]University of Minnesota Department of Orthopaedic Surgery, Regions Hospital and TRIA Orthopedic Center, St. Paul, MN, USA
[2]Department of Orthopaedic Surgery, University of Arizona College of Medicine, Phoenix, AZ, USA

Clinical scenario

- A 23-year-old man comes to the Emergency Department after being tackled during a football game and injuring his left shoulder.
- On examination, he has swelling and deformity at the distal end of his clavicle. His upper extremity is neurovascularly intact. It is an isolated injury.
- Radiographs reveal a high-grade (Rockwood type V) acromioclavicular (AC) joint dislocation.

Top three questions

1. In patients with AC joint injuries undergoing operative repair, do those with low-grade injuries have worse functional outcomes compared to those with high-grade injuries?
2. In patients with high-grade AC joint injuries treated operatively, do reconstruction methods offer improved results over temporary hook plate fixation?

3. In patients with AC joint injuries treated operatively, does early intervention offer improved outcomes compared to delayed surgery?

Question 1: In patients with AC joint injuries undergoing operative repair, do those with low-grade injuries have worse functional outcomes compared to those with high-grade injuries?

Rationale

Patients with high- and even low-grade AC joint injuries often present with pain, deformity, and expectations of returning to normal. Understanding of our ability to improve clinical outcomes continues to evolve and surgeons should carefully deliver realistic expectations in counseling.

Clinical comment

Most AC injuries are best treated symptomatically with or without physical therapy, while some may benefit from operative intervention, either acutely or secondarily.

Available literature and quality of the evidence

This clinical question was answered with nine studies, of which four were level I studies.

Findings

Increasing soft tissue damage with increasing grades of AC joint injury lead to greater functional deficits and pain. Particularly poor outcomes have been noted in higher grades that are associated with deltotrapezial fascia disruption and horizontal plane instability. Authors have

reported concomitant intra-articular glenohumeral pathology in up to 84% of patients with an acute AC injury, which impacts treatment and outcome in select patients.[1]

There are no prospective comparison studies specifically looking only at *low grade* (Rockwood type I–III) injuries and nonoperative treatment is considered standard of care for type I and II AC separations. However, Bergfeld et al. reported persistent pain and activity limitations in 9% of type I and 23% of type II AC injuries in an active military population.[2]

Type III injuries have been the center of debate. Gstettner et al. performed a retrospective cohort study comparing patients with type III injuries treated either with hook plates (n = 24) or nonoperatively (n = 12). Treatment choice was based on patient's preference. They found improved Constant scores (90.4 vs 80.7; p <0.05) and AC joint reduction in the operative group but no difference in return to sport.[3] Smith performed a meta-analysis comparing operative (trans-acromial Kirschner wires [K-wires], coracoclavicular screws, or hook plates) and nonoperative treatment of type III separations. The operative group had improved cosmesis (risk difference [RD] = 0.64; 95% confidence interval [CI]: 1.09, 0.19; p <0.0001), slower return to work (RTW) (mean difference [MD]: 3.3 days' sick leave; 95% CI: 2.10–4.50; p <0.001), similar function, but there was no difference in strength, throwing ability, and AC arthritis.[4] A more recent systematic review of 22 low-quality studies showed a 14% loss of reduction in type III injuries with fixation and no difference in Constant score (87.3 operative vs 88 nonoperative; p = 0.6832), or arthritic change (38.4% operative vs 40.5% nonoperative; p = 0.9413). There was a trend toward lower persistent pain with operative treatment (11% vs 25%; p = 0.07).[5] These analyses should

be interpreted with caution due to the inclusion of heterogeneous (and sometimes outdated) techniques, but in general they support the conservative management of most type III separations with acceptable outcomes. However, a portion of patients treated nonoperatively will have persistent symptoms.[4,5] In general, operative management is reserved for those who fail nonoperative management. This is most commonly due to persistent pain and weakness. Other causes of failure include intra-articular glenohumeral pathology, dynamic posterior instability, scapular dyskinesia, thoracic outlet syndrome, deformity, or cosmetic concerns.

Operative indications have remained largely unchanged since the first randomized trial by Bannister in 1989.[6] They randomized 54 patients with *AC dislocations* of various grades to nonoperative treatment versus fixation with a coracoclavicular screw. They noted significantly faster RTW (manual workers RTW average 4 vs 11 weeks; clerical workers RTW average 1 vs 4 weeks; $p < 0.01$), return to sport (7 vs 16 weeks; $p < 0.05$), and fewer unsatisfactory results in the conservative management group (0% vs 16% fair at 4 years). Better results were noted with early surgical fixation for *severe displacement* of ≥2 cm displacement (consistent with Rockwood type V).[6] Bannister confirmed these results in another prospective study of 48 patients, showing the highest benefit for early surgery in those with displacement ≥2 cm.[7]

The Canadian Orthopaedic Trauma Society performed an RCT of 83 patients with grade III–V AC separations comparing hook plate versus nonoperative treatment.[8] Hook plate offered better radiographic reduction ($p < 0.05$) but more frequent complications. Nonoperative treatment yielded better early function – DASH up to three months 16.03 (standard deviation [SD]: 17.03) vs 28.76 (SD: 15.3);

p = 0.005, Constant score up to six months – 91.53 (SD: 7.09) vs 80.22 (SD: 17.56); p = 0.0001 – earlier RTW (76% vs 43% at three months; p = 0.004) and lower re-operation rate (38 planned and 2 unexpected in the operative group vs 2 conversion to surgical in the conservative group; p <0.05). This is biased by the standardized removal of hardware necessitated by this procedure which occurred in 38 (79%) of the patients during this study. There was no difference in perceived cosmesis at one year (p = 0.091) or function from six months through two years.[8] A follow-up study of this data analyzing health-related quality of life showed these patients have pre-injury function higher than population norms and they return to this physical function faster with nonoperative management (six months vs two years), concluding that hook plate fixation does not lead to improved general health status.[9] Although there were patients in the nonoperative group who had a poor outcome and required later reconstruction, the authors were unable to predict factors associated with nonoperative failure. Despite the rigorous nature of this multicenter trial, they were unable to show a benefit in high-grade injuries due to lower recruitment of these rare entities.

Resolution of clinical scenario

- Low-quality evidence and common practice supports conservative management for Rockwood type I and II injuries.
- Patients with type III injuries are best managed with nonoperative treatment initially and delayed reconstruction on rare clinical occasions when required.
- This active patient with type V AC separation is likely best treated with primary operative repair but RCTs focusing specifically on this entity are lacking.

Question 2: In patients with high-grade AC joint injuries treated operatively, do reconstruction methods offer improved results over temporary hook plate fixation?

Rationale

There are currently over 60 techniques described for AC joint fixation with variable success, and new variations are continuously being reported. This speaks to the lack of consensus, and clouds the ability to identify a gold standard.

Clinical comment

This is a case of a young, active patient who has sustained a grade V AC joint injury for which the current standard is early surgical reduction. However, the ideal surgical treatment is still being debated.

Available literature and quality of the evidence

This question is addressed using 11 low- to high-quality studies clinical studies, of which there was one systematic review (level I) and three level III studies included.

Findings

Active patents with type V injuries have mediocre outcomes when managed nonoperatively (Disabilities of the Arm, Shoulder, and Hand [DASH] score 27.8 ± 17.7, American Shoulder and Elbow Surgeons [ASES] score 62 ± 17.1).[10] No RCTs exist in the literature comparing fixation techniques for AC joint dislocations. Result of meta-

analyses show heterogeneity of indications and techniques and should be interpreted with caution.

Contemporary literature has seen multiple low-quality (level III–IV) studies reporting novel techniques. These techniques can be broken down into biologic and nonbiologic fixation, each of which may be anatomic or nonanatomic. Nonbiologic fixation is used acutely to reduce the joint long enough to allow permanent ligament and capsule scarring. The hook plate has been widely used and studied for this indication since its introduction in the 1980s as a more durable alternative to K-wire fixation. It is biomechanically powerful, but currently available designs have high rates of acromial erosion, impingement, and hardware irritation. This results in the need for subsequent plate removal which usually performed 3–6 months postoperatively.[3] More recently coracoclavicular cortical suture buttons have been introduced as an alternative method with the added theoretical benefits of anatomic motion, the possibility for arthroscopic glenohumeral treatment of concomitant pathology, and lower removal of hardware rates. Unfortunately, early reports showed loss of reduction (failure) as high as 100% secondary to suture breakage/slippage with mediocre clinical results.[11,12] A prospective multicenter study by Clavert et al. of 116 early suture button fixations for grade III–V injuries showed a 22% complication rate and a 41% loss of reduction (>150% coracoclavicular [CC] distance), which was associated with decreased overall function (Constant score 71 vs 93; $p < 0.0001$). Persistent dislocation (radiographic failure) occurred in 48/116 (41.3%) of patients and was associated with worse overall constant score (88.4 vs 82.8; $p = 0.024$), mainly the subgroups of pain (9.7 vs 13.8; $p = 0.023$) and activity level (14.9 vs 18.9; $p = 0.044$). Those with complications had significantly decreased overall function (Constant score 71 vs 93; $p < 0.0001$).[13] A systematic

review and meta-analysis of 38 level III and IV studies (with highly heterogeneous results) compared suture button repair to hook plate fixation. The authors found suture button to have significantly lower pain (Visual Analog Scale [VAS]: 0.32 [95% CI: 0–0.64] vs 1.51 [95% CI: 0.73–2.00]), a trend toward improved Constant scores but a higher complication rare (RR = 1.7; 95% CI: 1.07–2.6) including loss of reduction, implant migration and osteolysis.[14] Natera-Cisneros et al. performed a retrospective cohort study comparing arthroscopically assisted suture button to hook plate fixation for 31 type III–V injuries. They found significantly improved quality of life (SF-36 Physical; 58.2 ± 2.2 vs 53.7 ± 4.3; p <0.001, SF-36 Mental; 56.2 ± 2.2 vs 53.1 ± 6.1; p = 0.049), VAS (0.4 ± 0.5 vs 1.5 ± 1.5; p = 0.007), Constant score (95.3 ± 2.5 vs 91.4 ± 6.8; p = 0.026), and patient satisfaction (8.9 ± 0.9 vs 8.0 ± 1.2; p = 0.035) with the suture button technique. Both groups had comparable rates of scapular dyskinesia and persistent vertical instability (40% suture vs 36.4% hook plate).[15] Although mechanically highly effective, subacromial pain and erosion remain common with older designs of hook plates that do not match the undersurface of the acromion. Newer designs may offer improved results.

The Weaver–Dunn technique is a biological, nonanatomic, coracoacromial (CA) ligament transfer performed with or without augmentation. This technique has been criticized due to the strength of this transfer being inferior to physiological demand.[16,17] Boström Windhamre et al. retrospectively compared 23 CA transfers with PDS-Suture to 24 CA transfers with temporary hook plate for mostly type V separations. They found no difference in function or stability but more pain with movement – VAS 32 (range 0–86) vs 10 (range 0–47); p = 0.003 – with hook plate and a trend towards lower function.[18] *Anatomic reconstruction* traditionally refers to biologic reconstruction of both the

conoid and trapezoid, but it is often misused in the literature when referring to nonbiologic suture button fixation. In 2010, Carofino and Mazzocca popularized anatomic reconstruction with tendon autograft in a series of 18 cases. They showed good to excellent results (ASES improved from 53 to 92, Constant score improved 76 to 95), but also an 18% failure rate.[19] In a cadaver study looking at load to failure, this anatomic reconstruction technique with ligament graft (948N) was found to be biomechanically superior to suture button fixation (578N; p = 0.01), Weaver–Dunn (523N; p = 0.001), and nonanatomic graft (591N; p = 0.003).[17]

Rush performed a multicenter retrospective cohort study comparing suture button fixation with anatomic tendon reconstruction in 38 cases.[20] The anatomic tendon reconstruction resulted in lower failure (38.8% symptomatic loss of reduction with suture button vs 15% asymptomatic loss of reduction with tendon graft; p = 0.002) and complications (61% vs 25%; p = 0.0243). They concluded that the suture button fails to provide horizontal stability.[20] A dynamic cadaver study showed less laxity and anterior–posterior translation with anatomic graft reconstruction compared to Weaver–Dunn or suture fixation.[21] Tauber performed a prospective cohort study comparing 12 modified Weaver–Dunn procedures vs 12 anatomic autograft reconstructions in type III–V injuries. The anatomic autograft reconstruction group had improved functional scores (p <0.001) and significantly less radiographic displacement with stress loading (2.6 mm vs 0.4 mm; p = 0.027).[22] This was confirmed in a cohort study of 10 chronic type III injuries.[23] Anatomic reconstruction does have limitations, particularly loss of reduction, which has been noted to be as high as 47% and a distal clavicle fracture rate as high as 10%.[24]

Resolution of clinical scenario

- Low-quality evidence supports the use of hook plates as a biomechanically sound option for early AC joint reduction in high-grade AC separations but almost universally require removal of hardware due to symptomatology.
- Moderate- to high-quality evidence shows suture button fixation to have a higher overall complication rate and loss of fixation.
- Low- to moderate-quality evidence shows anatomic reconstruction with tendon autograft has clinically superior maintenance of reduction, lower complications, and improves horizontal stability compared to suture button and Weaver–Dunn but with a 10% distal clavicle fracture rate.

Question 3: In patients with AC joint injuries treated operatively, does early intervention offer improved outcomes compared to delayed surgery?

Rationale

Not all patients with grade III–V require or undergo early reconstruction. It is important to understand the role for delayed reconstruction in those who fail nonoperative treatment.

Clinical importance

Most patients with type III should undergo a nonoperative trial and some patients with type V may elect this course as

well. Patients and surgeons should understand the differences in outcome between acute and delayed reconstruction if they fail conservative treatment.

Available literature and quality of the evidence

This question was answered with four studies utilizing multiple level III studies and systematic review.

Findings

Rolf looked retrospectively at 49 patients, 20 with delayed repair of their AC joint injury and 29 with acute repair using different techniques.[25] Acute repair resulted in improved Constant scores (87.17 vs 78.10; p = 0.019) (minimal clinically important difference [MCID] of 8), lower loss of reduction (34% vs 58%; p = 0.037) and a lower complication rate with acute repair.[25] Von Heideken et al. performed a retrospective cohort study comparing early (<4 weeks) and late (>4 months) Weaver–Dunn and hook plate for type V injuries. There was no difference in Constant score, but acute reconstruction offered superior Shoulder Pain and Disability Index (0 vs 14; p = 0.006), QuickDASH (0 vs 18; p = 0.002), subjective shoulder value (p = 0.032), less pain with movement (p = 0.005) and rest (p = 0.014), and less subluxation on weighted images (p = 0.011).[26] Virk looked at early versus late reconstruction in five retrospective studies including 135 patients in five level III studies showing favorable outcome (defined specifically in each investigation as a tool for subjective evaluation) in 91% of those treated acutely vs 73% of those treated delayed.[27] This was low-quality evidence. A recent systematic review including eight studies showed early reconstruction had better functional outcomes using the Constant score and subjective shoulder value (p <0.05) and lower partial-dislocation or redislocation (39/150 [26%] vs

40/150 (38.1%); p <0.05) but no statistical difference in complications (12.5% early vs 17.7% delayed).[28]

Resolution of clinical scenario

- Early reconstruction is warranted in this active patient with a high-grade AC injury and is supported in the literature with superior functional outcomes, less loss of reduction and lower complications compared to late reconstruction.

Summary of answers

- Patients with Rockwood type I and II injuries are best managed nonoperatively.
- Patients with type III injuries are best managed with nonoperative treatment initially.
- Patients with a type V AC separation are probably best treated with primary operative repair.
- Hook plates are a biomechanically sound option for early AC joint reduction in high-grade AC separations but usually require removal of hardware due to symptomatology.
- Coracoclavicular suture button repair can result in good function but has a high complication and loss of reduction rate.
- Anatomic reconstruction with tendon autograft is biomechanically superior to suture button, Weaver–Dunn, and nonanatomic graft.
- Anatomic reconstruction with tendon autograft is clinically and biomechanically superior and has lower complications and loss of reduction compared to suture button and Weaver–Dunn.

- Anatomic reconstruction with tendon autograft is associated with up to a 10% distal clavicle fracture rate.
- Early reconstruction is associated with superior functional outcomes, less loss of reduction and lower complications compared to late reconstruction.

80
Proximal Humeral Fractures

Benjamin Kopp MD[1] and David Ring MD PhD[1]
Department of Surgery and Perioperative Care, Dell Medical School – The University of Texas at Austin, Austin, TX, USA

Clinical scenario

- A 69-year-old woman presents to the Emergency Department after a slip and fall at home. She is an avid golfer and does not take any medication. On examination, she has pain, swelling, and ecchymosis of her right dominant shoulder and arm and a normal neurovascular exam. Radiographs reveal a minimally displaced fracture of the proximal humerus. She is concerned about radiation exposure, and asks whether a computed tomography (CT) scan is necessary.
- She is anxious to get back to golf and would like to know when she should start exercises to most effectively regain function.
- A friend of hers recently had surgery. She is wondering if she should have surgery too.

Top three questions

1. In patients with a proximal humerus fracture, does adding CT imaging improve classification of fractures or improve patient outcomes compared with radiographs alone?

2. In patients choosing nonoperative treatment of a fracture of the proximal humerus, does early initiation of exercises (before one week) improve pain or patient-reported function compared with delayed exercise programs (after three weeks)?
3. In patients with displaced three- or four-part humerus fractures, does nonoperative treatment lead to better outcomes than surgical treatment (open reduction and internal fixation, hemiarthroplasty, or reverse total shoulder arthroplasty)?

Question 1: In patients with a proximal humerus fracture, does adding CT imaging improve classification of fractures or improve patient outcomes compared with radiographs alone?

Rationale

Surgeons and patients hope that more detailed imaging will better guide management and lead to improved outcomes.

Clinical comment

Due to complex three-dimensional (3D) anatomy of proximal humerus fractures, some can be challenging to characterize on radiographs. CT scans are commonly used to get a more detailed image of the fracture pattern, which could potentially lead to better tailored treatments and improve outcomes.

Available literature and quality of the evidence

Two prospective studies have evaluated the reliability and accuracy of classification using radiographs and CT scans (level II).[1,2] One study assessed interobserver reliability of AO classification between 2D and 3D CT scans (level III).[3] Multiple retrospective studies studied inter- and intraobserver reliability regarding specific fracture characteristics (level III)[4] and fracture classification with AO classification (level III)[5] or Neer classification (level III).[6]

Findings

In a prospective diagnostic study three observers classified 44 consecutive fractures and found better assessment of relevant structures (tuberosities, the glenoid, and humeral head) using a four-grade scoring system (1 = excellent, 2 = good, 3 = fair, and 4 = inadequate) based on CT compared to radiographs (AP view, scapular Y-views, and axillary views) independent of fracture severity (i.e. Neer two-, three-, or four-part fractures) ($p < 0.05$) (level II).[1] A study comparing 2D to 3D CT scans found higher, but still only fair, interobserver reliability for 3D CT scans regarding displacement of the greater tuberosity ($\kappa = 0.35$ vs 0.30, $p < 0.001$).[3]

In a retrospective study three3 observers evaluated 40 nonconsecutive fractures and found better assessment of fracture displacement, impaction, and anatomic neck involvement with CT compared to radiographs, but no influence on AO classification or decision on whether to operate (level III).[5]

In another retrospective study four observers evaluated 40 consecutive fractures and documented better interobserver reliability by adding CT: “moderate” for radiographs ($\kappa = 0.42$) and 2D CT ($\kappa = 0.56$) to “good” for 2D CT with 3D volume renderings ($\kappa = 0.76$) for the Neer classification

system intraobserver reliability improved ($p < 0.001$) from "moderate" for radiographs ($\kappa = 0.48$) and 2D ($\kappa = 0.63$) to "excellent" for 2D CT with 3D volume renderings ($\kappa = 0.84$) for the Neer classification (level II).[2]

In another study, seven observers evaluated 40 consecutive fractures and compared 2D versus 3D CT with no difference in intraobserver reliability.[6] There was a difference in interobserver reliability among the junior resident observers (level III). This difference amongst more junior surgeons was also reflected in a prior study comparing 2D and 3D CT scans where less experienced surgeons had significantly higher levels of agreement with 3D ($\kappa = 0.14$) CT than 2D ($\kappa = 0.17$) ($p = 0.014$).[3]

In another study, three observers reviewed 20 fractures with no difference in diagnosis of fracture characteristics (existence of medial hinge, metaphyseal extension) on radiographs compared to 2D CT (level III).[4]

Resolution of clinical scenario

- Level II evidence suggests that CT does not improve overall classification of proximal humerus fractures, but it may be more reliable for defining specific fracture characteristics and therefore may be helpful when making treatment decisions for patients.
- Level III evidence suggests 3D CT may improve the reliability of classification over 2D CT among less-experienced observers.
- It is not known whether more reliable classification leads to improved outcomes.

Question 2: In patients choosing nonoperative treatment of a fracture of the proximal humerus, does early initiation of exercises (before one week) improve pain or patient-reported function compared with delayed exercise programs (after three weeks)?

Rationale

Immediate initiation of exercises might result in better final shoulder motion but could also theoretically interfere with healing. Controversy exists between early (within one week) or late (three weeks or greater, once healing is underway) initiation of exercises after a proximal humerus fracture.

Clinical comment

Most fractures of the proximal humerus are adequately aligned, stable, and associated with limited functional impairment after nonoperative treatment.[7,8] Many of these have good results treated in a simple arm sling. Due to the impact on activities of daily living in the generally older patient population, early return of function is important for maintaining independence.[9]

Available literature and quality of the evidence

Three prospective randomized controlled trials (RCTs) (level II) have studied the effect of mobilization within one week of injury on multiple patient-reported outcome measures (PROMs).[9–11]

Findings

Shoulder function

Two prospective RCTs (160 patients) with methodological limitations (possible bias; allocation concealment unclear, some blinding outcome assessors, blinding patients impossible, inclusion/exclusion criteria not clearly defined) showed that early mobilization within one week resulted in significantly better Constant Shoulder Scores at 12 weeks[9] for impacted (stable) proximal humeral fractures (weighted mean difference [MD]: 9.9; 95% confidence interval [CI]: 2.1–17.7; $p < 0.05$) and 16 weeks[10] for non- and minimally displaced two-part fractures (MD: 16.0; 95% CI: 7.1–24.9; $p < 0.001$). There were no significant differences at six months[9] (MD: 6.1; 95% CI −0.2–12.4, $p = 0.06$) and one year[10] (MD: 7.0; 95% CI: −3.4–17.4; $p = 0.19$) after fracture (level II).

General health status (Short Form 36)

One prospective RCT (86 patients) showed that early mobilization within one week for patients with non- and minimally displaced proximal humerus fractures resulted in significantly better health-related quality of life scores at 16 weeks in two dimensions of the SF-36 (role limitation physical: MD: 22.2; 95% CI: 3.8–40.6; pain: MD: 12.1; 95% CI: 3.2–20.9).[10] There were no statistically significant differences between the two treatment groups in the other six dimensions (e.g. physical functioning) of SF-36, nor in any of the eight dimensions at one year (level II).

Pain

One prospective controlled trial by Lefevre-Colau and colleagues of patients with impacted proximal humeral fractures (64 patients) reported significantly less pain in

patients that started pendulum exercises immediately compared to those that were immobilized for a month as measured on a 100 mm Visual Analog Scale (VAS) pain score at three months (MD: 15.7; 95% CI: 0.52–30.9; p <0.05), but not at six weeks (MD: 3.6; 95% CI: −13.6–20.8; p = 0.68) or six months (MD: −0.20; 95% CI: −14.4–14.0, p = 0.98) (level II).[9]

Resolution of clinical scenario

- Evidence suggests that for the above-mentioned patient with a minimally displaced two-part fracture or an impacted fractures of the proximal humerus, early initiation (within one week) of exercises does not influence impairment or disability six months or more after fracture of the proximal humerus, and may facilitate quicker recovery and return to activities like golf.
- No risk of nonunion was seen with early initiation of exercises in patients similar to the patient in this scenario, but these were small studies unable to assess for the risk of uncommon events.

Question 3: In patients with displaced three- or four-part humerus fractures, does nonoperative treatment lead to better outcomes than surgical treatment (open reduction and internal fixation, hemiarthroplasty, or reverse total shoulder arthroplasty)?

Rationale

Multiple surgical treatments are available for displaced proximal humerus fractures, including open-reduction and internal fixation with a locking plate, reverse total shoulder arthroplasty, or hemiarthroplasty. Which surgical option, if any, can improve outcomes for patients with displaced three- or four-part proximal humerus fractures is still unclear.

Clinical comment

Studies have not consistently shown that surgical intervention improves outcomes, and operative interventions come with different sets of complications. Difficulties associated with loss of fixation, nonunion, malunion, and osteonecrosis after open reduction and internal fixation make prosthetic arthroplasty an appealing treatment option. Function is inconsistent after hemiarthroplasty and might be better with reverse arthroplasty.

Available literature and quality of the evidence

Multiple high-quality RCTs (level I) have investigated differences in outcomes between nonoperative and operative management of three- or four-part proximal humerus fractures[12–19] along with an RCT with <80% follow-up.[20] There are two systematic reviews with meta-analysis (level I).[21,22]

Direct comparisons of different operative methods are more limited, but high-quality RCTs (level I)[23,24] have been performed, along with lower-quality RCTs (level II)[25] and a systematic review and network meta-analysis (level II)[26] which combines six RCTs to compare multiple treatment modalities.

Findings

Shoulder function: operative versus nonoperative

Seven prospective controlled trials[12–20] (518 patients) with methodological limitations (unable to blind patients and caregivers, outcome assessors not blinded, one[20] with <80% follow-up) randomized patients to nonoperative treatment versus hemiarthroplasty for displaced fractures[12,13,16] (142 patients), versus locking plate for displaced three-part (60 patients)[17] or displaced three- or four-part (50 patients),[14,15] versus surgeon preference (90 locking plate, 10 hemiarthroplasty) and versus tension-band osteosynthesis for three- or four-part proximal humerus fractures (40 elderly patients, mean age 74 years).[20] Five studies used standardized shoulder-specific outcome measures.[13,14,16,17,20] All five studies measured constant scores, and no individual study or meta-analysis of these studies[21] showed a significant difference at 12[13,14,16,17] or 24 months.[15–17,20] Two studies compared Disabilities of the Arm, Shoulder, and Hand (DASH) scores in nonoperative versus hemiarthroplasty[16] or open

reduction and internal fixation (ORIF) with a locking plate.[17] Both studies showed no significant differences in DASH scores in the operative groups (26 for ORIF, 35 nonoperative; p = 0.19)[17] (30 for hemiarthroplasty, 37 nonoperative; p = 0.25).[16] The Oxford Shoulder Score was also measured in the largest of the level I studies and showed no significant difference at any timepoint during the first two years in the original publication (231 patients) or in three-year (164 patients), four-year (155 patients), or five-year (149 patients) extensions.[14,15]

Complications: operative versus nonoperative

Two meta-analyses showed a higher rate of surgery subsequent to the initial treatment in the operative patients compared to nonoperative (seven studies, 523 patients; risk ratio [RR]: 2.06; 95% CI: 1.18–3.6; p = 0.011; I^2 = 29%).[21,22] The meta-analyses did not find significant differences between operative and nonoperative treatment in any other complications or adverse events including mortality, avascular necrosis, nerve injury, nonunion, nerve injury, or shoulder impingement.

Hemiarthroplasty versus ORIF with locking plate

One RCT (32 patients, two-year follow-up) with methodological limitations (unclear allocation concealment, unclear blinding of patients or outcome assessors) reported significantly higher constant scores (73 vs 60; p = 0.017), lower pain on VAS (3.6 vs 6.4; p = 0.018) and lower DASH scores (9.2 vs 15; p = 0.023) for hemiarthroplasty compared to ORIF with locking plate.[24] No significant difference in strength or range of motion (ROM) was observed.

Reverse shoulder arthroplasty versus hemiarthroplasty

One RCT (62 patients) comparing reverse shoulder arthroplasty (RSA) to hemiarthroplasty in four-part fractures deemed not amenable to ORIF showed significantly superior outcomes for RSA.[23] RSA had significantly higher constant scores (56.1, range 24–80 vs 40.0, range 8–74; p = 0.001), higher UCLA scores (29.1, range 16–34 vs 21.1, range 6–34; p = 0.001), and lower DASH (17.5, range 12–30 vs 24.4, range 13–41; p = 0.001). Shoulders in the RSA group also had significantly better ROM in anterior forward elevation (120° vs 80°; p = 0.01), abduction (113° vs 79°; p = 0.001), and external rotation (4.7 Constant sub-score vs 3.3; p = 0.23). No significant difference was seen in internal rotation. They also noted a nonsignificant higher rate of implant survival at 40 months in the RSA group (97% vs 80%; p = 0.43).

Comparison of multiple surgeries in network meta-analysis

A Bayesian network meta-analysis of seven RCTs was performed to compare nonoperative management, hemiarthroplasty, ORIF, and RSA simultaneously.[26] This analysis did not show any significant difference regarding Constant scores or revision rates between treatments.

Resolution of clinical scenario

- If our patient's fracture was displaced, multiple level I studies show no significant differences in PROMs between operative and nonoperative management.
- Operative treatment of a displaced fracture is associated with a higher risk of needing further surgery than nonoperative management without other significant differences in rates of adverse events.
- Hemiarthroplasty may lead to better PROMs than ORIF in elderly patients with displaced four-part proximal

humerus fractures.

- If our patient's fracture was four parts and displaced, RSA may lead to better PROMs, increased ROM, and increased implant survival rates compared to hemiarthroplasty.

Summary of answers

- CT scans do not significantly increase reliability or accuracy of fracture classification in proximal humerus fractures amongst experienced surgeons, but they may be beneficial to assess particular fracture characteristics, which may change treatment decisions. It is not known whether CT affects outcomes.
- Early mobilization and home exercises within a week of injury have not been shown to negatively impact union rate, and may expedite recovery of function.
- There is insufficient evidence from RCTs to determine the optimal intervention in patients with proximal humeral fractures, but high-quality studies have shown no significant benefit and higher risks with operative management of proximal humerus fractures in the elderly.

Humeral Shaft Fractures

David J. Hak MD MBA FACS and Cyril Mauffrey MD FRCS FACS
University of Colorado, Denver Health Medical Center, Department of Orthopedic Surgery, Physical Medicine, and Rehabilitation, Denver, CO, USA

Clinical scenario

- A 35-year-old man is brought to the Emergency Department following a motor vehicle accident.
- He is complaining of right arm pain and has an obvious deformity of his right upper arm, which appears to be his only orthopedic injury.
- After your resident attempts a reduction application of a hanging cast, the patient reports numbness and weakness in his radial nerve distribution.

Top three questions

1. In adult patients with displaced humeral shaft fractures, does operative treatment result in improved function compared to nonoperative treatment?
2. In adult patients with displaced humeral shaft fractures undergoing operative treatment, how does plate osteosynthesis compare to intramedullary nailing in terms of fracture union and complication rates?
3. In adult patients sustaining humeral shaft fractures with radial nerve palsy, is there a difference in the recovery rate with primary radial nerve palsy, as

compared to secondary radial nerve palsy (i.e. with fracture manipulation) radial nerve palsy?

Question 1: In adult patients with displaced humeral shaft fractures, does operative treatment result in improved function compared to nonoperative treatment?

Rationale

Nonoperative treatment has historically been the standard of care for isolated closed humeral shaft fractures. Similar to clavicle fractures, it has been assumed that the majority of fractures heal with a low level of complication, but level I evidence regarding the treatment of isolated closed humeral shaft fractures is lacking.

Clinical comment

Understanding the outcomes of operative and nonoperative treatment is important in order to recommend treatment and guide patients regarding their expected outcomes.

Available literature and quality of the evidence

To date, only a single level I study has compared operative with nonoperative treatment of humeral shaft fractures.[1]

Findings

Matsunaga and colleagues performed a prospective randomized study of 110 adult patients sustaining humeral shaft fractures treated with either minimally invasive bridge plating or nonoperative treatment with a functional brace. The primary outcome was the Disabilities of the

Arm, Shoulder, and Hand (DASH) score at six months. Secondary outcome measures include the Short Form 36 (SF-36) life-quality questionnaire, Constant–Murley score for the shoulder, pain level, treatment complications, and radiographic results.[1]

Surgical treatment with bridge plating was statistically superior to conservative treatment with respect to the mean DASH at six months (mean scores: 10.9 ± 10.5 for bridge plating and 16.9 ± 18 for conservative treatment; $p = 0.046$), but this difference is of uncertain clinical benefit since other studies suggest that 10 points is the minimal clinically important difference.[2,3] The union rate in the bridge plate group was significantly better than in the nonoperative group (100% vs 85% respectively; $p < 0.05$). Mean residual angular displacement seen on the anteroposterior radiograph was significantly less in the bridge plate group (2.0° ± 4.7° vs 10.5° ± 8.9°; $p < 0.05$). There was no difference between the groups with regard to the SF-36 score, pain level, Constant–Murley score, or angular displacement seen on the lateral radiograph.

Resolution of clinical scenario

- Operative treatment with bridge plating results in a superior mean DASH score at six months, but the clinical importance of this difference is uncertain.
- Operative treatment using a minimally invasive bridge plating technique results in a significant higher union rate compared to nonoperative treatment.
- This recommendation is based on only a single study with low external validity since it was conducted at a single center. There are two randomized clinical trials comparing surgical and nonsurgical treatment of humeral shaft fractures in progress.[4,5]

- Given that the current evidence does not show significant functional differences between operative and nonoperative management, patient preferences such as time to return to activity and feelings toward surgical risk should be considered

Question 2: In adult patients with displaced humeral shaft fractures undergoing operative treatment, how does plate osteosynthesis compare to intramedullary nailing in terms of fracture union and complication rates?

Rationale

There is debate regarding the choice of humeral shaft fracture operative treatment. The main operative treatment options are plate fixation or intramedullary nailing. Plate fixation has traditionally been done through an open reduction approach, but a minimally invasive approach in which the plate is inserted through small incisions has gained popularity.

Clinical comment

A significant number of clinical studies have compared plate fixation or intramedullary nailing of humeral shaft fractures in an attempt to identify the optimal treatment option.

Available literature and quality of the evidence

There have been 16 downgraded randomized controlled trials (RCTs) (level II), including 832 participants,

comparing the different operative treatment options for humeral shaft fractures.[6–21] Individual sample sizes ranged from 28 to 89 participants. A network meta-analysis of these downgraded RCTs (level II) has pooled the results to assess the outcomes of different operative treatment options.[22]

All of these studies have a risk of bias. Blinding was not possible for the participants and clinicians because of the nature of the surgical treatment. None of studies reported whether they received grants in support of their research. None of the studies mentioned whether an *intention to treat* analysis was performed. Based on the Oxford Centre for Evidence-based Medicine Levels of Evidence, all of the trials were assessed as level II evidence.

Findings

The results of a network meta-analysis of these clinical trials showed that shoulder impingement occurred more commonly in the intramedullary nail group than with either open reduction and plate fixation (odds ratio [OR] = 0.13; 95% confidence interval [CI]: 0.03–0.37) or minimally invasive plate fixation (OR = 0.08; 95% CI: 0.00–0.69). Iatrogenic radial nerve injury occurred more commonly in the open reduction and plate fixation group than in the minimally invasive plate fixation group (OR = 11.09; 95% CI: 1.80–124.20). There were no significant differences among the three procedures in nonunion, delayed union, and infection.[22]

Resolution of clinical scenario

- Minimally invasive plate fixation is the preferred treatment method for humeral shaft fractures since it has a lower complication rate than intramedullary nailing or open reduction and plate fixation.

Question 3: In adult patients sustaining humeral shaft fractures with radial nerve palsy, is there a difference in the recovery rate with primary radial nerve palsy, as compared to secondary radial nerve palsy (i.e. with fracture manipulation) radial nerve palsy?

Rationale

When radial nerve palsy develops following fracture manipulation, many surgeons have advocated radial nerve exploration because this scenario suggests that the radial nerve might be trapped within the fracture.

Clinical comment

A survey of current practice among trauma surgeons in England showed that surgeons still differ in the ways of managing radial nerve palsy associated with humeral fractures, with a slightly higher percentage of surgeons preferring conservative treatment.[23]

Available literature and quality of the evidence

No RCTs have been performed to date on the topic of radial nerve palsy secondary to humeral shaft fracture. A single prospective cohort is registered on clinicaltrials.gov, and the status marked as completed, though no publications from the group could be found. Shao et al. performed a systematic review (level IV) of 35 studies which included a total of 1079 patients.

Findings

Shao et al. reported that a spiral fracture pattern of the distal humerus with associated nerve palsy is not an absolute indication for radial nerve exploration and showed no significant difference in the rate of recovery between primary (88.6%) and secondary nerve palsies (93.1%).[24] A limited period of waiting also had no effect on the final recovery. Eleven studies (n = 98 patients) showed that the mean delay to first exploration was 4.3 months (range 1–15). In 101 cases treated expectantly at first, the mean spontaneous recovery onset time was 7.3 weeks, which may indicate the minimum waiting time before exploration.

The rationale for this type of injury is not to be indicated for open reduction unless it constitutes an increase in radial nerve deficit. It is reported that nerve fibers will regenerate in three months' time. When recovery in this time period has failed, further treatment options such as exploration, neurorrhaphy, and tendon transfers may start to be considered. Because irrigation and debridement is required for open fractures, it is reasonable to explore the nerve at this same operation. Shao et al. did not identify a significant difference in the spontaneous recovery of radial nerve palsies in open versus closed fractures.[24]

Resolution of clinical scenario

- Exploration is recommended at 4–6 months if there is no resolution following a primary radial nerve palsy (overall quality: low).
- In patients with indications for earlier operative fixation, exploration of the nerve should be at the time of internal fixation (overall quality: low).
- Primary and secondary nerve palsies show no difference in recovery rate so in this case the patient

should be counseled about the high expected recovery rates with observation alone and the timing to recovery to create appropriate expectations (overall quality: moderate).

Summary of answers

- Operative treatment using a minimally invasive plate fixation results in improved function compared to nonoperative treatment.
- Minimally invasive plate fixation is the preferred treatment method for humeral shaft fractures since it has a lower complication rate than intramedullary nailing or open reduction and plate fixation.
- The recovery rate of radial nerve palsy associated with humeral shaft fractures averages from 88 to 93%. Primary and secondary nerve palsies show no difference in recovery rate.

82
Distal Humerus Fractures

Brandon Girardi MD[1], Emil H. Schemitsch MD[2] and Aaron Nauth MD MSc[1]
[1]St. Michael's Hospital, University of Toronto, Toronto, ON, Canada
[2]Division of Orthopaedic Surgery, Department of Surgery, Western University, London, ON, Canada

Clinical scenario

- An 81-year-old female patient, who lives independently, presents to the Emergency Department after a fall from standing height on her right arm.
- She is complaining of pain in her right elbow.
- There are no open wounds and her limb is neurovascularly intact.
- The x-rays show a displaced C3-type distal humerus fracture with significant comminution (Figure 82.1).

Top three questions

1. In patients with intra-articular distal humerus fractures, does a triceps splitting approach result in better patient outcomes when compared to an olecranon osteotomy?
2. In patients with distal humerus fractures, does parallel plating result in better outcomes when compared to orthogonal plating?

3. In elderly patients with comminuted, intra-articular, distal humerus fractures does total elbow arthroplasty (TEA) result in better outcomes than open-reduction and internal fixation?

Question 1: In patients with intra-articular distal humerus fractures, does a triceps splitting approach result in better patient outcomes when compared to an olecranon osteotomy?

Rationale

Numerous surgical approaches have been described for the fixation of distal humerus fractures. With the exception of approach strategies for coronal shear fractures, all of these involve a posterior skin incision with various strategies of working through, or around, the triceps. Described approaches include the triceps-splitting, olecranon osteotomy, triceps-reflecting (Bryan–Morrey), triceps-reflecting anconeus pedicle (TRAP), and para-tricipital approaches. Surgeon opinion regarding the optimal surgical approach to distal humerus fractures is widely divergent.

Clinical comment

One goal of surgical fixation of distal humerus fractures is achieving an upper extremity with functional range of motion and strength. The surgical approach of choice would ideally provide the maximum visualization of the joint surface while minimizing negative effects on function postoperatively.

Available literature and quality of the evidence

- Level III: 4 studies[1–4]
- Level IV: 11 studies.[5–15]

The evidence to answer this important question is limited to multiple level III and level IV studies.

Findings

Four level III studies retrospectively compared the triceps-splitting approach and the olecranon osteotomy approach for distal humerus fractures fixation. Three of these studies showed no statistically significant differences between the approaches with regards to either objective elbow strength, range of motion (ROM), or functional outcomes (n = 62 patients).[1,2,4] Other level IV series of patients treated with olecranon osteotomy have reported rates of hardware removal ranging from 6 to 30% and nonunion of the olecranon osteotomy in 0–9% of patients.[5–9] One level III study compared the two approaches for the fixation of open distal humerus fractures and found better functional outcomes and a trend toward improved ROM in the triceps-splitting group (n = 26 patients).[3] Mayo Elbow Performance Score (MEPS) were 84.5 versus 73.5 (p = 0.05), and Disabilities of the Arm, Shoulder, and Hand (DASH) scores were 29.5 versus 64.1 (p = 0.05). Authors hypothesized that this effect was due to the fact that open fractures had a large tear in the triceps that was easily incorporated into the triceps splitting approach. Multiple level IV studies have reported satisfactory results using the olecranon osteotomy, triceps-splitting,[10] triceps-reflecting,[11,12] and triceps sparing[13–15] approaches. A meta-analysis of the literature looked at both the triceps-splitting and Bryan–Morrey approaches independently

compared to an olecranon osteotomy.[16] The authors noted the overall low quality of evidence currently available. When comparing the Brian–Morrey approach with olecranon osteotomy, the MEPS showed no significant difference (standardized mean difference [SMD]: 0.20; 95% confidence interval [CI]: −0.40, 0.80; I^2 = 55%). Similarly, using the flexion extension arc as the performance outcome, there was no significant difference noted between the triceps-splitting approach and olecranon osteotomy (SMD: −0.22; 95% CI: −1.53 to 1.08; I^2 = 86%). Analysis revealed no significant differences in terms of ulnar nerve injury, heterotopic ossification, infection, or post-traumatic arthrosis. They did note a higher rate of re-operation with olecranon osteotomy for hardware removal, although this finding was heavily weighted by one study in the analysis.

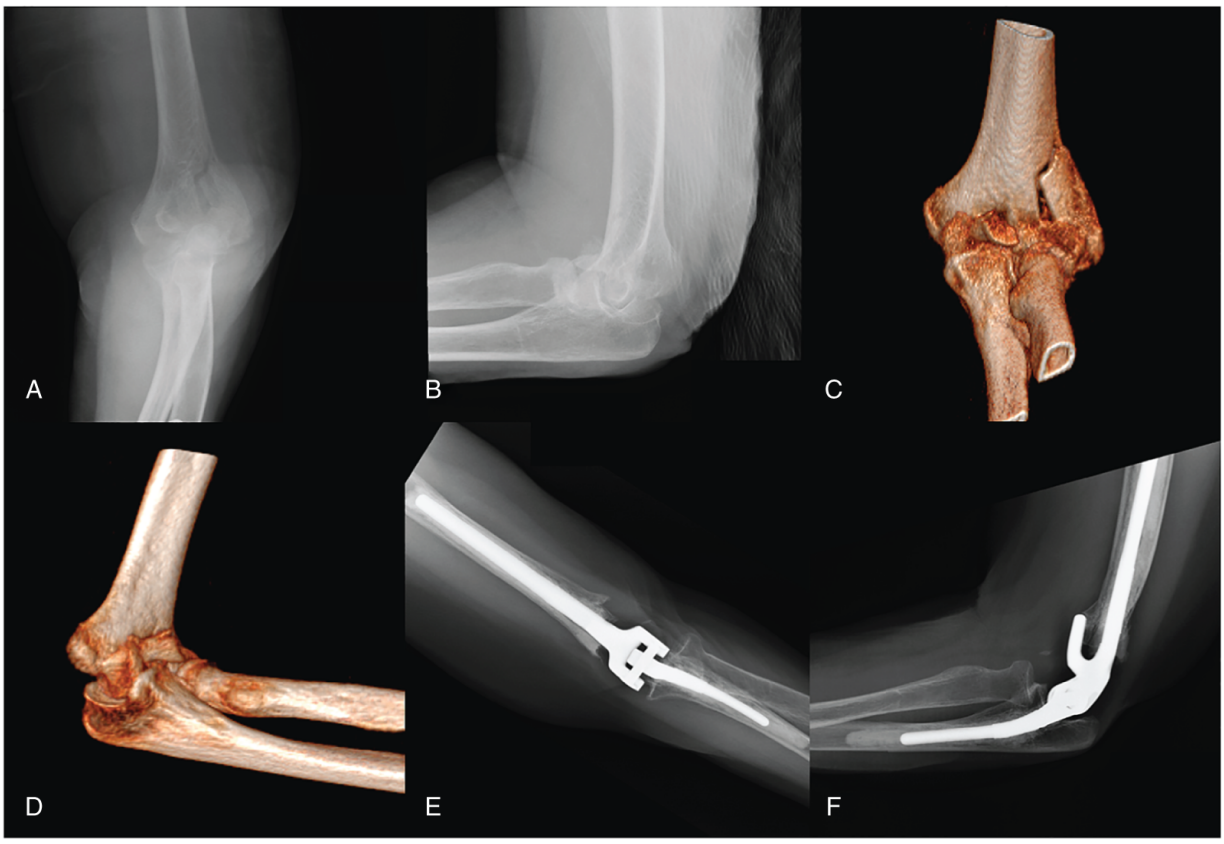

Figure 82.1 Radiographs and three-dimensional (3D) CT scan reconstructions of an 81-year-old female patient with a comminuted intra-articular distal humerus fracture, including a coronal shear component (A–D). Six-month postoperative radiographs following treatment with a semi-constrained total elbow arthroplasty (TEA) performed through a triceps sparing, para-tricipital approach (E and F).

Resolution of clinical scenario

In patients with an intra-articular distal humerus fracture, who are considered candidates for operative fixation of the fracture, it is the authors' approach to use a triceps-splitting technique (Figure 82.2) except in cases where there is extensive articular comminution, particularly those with a coronal shear component to the articular fracture. In these cases, the authors recommend an olecranon

osteotomy to improve visualization based on the evidence that suggests a triceps-splitting approach gives equivalent functional outcomes and a decreased need for removal of hardware when compared to olecranon osteotomy (overall quality: low).

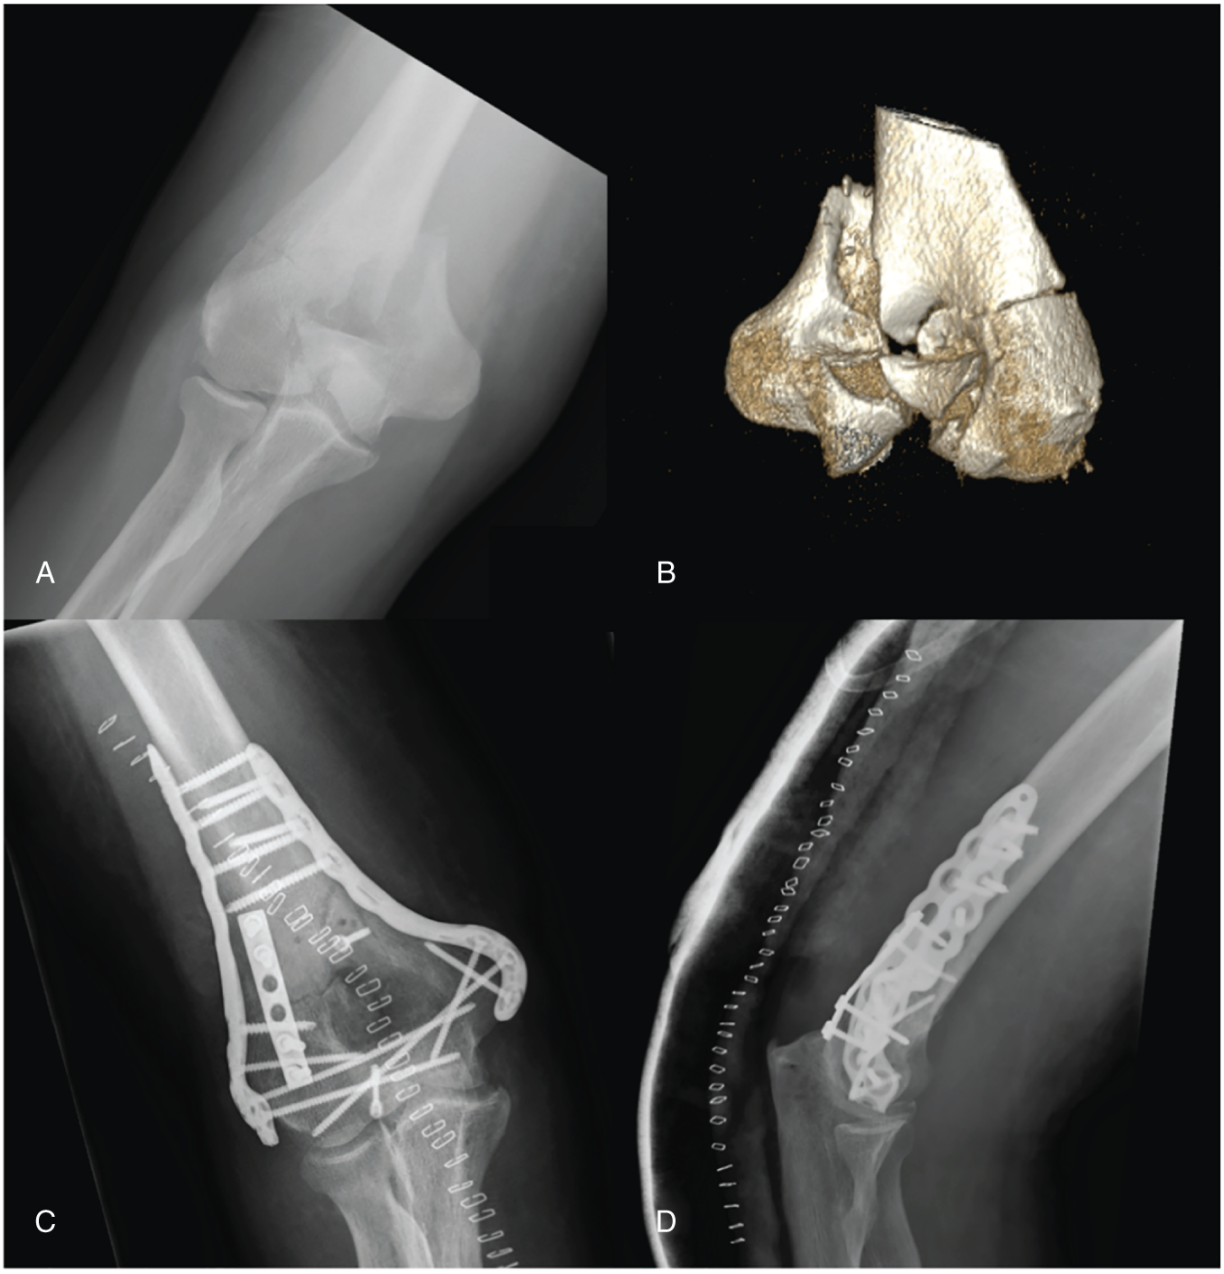

Figure 82.2 AP radiograph and 3D CT scan reconstruction of a 58-year-old male patient with a comminuted intra-articular distal humerus fracture (A and B). Postoperative radiographs following ORIF with parallel plating performed through a triceps-splitting approach (C and D).

Question 2: In patients with distal humerus fractures, does parallel plating result in better outcomes when compared to orthogonal plating?

Rationale

Since the introduction of AO techniques involving dual column plating for the fixation of distal humerus fractures, significant improvements in surgical outcomes have been observed. Evidence shows that plate fixation is superior compared to minimal fixation with screws and/or Kirschner wires (K-wires).[17,18] However, controversy remains regarding the position/orientation of plate fixation and the role of locked plating systems.

Clinical comment

Fixation for distal humerus fractures must achieve anatomic and absolute stability of the articular surface. Fixation strategies must also bridge metaphyseal comminution while allowing for early ROM to avoid significant postoperative stiffness. Research has focused on identifying the ideal dual plating construct to resist early failure while achieving reliable union rates.

Available literature and quality of the evidence

- Level II: 1 study[19]
- Level IV: 22 studies.[20–23]

Limited clinical evidence is available to answer this question. Most data come from a variety of biomechanical

studies using various fracture models to analyze the properties of these two constructs.

Findings

One level II study compared parallel plating to perpendicular plating in a prospective, randomized fashion (n = 35 patients).[19] Although no statistically significant differences were found between the two groups, there were two nonunions in the perpendicular plating group versus no nonunions in the parallel plating group. This study may have been underpowered to detect a clinically significant difference in union rates. Multiple level IV series have reported satisfactory results with perpendicular plating techniques[20–24] and parallel plating techniques.[25–30]

Several biomechanical studies have demonstrated that parallel plate configurations at 180 degrees to each other are biomechanically superior to perpendicular plates when a gap model is used to simulate fracture comminution.[31–33] Specifically, there is a significant increase in internal torsional stiffness with a parallel plating construct, parallel 2.9 ± 0.7 N-m/deg versus orthogonal 2.3 ± 0.6 N-m/deg, $p < 0.0001$, $R^2 > 0.98$.[34] In addition, axial loading of orthogonal plate constructs leads to anterior movement of capitellum relative to the trochlea which can lead to distal screw pull out in the posterolateral plate.[35]

Two clinical level IV studies have reported on the results of locked plating of distal humerus fractures (n = 52 patients).[36,37] Pooled analysis showed good/excellent results in 79% of patients, with only a single case of implant failure.

Biomechanical studies have shown improved stiffness with the use of locked plating constructs in gap models of comminuted distal humerus fractures. When comparing

fixation between an orthogonal locked plating system and orthogonal conventional plates, there was a 52% increase in stiffness ($p < 0.001$).[38]

Resolution of clinical scenario

In the case of our patient, the evidence supports the need for dual column fixation, either in perpendicular or parallel (overall quality: moderate). It is the authors' approach to use a parallel plating technique with pre-contoured, peri-articular, locking plates (Figures 82.2 and 82.3). This maximizes stability in fractures with metaphyseal comminution to allow for early ROM postoperatively. In some cases, with limited metaphyseal comminution but the fracture has a shear component laterally, a posterolateral plate is selected as it allows fixation from a posterior to anterior direction to capture large shear fragments.

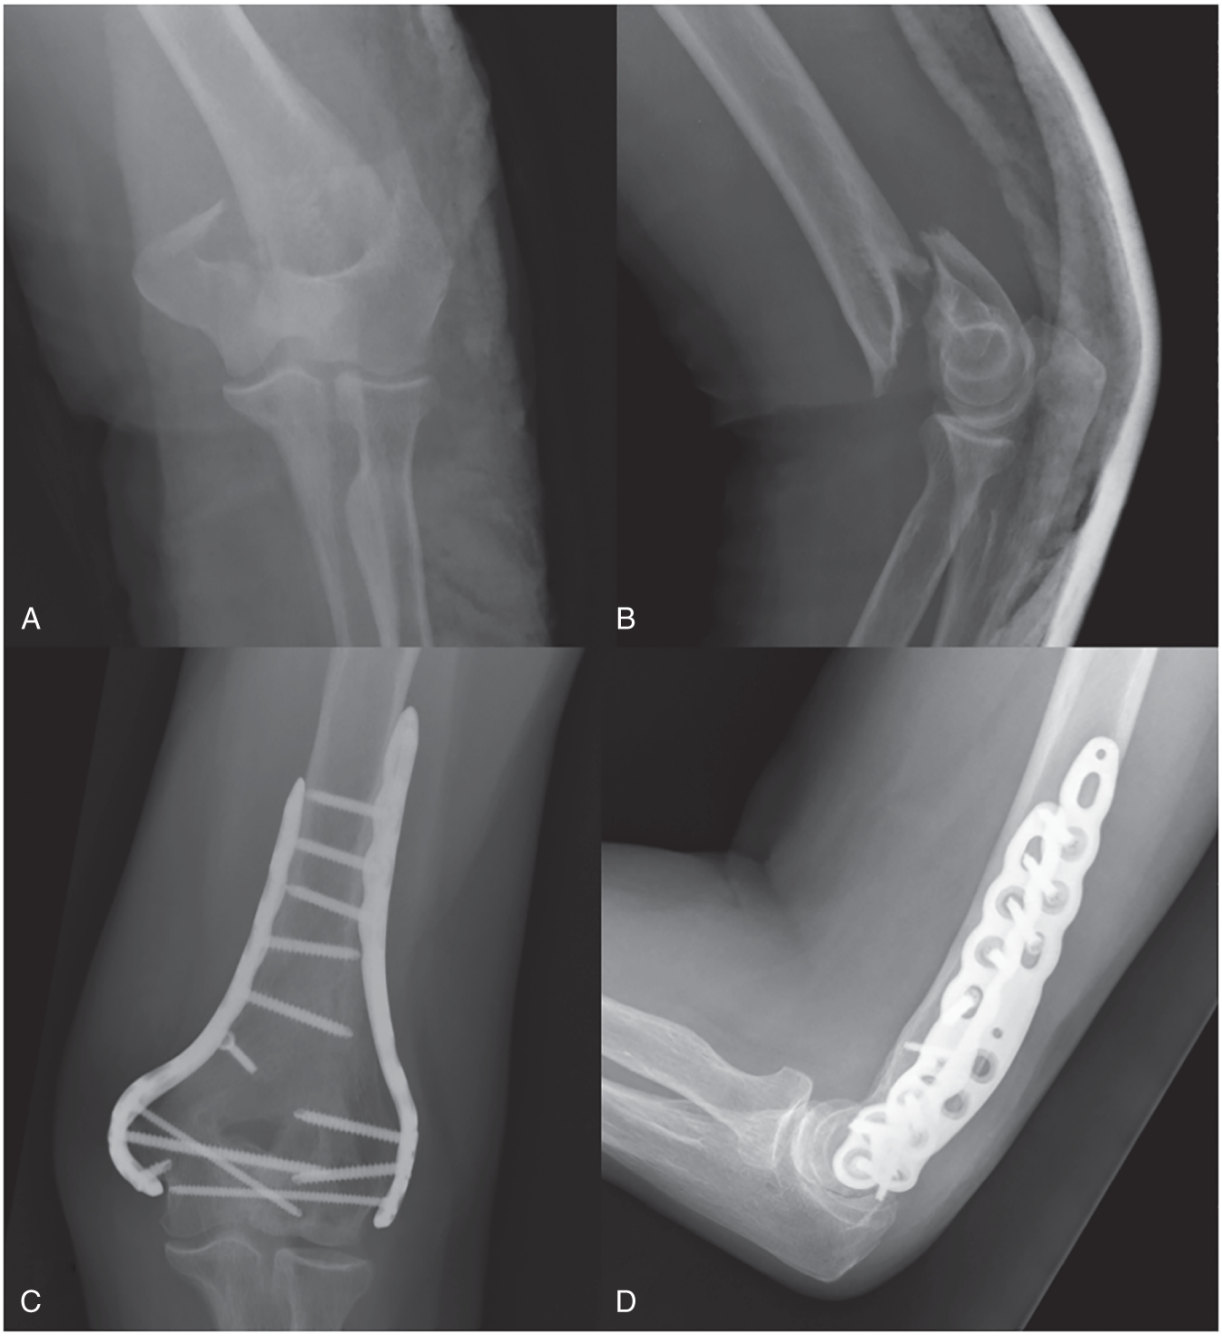

Figure 82.3 Preoperative radiographs of a 67-year-old female patient with an intra-articular distal humerus fracture (simple intra-articular split) (A and B). Six-month postoperative radiographs following ORIF with parallel plating performed through a para-tricipital approach (C and D).

Question 3: In elderly patients with comminuted, intra-articular, distal humerus fractures does total elbow arthroplasty (TEA) result in better outcomes than open-reduction and internal fixation?

Rationale

Distal humerus fractures with comminution of the articular surface can be difficult to manage, even in young patients with excellent bone quality. In elderly patients with poor bone quality and significant articular comminution, this challenge increases exponentially, and surgical outcomes have historically been poor in these patients. This has prompted many authors to investigate, and advocate for, the role of acute TEA in the management of distal humerus fractures in elderly patients, with a 2.6-fold increase in use between 2002 and 2012 in a US-based study.[39]

Clinical comment

In the setting of a comminuted distal humerus fracture, a semi-constrained TEA can be performed through a triceps-sparing, para-tricipital approach. This creates an immediately stable construct, which allows for early functional rehabilitation and avoids the complications of fracture nonunion and post-traumatic osteoarthritis. However, a TEA comes with inherent lifelong limitations in carrying weight (typically restricted to 10–15 pounds) as well as the risk for infectious or aseptic failure requiring revision.

Available literature and quality of the evidence

- Level II: 1 study[40]
- Level III: 7 studies[39–45]
- Level IV: 2 studies.[46,47]

Findings

A prospective, randomized, multicenter study compared ORIF versus TEA for displaced, intra-articular fractures of the distal humerus (OTA/AO type C) in patients over the age of 65 years (n = 40 patients).[40] The authors reported better functional outcomes in the TEA group vs the ORIF group at two-year follow-up. MEPS for TEA versus ORIF at two years were 86 versus 73 (p = 0.015); DASH scores showed a trend toward TEA at 32 versus 43 (p = 0.18). In addition, there was a 25% rate of intra-operative conversion to TEA in the ORIF group due to extensive comminution and inability to achieve stable fixation.

A systematic review and meta-analysis of studies published prior to 2014, involving geriatric distal humerus fractures, looked at outcomes between ORIF and TEA.[45] Based on the 27 studies identified, including 563 patients, the authors reported no clinically significant difference in functional outcomes. The number of patients experiencing at least one complication in the TEA group was 33.3 (CI: 21.6–44.9%) compared to the ORIF group 32.6 (CI: 21.8–43.5%), which did not differ significantly. Total complications were higher overall in the TEA group (37.6 vs 34.2%); however, major complications were higher after ORIF (11 vs 13.7%), resulting in a higher reoperation rate after ORIF (5.7 vs 9.4%).

Two level IV studies reported on 10-year outcomes data for TEA in the setting of distal humerus fractures.[46,47] Pooled analysis shows 47% patient survival at 10 years' follow-up, with a mean age at time of surgery of 71.

One level III study retrospectively compared the outcome of acute TEA for distal humerus fractures versus delayed TEA following failed ORIF or conservative treatment (n = 32 patients).[43] The authors reported a high rate of good/excellent functional outcomes (82%) with no significant differences between the two treatment groups. However, the results showed trends toward increased rates of infection, nerve injury, and implant failure in the delayed treatment group, and the study was likely underpowered to detect clinically significant differences in the rates of these complications between groups.

Resolution of clinical scenario

In the case of an elderly patient with a comminuted intra-articular distal humerus fracture, it is the authors' approach to evaluate the fracture with a computed tomography (CT) scan. This allows for the evaluation of the degree of comminution, presence of coronal shear components, and assessment of the joint for pre-existing osteoarthritis. In highly comminuted fractures, the evidence supports the use of TEA (Figure 82.1). This recommendation is strengthened in the presence of pre-existing osteoarthritis of the elbow. In this setting, elbow stiffness related to arthritis increases the stress through the fractured metaphysis, which may predispose to early hardware failure or nonunion.

Summary of answers

- The use of a triceps-splitting approach may lead to equivalent functional outcomes and a decreased need for re-operation when compared to an olecranon osteotomy (overall quality: low).

- A triceps-splitting approach is preferred over olecranon osteotomy for the treatment of open fractures of the distal humerus (overall quality: moderate).
- All distal humerus fractures involving both columns should be treated with dual plate fixation in either a perpendicular or parallel configuration (overall quality: moderate).
- In elderly patients (>65 years) with displaced, intra-articular distal humerus fractures not amenable to stable internal fixation acute TEA is preferred (overall quality: moderate).

Elbow Dislocations

Lisa C. Howard MD[1] and Jason W. Pollock MD[2]
[1]Department of Orthopaedics, University of British Columbia, Vancouver, BC, Canada
[2]University of Ottawa, Ottawa, ON, Canada

Clinical scenario

- You see two patients in the Emergency Department after sustaining complex elbow fractures after falling while downhill biking.
- The first, a 35-year-old male, has an anteromedial facet (AMF) coronoid fracture (O'Driscoll subtype I) and a lateral collateral ligament (LCL) injury that you are not sure requires surgical management.
- The second, a 40-year-old male, has a terrible triad injury with a type I coronoid and severely comminuted radial head fracture. You are not sure if the coronoid requires fixation and want to avoid radial head replacement, if possible.

Top three questions

1. In patients with AMF fractures, does operative management result in improved outcomes compared to nonoperative management?
2. In patients with terrible triad injuries, does surgical management of the coronoid improve clinical outcomes compared to nonoperative management?

3. In patients with terrible triad injuries, does radial head arthroplasty lead to improved clinical outcomes compared to internal fixation?

Question 1: In patients with AMF fractures, does operative management result in improved outcomes compared to nonoperative management?

Rationale

The AMF is an important structure to varus posteromedial elbow stability. Understanding the evidence-based indications for operative and nonoperative treatment is important in properly managing these fractures.

Clinical comment

AMF fractures can be difficult injuries to diagnose and treat. They are often associated with ligamentous injuries that also often require surgical management. If not appropriately treated, they may be associated with poor outcomes, including ulnohumeral arthritis, with limited options for future management. Nonoperative management, however, can be considered in patients that meet specific injury criteria.[1,2] Understanding the implications of operative and nonoperative treatment is essential. O'Driscoll classification separates coronoid fractures into three types with subdivisions. Type I fractures involve the tip, type II fractures involve the AMF while type III involve the base. Type II fractures are further subdivided into those involving the rim, the rim and AMF, and those involving the sublime tubercle.[3]

Available literature and quality of the evidence

No level I or II evidence was found, and only one study, a retrospective cohort classified as level III,[4] while the remainder of the literature are case series with low patient numbers or biomechanical studies.[1,5–8]

Findings

Doornberg et al. followed 18 patients with AMF fractures (O'Driscoll subtype I in one case, subtype II in three cases and subtype III in 13 cases).[4] Fifteen of the cases had associated LCL injuries with two medial collateral ligament (MCL) injuries. Nine patients were treated with coronoid fixation and LCL reconstruction. Functional results were good or excellent in all but one patient with an average Bryan–Morrey elbow score of 97 and range of movement (ROM) of 131° (range 108–145°) and without instability. The other nine patients were characterized with either non- or tenuous fixation of the AMF. Average ROM of this group was 99° (30–140°) with an average score of 83. Seven of these patients had persistent instability in which six developed arthrosis. The authors concluded that all AMF fractures should be addressed surgically, even when small.

Pollock et al. biomechanically tested the stability of 10 cadaver elbows under varus and valgus gravitational loading with simulated type II (all subtypes) AMF fractures.[8] They found isolated LCL repair did stabilize the elbow with subtype I factures 2.5 mm or smaller. However, in the presence of 5 mm subtype I fractures, LCL repair alone did not achieve stability in the varus position (6.2° ± 4.5° internal rotation compared to 3.3° ± 3.1° normal elbow; $p < 0.05$). The authors recommended fixation of AMF fractures larger than 2.5 mm and that LCL repair alone cannot restore normal kinematics in the majority of cases.

Park et al. followed 11 patients with isolated AMF fractures consisting of subtypes I–III for an average of 31 months all of which were associated with an LCL injury, while six cases (mostly subtype I and II) also had a concurrent MCL injury.[7] Two patients with subtype I were treated with isolated LCL repair while the nine patients with subtypes II and III were treated with buttress plating. They documented a mean ROM of 128° and an average Mayo Elbow Performance Score (MEPS) of 89. Outcomes were classified as good or excellent in 10 patients. Rhyou et al. followed 18 patients with O'Driscoll type II AMF fractures (all subtypes) with or without LCL repair for a mean of 37 months.[6] Both cases of subtype I had fragments <5 mm and were treated with isolated LCL repair. Five of the subtype II fractures had open reduction and internal fixation (ORIF) and LCL repair, while six had only ORIF as they were deemed stable to varus and pronation testing after fixation. Two cases had fragments <5 mm and had isolated LCL repairs. Both subtype III fractures were managed with ORIF, while one also had LCL repair. The mean MEPS and Disabilities of the Arm, Shoulder, and Hand (DASH) scores were 98 and 5.6, respectively. There was no statistically significant difference between the outcomes scores, subtype, fixation method, or whether the LCL was repaired. Authors concluded that fragments <5 mm could be treated with isolated LCL repair. They also suggested that even fractures >5 mm with fixation stable to varus testing did not require LCL reconstruction.

Chan et al. specifically looked at fracture patterns that could be treated nonoperatively.[1] Nonoperative treatment was considered if there was concentric joint location, no block to mechanical rotation, a small coronoid fracture and a stable ROM arc to 30° of extension. Nine were classified as subtype II, while one was subtype III with an average size and displacement of 5 and 3 mm, respectively. Early

ROM was performed and all outcomes were reported as good to excellent. There was no significant difference between ROM and strength to the contralateral side at a mean follow-up of 50 months (range 12–81 months). The authors did caution, however, that the nonoperative approach required careful supervision and also cautioned the reliability of proper varus testing in acute elbow injuries.

Resolution of clinical scenario

- Small AMF fractures (subtype I), such as the patient in the clinical scenario, can likely be treated with isolated LCL repair provided the elbow is stable (overall quality: low).
- Elbow stability is of primary importance in AMF fractures and all stabilizing structures (LCL and MCL) should be addressed surgically, if necessary (overall quality: low).

Question 2: In patients with terrible triad injuries, does surgical management of the coronoid improve clinical outcomes compared to nonoperative management?

Rationale

The terrible triad (TT) injury of the elbow consists of a posterolateral ulnohumeral dislocation with fractures of the radial head, coronoid process and LCL. Coronoid fractures that occur in TT injuries tend to be transverse in nature and are often classified as O'Driscoll type I, or type I or II by the Regan and Morrey classification.[9] Fixation of the

coronoid process in TT injury of the elbow is controversial in the literature with early nonoperative studies showing poor outcomes.[10]

Clinical comment

Coronoid fractures accompany TT injuries, and it is important to understand when surgical management is indicated in these injuries as resultant instability contributes to poor outcomes.

Available literature and quality of the evidence

No level I or II evidence was found. One study, a retrospective cohort, is classified as a level III,[11] while the remainder of the literature is case series and cadaveric studies.[2,12–15]

Findings

Several studies have involved coronoid fixation in all cases and generally report good to excellent outcomes in 77–83% of cases with a mean arc of motion reported as 112–19°.[11,13,16] Arthrosis was reported as 28–67% while heterotopic ossification was reported as 8–14%. Recurrent instability was reported as 4–20%.[11,13,16]

Furthermore, Garrigues et al. reported a statistically improved reduction in instability using the suture lasso technique compared to suture anchors or screw fixation.[11] Elbows treated with suture lasso had instability via the hanging arm test in 4%, while suture anchors and screw fixation had instability in 57 and 20%, respectively ($p < 0.05$), which persisted at 18 months.

Papatheodorou et al. looked at TT injuries with type I and II coronoid fractures.[2] After radial head and LCL fixation, intraoperative fluoroscopy was utilized to assess stability,

and none of the coronoid fractures was fixed. The mean Broberg and Morrey score and DASH scores were 90 (range 70–100) and 14 (range 0–38), respectively, indicating good outcomes and no recurrent instability. One patient developed arthritic changes, while one had clinically insignificant heterotopic ossification.[2] The authors suggest that type I and II coronoid fractures may not require fixation provided the LCL, MCL, and radial head are all managed properly. This is in keeping with a cadaver study which showed that type I coronoid fracture suture repair had no effect on elbow biomechanics when the MCL, LCL, and radial head were appropriately managed.[12] Zhang et al. studied 13 TT patients with type I–III coronoid fractures. All coronoids were fixed except type I fractures, which were not attached to the anterior soft tissue complex. Eighty percent of patients had good to excellent outcomes at an average of 28 months. Recurrent instability was noted in two patients while heterotopic ossification and a synostosis were noted in 1 patient.[14]

Chan et al. studied nonoperative treated TT injuries in 12 elbows with the following criteria: the radial head did not cause a block to forearm rotation, the elbow was concentrically reduced, a stable ROM to 30° of extension and type I and II coronoid fractures. The mean MEPS outcomes scores were good to excellent in 10 elbows with only one recurrent instability while the mean DASH score was 7. Four patients developed arthritic changes, while one developed heterotopic ossification.[15] Another study reported a DASH and MEPS scores of 4.76 and 95, respectively, in 10 patients followed nonoperatively involving type I and II coronoids. Post-traumatic arthritis was noted in 30% of patients.[17] Both of these studies emphasized the importance of very careful surveillance for failure, which may not be available in every center.

Resolution of clinical scenario

- Some TT injuries can be managed nonoperatively if specific injury criteria are confirmed.
- Patients with type I coronoid fractures in the setting of a TT do not require coronoid fixation in the setting of a stable elbow.
- Although some studies suggest type II coronoid fractures do not require fixation, most authors advocate for surgical management as it is likely associated with improved outcomes.

Question 3: In patients with terrible triad injuries, does radial head arthroplasty lead to improved clinical outcomes compared to internal fixation?

Rationale

Radial head fractures are part of the TT elbow injury and often have multiple fragments. Fixation and arthroplasty are common treatment methods, and some debate exists on the optimal treatment.

Clinical comment

Arthroplasty and fixation are both methods utilized in the treatment of radial head fractures associated with TT injuries. Arthroplasty has become more common; however, some centers still prefer an attempt at ORIF prior to arthroplasty. Understanding the complications and technical considerations of these treatment methods is important to optimize outcomes.

Available literature and quality of the evidence

There are two level I randomized controlled trials (RCTs) as well as a meta-analysis.[18–20]

Findings

Chen et al. performed an RCT comparing ORIF versus arthroplasty in Mason III radial head fractures in the setting of complex elbow dislocations.[18] They enrolled 45 cases with a two-year follow-up. Either plates and/or screws or a monopolar implant were utilized. The overall satisfaction for the arthroplasty and ORIF groups were 91 and 65.2%, respectively ($p < 0.01$). There was a significantly higher complication rate in the ORIF group (47.9%) compared to the arthroplasty group (13.6%). Common complications in the ORIF group included stiffness, nonunion, hardware failure, and heterotopic ossification. The complication in the arthroplasty group included stiffness. The authors concluded that Mason III radial head fractures in the setting of a complex elbow dislocation should be managed with arthroplasty. Interestingly, they did not report any radiocapitellar arthrosis at two years.

Yan et al. also conducted an RCT involving Mason III fractures in the setting of a TT injury. Thirty-nine patients were randomized to ORIF or arthroplasty and followed for three years. They reported significantly longer surgical times for ORIF ($p < 0.001$). The MEPS was significantly improved in the arthroplasty group (85.8 vs 77.9; $p < 0.009$). The flexion–extension arc was also improved in the arthroplasty group (101 vs 92°; $p = 0.01$) as was the pronation–supination arc (114° vs 103°; $p = 0.04$). Furthermore, the overall complication rate for arthroplasty was lower ($p = 0.04$). Two patients in the arthroplasty group required revision, one for stiffness due to

overstuffing and one for heterotopic ossification. Four patients in the ORIF group had stiffness that required re-operation. In addition, two patients developed heterotopic ossification that required revision, while one had failed hardware that also required revision. As with the other study, no radiocapitellar erosion was seen.

A meta-analysis which included the two randomized trials as well as six other nonrandomized studies compared ORIF versus arthroplasty.[20] There were 138 fractures managed with ORIF and 181 with arthroplasty. The satisfaction rates for radial head arthroplasty (RHA) and ORIF were 94.6 and 72.9%, respectively (risk ratio = 0.72; 95% confidence interval [CI]: 0.44–1.18; p = 0.20), with high heterogeneity (I^2 = 89%). The MEPS (MD −7.08; 95% CI: -12.93 to −1.24; p = 0.02) and elbow score (−15.53, 95% CI: −23.16 to −7.91; p <0.001) showed statistically significant improvement with arthroplasty with low (I^2 = 0%) and high (I^2 = 93%) heterogeneity, respectively. The revision rate for arthroplasty and ORIF was 16.7 and 20.1%, respectively, and did not reach statistical significance. Common complications associated with ORIF was failure of fixation (15.5%), nonunion, and resorption (18.5%). Complications associated with arthroplasty were overstuffing and subluxation. There were no significant differences between infection, heterotopic ossification, stiffness, or nerve injury. The methodology for the studies was considered moderate to low and thus caution should be employed when generalizing these results.

Resolution of clinical scenario

- Level I literature suggests that unstable and comminuted radial head fractures associated with complex elbow dislocations (terrible triad injuries),

such as the one in the clinical scenario, are better managed with arthroplasty.

- Technical considerations for proper arthroplasty are critical for optimal outcome.

Summary of answers

- O'Driscoll type II/III AMF fractures are better treated with ORIF and concurrent LCL and MCL reconstruction, if necessary. Elbow stability in this setting is critical.
- Type I coronoid fractures in the setting of a terrible triad injury often do not require fixation. There is some evidence that type II and III fractures should be surgically addressed.
- Level I evidence shows that in the setting of a TT injury, radial head arthroplasty is associated with improved outcomes.

Radial Head Fractures

James D. Spearman Jr MD MBA, David Ring MD PhD and Lee M. Reichel MD
Department of Surgery and Perioperative Care, Dell Medical School – The University of Texas at Austin, Austin, TX

Clinical scenario

- A 36-year-old woman arrives at the Emergency Department with elbow pain after a fall onto her outstretched left hand while skating.
- On examination, her range of elbow motion is limited due to pain, and she has tenderness over the radial head.

Top three questions

1. In patients with radial head fractures, does aspiration/injection aid in the initial management compared to radiographs alone?
2. In patients with displaced isolated partial radial head fractures, does operative treatment result in better outcomes compared to nonoperative treatment?
3. In patients with unstable or displaced fractures of the radial head that are part of a complex injury, does open reduction internal fixation (ORIF) have better outcomes compared with excision with or without prosthetic replacement?

Question 1: In patients with radial head fractures, does aspiration/injection aid in the initial management compared to radiographs alone?

Rationale

Aspiration of the hemarthrosis and injection of local anesthesia might help determine if some radial head fractures are hindering forearm rotation, and thus change the treatment strategy to follow. The role of aspiration for pain relief alone is debatable.

Clinical comment

The patient's radiographs reveal a minimally displaced partial articular radial head fracture. Forearm motion is limited by pain. You would like to know if the patient has any blockage while moving the forearm from pronation to supination.

Available literature and quality of the evidence

- Level I: 2 systematic reviews and 1 randomized trials.
- Level III: 1 retrospective cohort study.

Findings

In one study, 80 patients with minimally displaced partial articular radial head fractures treated nonoperatively were randomized to aspiration and injection of bupivacaine with initiation of exercises or exercises alone.[1] Aspiration was associated with improved initial comfort and motion, but there was no difference in final motion.

A randomized trial of 40 patients with minimally displaced radial head and neck fractures treated nonoperatively to aspiration alone versus aspiration with intra-articular injection of bupivacaine. The authors found there was instant relief with aspiration with or without bupivacaine ($p < 0.001$). In both groups on average the Visual Analog Score (VAS) dropped from a VAS of 8 (IQR 7 to 8) in Group A (aspiration only) and 8 (IQR 7 to 9) in Group B (aspiration with bupivacaine injection) to an average of 1.5 and 1, respectively, following intervention. But at all time points thereafter there was no difference in pain with both groups having a VAS of 0 (no pain) at six weeks. ROM (flexion, extension, supination, and pronation) additionally had significant improvement one day after intervention in both groups but had very similar results at six weeks.[2]

A meta-analysis concluded that the quality of evidence for aspiration of a traumatic elbow effusion was low and insufficient to recommend it as a routine procedure.[3]

Resolution of clinical scenario

- Aspiration of the hematoma of the elbow joint might aid in pain relief in the acute setting (overall quality: moderate).
- There is insufficient evidence to determine whether joint aspiration and/or injection can improve final elbow motion.

Question 2: In patients with displaced isolated partial radial head fractures, does operative treatment result in better outcomes compared to nonoperative treatment?

Rationale

In the acute setting, patients often wonder what, if any, limitations they will have in the future due to their injury, and how this may relate to treatment options. Nonoperative treatment of displaced partial articular fractures of the radial head without elbow dislocation or associated fractures is associated with good recovery. Operative treatment is straightforward; has similar outcomes; and is associated with some operative risks, discomforts, and inconveniences.

Clinical comment

The patient radiographs reveal an isolated, displaced (2 mm step in the articular surface) partial articular radial head fracture. What evidence exists to inform the decision between operative and nonoperative treatment?

Available literature and quality of the evidence

- Level II: 1 systematic review.
- Level IV: 1 systematic review and 2 retrospective case series.

Findings

A systematic review of 28 studies identified 14 studies involving 519 patients treated operatively and 7 studies involving 430 patients treated nonoperatively. Fifty-two percent of patients treated nonoperatively and 88% of patients treated operatively had satisfactory Broberg and Morrey ratings (reported as good to excellent with scores ranging from 80 to 100). Residual pain was reported in 42% of patients treated nonoperatively and 32% of the patients treated operatively. Authors noted high

heterogeneity in the review and refrained from pooling all the results of the study.[4]

In a second review limited to nine retrospective case series with an adequate description of the treatment method and a well-defined rating system (Broberg and Morrey, Mayo Elbow Performance, or Riseborough and Radin scores), 142 patients were treated nonoperatively and 82 were treated with open reduction and internal fixation (ORIF). Treatment was rated successful in 80% of patients treated nonoperatively and 93% treated operatively with ORIF. Complications were not reported in any of the studies.[5]

In 2005, Herbertsson and colleagues examined 32 patients treated nonoperatively for stable, isolated, minimally displaced fractures of the radial head or neck an average 21 years after injury.[6] Twenty-nine of the patients had no symptoms and three had occasional elbow pain.

In 2006, the same group published an average 19-year evaluation of 49 patients with isolated, displaced, partial articular fractures of the radial head (2–5 mm displacement) treated nonoperatively.[7] At the final evaluation, 40 patients had no symptoms, 8 had occasional elbow pain, and 1 had daily pain. On average, there was a slight decrease in flexion (mean/standard deviation [SD]: 138 deg ± 8 compared with 140 deg ± 7), and extension (mean/SD: −4 ± 8 compared with −1 ± 6), compared with the contralateral side ($p < 0.001$).

In 2012, a cohort study of 100 patients described the long-term results of isolated, stable radial head fractures both nondisplaced (Mason 1) and displaced (Mason 2) treated nonoperatively. Ninety-two patients were satisfied with the result. Only 1 of 43 patients with a Mason 2 fracture (average displacement 2.5 mm, range 2–5 mm) had surgery, because the fracture was thought to be restricting forearm rotation. Stiffness (14%) and residual pain (24%) were the

most common problems an average of 10 years after injury. Factors independently associated with greater symptoms and limitations (higher Disabilities of the Arm, Shoulder, and Hand [DASH] score) included older age, comorbidities, greater socioeconomic deprivation, greater fracture displacement, and a legal dispute.[8]

Resolution of clinical scenario

- There are no randomized trials comparing operative and nonoperative management of displaced partial articular radial head fractures.
- In the long-term, patients with non- or minimally displaced fractures of the radial head and neck can expect minimal impairment or discomfort with slight radiographic arthrosis (overall quality: low).
- Patients with displaced partial articular fractures that are not part of a more complex injury can expect some limitation of range of motion and some pain whether treated operatively or nonoperatively. (overall quality: low).
- The relative advantages and disadvantages of surgery for isolated, stable, partial articular fractures displaced more than 2 mm are uncertain.

Question 3: In patients with unstable or displaced fractures of the radial head that are part of a complex injury, does open reduction internal fixation (ORIF) have better outcomes compared with excision with or without prosthetic replacement?

Rationale

Treatment of displaced and unstable radial head fractures is debated. Fractures that were once treated with excision are now often treated with ORIF or prosthetic replacement, particularly in a complex injury that includes an associated coronoid fracture.

Clinical comment

The patient had a concomitant elbow dislocation that was reduced. Her radiographs reveal a displaced, unstable articular fracture of the radial head. You plan to treat her operatively.

Available literature and quality of the evidence

- Level I: 1 meta-analysis.
- Level II: 1 randomized controlled trial (RCT).
- Level III: 4 retrospective comparative studies.

Findings

Our review of published evidence identified one small RCT evaluating ORIF versus prosthetic replacement of the radial head for displaced, unstable radial head fractures.[9]

Fourteen patients were randomized to radial head replacement and eight patients received ORIF. Patients were followed for an average of 16 and 14 months, respectively. Using the Broberg and Morrey score, the authors found good to excellent results in 12 out of 14 (93%) patients treated with radial head replacement, compared to 1 of 8 (12.5%) patients treated with ORIF. Despite the small numbers, the magnitude of this difference was enough to achieve statistical significance ($p = 0.0004$).

A study using claims data identified 58 000 radial head fractures: 2981 treated operatively including 57% treated with ORIF, 38% with radial head arthroplasty (RHA), and 5% with radial head excision. Radial head fractures initially treated with ORIF were more likely to have a second surgery within two years compared to those treated initially with RHA (12.7% at one year and 14.4% at two years compared to 8.6 and 10.7% for RHA ($p < 0.05$). The study also suggests that radial head arthroplasty is utilized more frequently as the complexity of injury increases and has lower rates of revision surgery.[10]

A meta-analysis of nine studies with 365 patients with displaced fractures of the entire radial head (169 treated with radial head replacement and 196 treated with ORIF) found that patients who received radial head replacement had a significantly higher percentage of good to excellent categorical results (odds ratio [OR] = 3.48; 95% confidence interval [CI]: 1.98–6.11; $p < 0.0001$; I^2 4%; $p = 0.40$ better Broberg and Morrey elbow scores (weighted mean difference [WMD] = 9.79; 95% CI: 4.22–15.36; $p = 0.0006$; I^2 94%; $p < 0.0001$), and significantly fewer postoperative complications (OR = 0.33; 95% CI: 0.16–0.69; $p = 0.003$; I^2 0%; $p = 0.64$).[11]

A cohort study of operative management of displaced, unstable radial head fractures in young, active, high-demand patients compared 67 treated with ORIF and 10 treated with RHA. Injury complexity had a negative impact on motion, complications, and reoperation, but RHA versus ORIF did not. RHA was associated with more heterotopic ossification (30 vs 14%), implant loosening (20%), and neurologic injury (10%).[12]

Resolution of clinical scenario

- Limited retrospective and prospective data also support prosthetic replacement over ORIF for complex, displaced fractures of the entire head of the radial head (overall quality: moderate).

Summary of answers

- Aspiration of the hematoma of the elbow joint might aid in pain relief in the acute setting, but there is insufficient evidence to determine whether joint aspiration and/or injection can improve final elbow motion.
- Limited retrospective and prospective data also support prosthetic replacement over ORIF for complex, displaced fractures of the entire head of the radius (overall quality: moderate).
- In the long-term, patients with a minimally displaced fracture of the radial head or neck can expect minimal impairment (overall quality: low).
- Patients with a displaced, isolated, stable partial articular fracture can expect some limitation of range of motion and some pain whether treated operatively or nonoperatively (overall quality: low).

85
Olecranon Fractures

Michael C. Daly MD[1] and Jesse B. Jupiter MD[2]
[1]Massachusetts General Hospital, Boston, MA, USA
[2]Harvard Medical School, Boston, Massachusetts General Hospital, Boston, MA, USA

Clinical scenarios

Cases 1 and 2

- A 76-year-old female presents to the Emergency Department with left elbow pain after a fall from standing height after tripping on the carpet in her nursing home.
- On physical examination, she is tender about the elbow with a palpable defect over the proximal ulna.
- She has no active elbow extension.
- Figures 85.1 and 85.2 show what the radiographs reveal.

Figure 85.1 Case 1.

Case 3

- A 43-year-old male motorcyclist presents to the Emergency Department with right elbow pain after a collision.
- On physical examination, he is swollen and tender about the elbow with a palpable defect over the

proximal ulna.

- He has no active elbow extension.
- Figure 85.3 shows the lateral radiograph (case courtesy of Chaitanya Mudgal, MD).

Top three questions

1. In patients with displaced olecranon fractures treated surgically, how do the outcomes compare between those treated with internal fixation vs fragment excision and triceps advancement?
2. In low-demand elderly patients with displaced olecranon fractures, does surgery result in improved outcomes compared with nonsurgical treatment?
3. In patients with simple or minimally comminuted, stable, displaced olecranon fractures treated with surgery, how does tension-band wiring (TBW) compare with dorsal plating in terms of outcomes, complications, and costs?

Question 1: In patients with displaced olecranon fractures treated surgically, how do the outcomes compare between those treated with internal fixation vs fragment excision and triceps advancement?

Rationale

As internal fixation implants and surgical techniques have been refined, our ability to achieve stable fixation constructs in comminuted fracture patterns has improved.

As a result, more fractures are being treated with open reduction and internal fixation, including olecranon fractures that may have previously been treated with fragment excision.

Figure 85.2 Case 2.

Figure 85.3 Case 3.

Clinical comment

Fragment excision with triceps advancement is usually now reserved for elderly patients with low functional demands and olecranon fractures with small proximal fragments and/or extensive comminution not amenable to internal fixation. Otherwise, internal fixation is typically the treatment of choice for acute displaced olecranon fractures.

Available literature and quality of the evidence

- Level III: 2 retrospective studies comparing excision versus internal fixation.[1,2]
- Level IV: 4 retrospective case series.[3–6]

Findings

Since the 1940s, fragment excision with triceps advancement has been considered in the management of select olecranon fractures, especially in low-demand elderly patients and injuries with extensive comminution not amenable to internal fixation.[1–6]

As the olecranon process contributes to the osseous constraint and stability of the ulnohumeral articulation,[7] partial excision of the olecranon raises concern for creating iatrogenic elbow instability. There are conflicting reports in the literature as to how much of the olecranon may be excised. Clinical studies suggest that up to 50%[2] (or perhaps as much as 60%,[8] 70%,[6] or 80%[4]) of the semilunar notch of the olecranon may be safely excised without causing clinically relevant instability of the elbow, assuming an intact coronoid, radial head, and collateral ligaments.[2,4,6,8] Cadaver studies of sequential olecranon resection have demonstrated increasing elbow angular and rotational laxity with increasing olecranon resection.[9,10] While the landmark study by An and Morrey suggests up to 50% of the olecranon may be removed without adversely affecting ulnohumeral joint stability,[7,9] a subsequent biomechanical study by Bell et al. suggested up to 75% of the olecranon articular surface can probably be removed, provided there are no concurrent injuries to the coronoid, radial head, or collateral ligaments.[10] In the same study, however, Bell et al. also demonstrated that elbow instability became evident following even small amounts of olecranon resection. The authors therefore cautioned against

olecranon resection if internal fixation is possible or alternative reconstructive options exist.[10]

Rettig et al. reported comparable range of motion (ROM) among four patients treated with excision and 34 patients treated with internal fixation, and a higher rate of complications (15% reoperation rate) with internal fixation. Despite these findings, the authors recommended excision only when internal fixation is not possible.[1]

Gartsman et al. compared primary excision (n = 53) with internal fixation (n = 54) for olecranon fractures.[2] Excision was used for all severely comminuted and small avulsion fractures; patients with two-part fractures were equally distributed between the excision and internal fixation groups. Twenty-nine patients were reviewed at minimum two-year follow-up (range 2–15 years); of the 15 patients who underwent primary excision, nine had 33–50% of the articular surface excised, and the six had ≥50% of the articular surface excised. Comparing patients treated with primary excision versus internal fixation at two years' minimum follow-up, there was no difference in pain, instability, ROM, or elbow extension strength.[2]

Resolution of clinical scenario

In Case 2, a low-demand elderly patient presented with a stable displaced olecranon fracture with small proximal fragments and extensive comminution (Figure 85.2). Key takeaways:

- For fractures involving up to 50% (and possibly up to 75%) of the articular surface, fragment excision and triceps advancement can be considered with the expectation of similar postoperative elbow strength compared to fracture fixation.

- Associated injuries to the primary or secondary stabilizers of the elbow may lead to instability with fragment excision; therefore, this technique may be best reserved for isolated, stable, severely comminuted fractures not amenable to fixation.

Question 2: In low-demand elderly patients with displaced olecranon fractures, does surgery result in improved outcomes compared with nonsurgical treatment?

Rationale

The literature regarding the management of displaced olecranon fractures is replete with studies debating the virtues of various surgical fixation constructs. Yet the more fundamental question has remained largely unanswered: which patients do better with surgery as compared with no surgery?

Clinical comment

Although displaced olecranon fractures are typically treated surgically, a recent prospective randomized trial comparing operative with no-operative care suggested comparable outcomes and fewer complications with nonsurgical management in low-demand elderly patients.[11]

Available literature and quality of the evidence

- Level II: 1 underpowered prospective randomized trial.[11]
- Level IV: 5 retrospective case series.[12–16]

Findings

Duckworth and colleagues published a prospective randomized trial comparing surgical and nonsurgical management for acute, closed, stable displaced (MEPS type 2A or 2B)[16] olecranon fractures in adults ≥75 years of age.[11] Nineteen patients were randomized to operative (n = 11) or nonoperative (n = 8) treatment. Patients were surgically treated with TBW (n = 9) or precontoured nonlocking plate (n = 2) fixation depending on fracture configuration, with plates being used for the more comminuted fractures. The decision on surgical technique was made by the treating surgeon.

Though 25 patients were needed in each arm according to a priori power analysis, the study was stopped prematurely due to the high rate of complications in the operative arm which caused loss of equipoise among surgeons involved in the study. With only six in the nonoperative group (two patients died from unrelated causes before they could be analyzed at one year postop) and only 11 in the operative group included in the final analysis, the study is underpowered: conclusions regarding the noninferiority of nonoperative management cannot be drawn based on this trial.

Outcomes

Although the study was underpowered, analysis of available data showed no difference ($p \geq 0.05$) in Disabilities of the Arm, Shoulder, and Hand (DASH) score at one year, or at any time point. Mean DASH at one year was 23 (range 0–59.6) in the nonoperative group and 22 (range 2.5 – 57.8) in the operative group ($p = 0.763$). At one year, mean elbow flexion arc was better in the operative group (129° [range 105–145°]) compared with the nonoperative group (106° [range 75–140°]) ($p = 0.049$). Otherwise, there was

no significant difference between groups for pain, forearm ROM, or surgeon-reported outcomes (Broberg and Morrey score,[17,18] Mayo Elbow Performance Score [MEPS][19] at any assessment point after injury (all p ≥0.05).

Complications

There were 13 complications in 10 patients, with significantly more complications in the operative group (9 of 11 patients = 81.4%) compared with the nonoperative group (one of seven patients = 14.3%) (p = 0.013). The one patient in the nonoperative group had an associated radial head subluxation (MEPS type III), which was initially missed and then ultimately treated with ORIF; this was complicated by failure of fixation due to infection requiring additional surgical irrigation and debridement, sinus tract excision, removal of hardware, and a prolonged course of antibiotics. The infection resolved and this patient developed a fibrous nonunion with a pain-free functional ROM at one year. Six of 11 patients (54%) in the operative group had loss of reduction of the fracture (all TBW). Three of 11 patients (27.3%) required removal of prominent metalwork (two plates, one TBW). One additional patient (plate) developed infection requiring excision of a chronic sinus.

Resolution of clinical scenario

In Case 1, a low-demand elderly patient presents with a stable displaced olecranon fracture (Figure 85.1). Key takeaways:

- An underpowered prospective randomized trial of low-demand elderly patients with stable displaced olecranon fractures suggests nonsurgical management results in comparable outcomes and fewer complications as compared with surgery

(predominantly TBW fixation).[11] These results, in combination with the results from retrospective case series,[12–16] suggest nonsurgical management of stable displaced olecranon fractures may be reasonable in older patients with lower functional demands.

Question 3: In patients with simple or minimally comminuted, stable, displaced olecranon fractures treated with surgery, how does tension-band wiring (TBW) compare with dorsal plating in terms of outcomes, complications, and costs?

Rationale

Although surgical fixation is often used for managing simple or minimally comminuted stable displaced olecranon fractures in young active patients, the choice of surgical technique remains controversial and there is no clear consensus.

Clinical comment

While stable displaced olecranon fractures in young active patients are often treated with TBW fixation, a recent prospective randomized trial comparing nonlocking plate with TBW fixation suggests comparable outcomes and costs and fewer complications with nonlocked plating.[20]

Available literature and quality of the evidence

- Level I: 1 prospective randomized trial.[20]

- Level II: 1 prospective randomized trial with methodological limitations.[21]

Findings

Duckworth and colleagues recently published a prospective randomized trial comparing nonlocking plate versus TBW fixation for acute, closed, stable displaced (MEPS type 2A)[16] olecranon fractures in adults ≥16 and <75 years of age.[20] Sixty-seven patients were randomized to treatment with either a pre-contoured nonlocking dorsal proximal ulnar plate (n = 33) or TBW (n = 34) fixation. The TBW group was significantly younger (43 ± 16 vs 52 ± 17 years, p = 0.028) with a trend toward fewer comorbidities (p = 0.100); otherwise baseline characteristics were comparable. Data were analyzed according to intention-to-treat principles and crossover was minimal. Based on *a priori* power analysis, the study was adequately powered to detect a clinically relevant mean difference of 10 points in DASH score 1 year after surgery.[22]

Outcomes

There was no significant difference in DASH at any time point. Mean DASH at 1 year was 12.8 ± 20 (range 0–79; 95% CI 5.3–20) in the TBW group and 8.5 ± 10 (range 0–41; 95% CI 4.4–12.5) in the plate group (p = 0.315). There was no statistically significant difference between groups in ROM, Broberg and Morrey score, or MEPS at any time point after surgery (all p≥0.05). Though these comparisons technically did not achieve statistical significance, there was a trend toward better surgeon-reported outcomes in the plate group (Broberg and Morrery score 95 vs 89, p = 0.072; MEPS 96 vs 90, p = 0.05). In their multivariate analysis controlling for covariates, increasing ASA grade was the only independent predictor of worse outcome.

Complications

Among the 62 patients (32 plate; 30 TBW) assessed for complications, the authors reported 41 complications in 31 patients, yielding an overall complication rate of 50%. Complications were significantly more common with TBW—19 of 30 patients (63.6%) had a complication in the TBW group, compared with 12 of 32 patients (37.5%) in the plate group ($p = 0.042$). The rate of removal of symptomatic implants was more than twice as high with TBW (15 of 30 patients [50%]) compared to plating (7 of 32 patients [21.9%]) ($p = 0.021$). Loss of reduction also occurred more than twice as often with TBW (8 of 30 patients [26.7%]) as compared with plating (4 of 32 patients [12.5%]), though this did not reach statistical significance ($p = 0.206$). Four patients (12.5%) had infections (two superficial infections that responded to antibiotics; two deep infections that required revision surgery) in the nonlocked plate group; no infections occurred in TBW group ($p = 0.114$).

Costs

Costs were analyzed for 62 patients taking into account number of days in hospital as well as the costs of inpatient and outpatient treatment, including the costs associated with complications (e.g., additional trips to the operating room, antibiotics, etc.). Despite the higher initial cost of the nonlocking plate and screws ($836.72) compared with the cost of the tension band wire ($30.28), the overall median cost per patient was higher in the TBW group ($8374 [range $4471–$42183, IQR $4471–$8538]) compared to the plate group ($7812 [range $5249–$34815, IQR $5273–$10310]), though this did not reach statistical significance ($p = 0.131$).[20]

In contrast, Amini et al retrospectively compared locking plate (n = 10) and TBW (n = 10) fixation for simple isolated transverse olecranon fractures and found significantly higher overall operative costs with locked plating ($14333.46 vs $6598.36, p<0.001), despite a higher rate of hardware removal in the TBW group (40% vs 10%).[23] The difference in cost analysis between the two studies may be at least partly explained by the fact that Amini et al did not consider other costs (e.g., length of inpatient stay, cost of outpatient follow-up) and the implants they used were locking plates which were much more expensive than the nonlocking plates used by Duckworth et al ($6688.52 vs $836.72).[21,23]

In 1992, Hume and Wiss published the only other prospective randomized trial comparing plate (n = 22) and TBW (n = 19) fixation for displaced olecranon fractures.[21] They included comminuted fractures and open fractures. Power analysis was not performed; patient-rated outcome measures were not utilized; costs were not analyzed. Similar to the results reported by Duckworth et al, Hume and Wiss found comparable ROM between groups at six months after surgery, with loss of reduction and symptomatic implant prominence significantly more common in the TBW group (both p <0.05).[20,21] Unlike the trial by Duckworth et al, Hume and Wiss found clearly superior surgeon-rated clinical results in the plate fixation group (86% good results with plate, vs 47% good results with TBW).[21] In contrast to these findings, the trial by Duckworth et al showed no significant difference in outcome between plate and TBW groups at 1 year, though there was a trend toward better outcomes in the plating group for patient- and surgeon-reported outcome measures.[21]

Resolution of clinical scenario

In Case 3, a young active patient presents with a stable displaced olecranon fracture with minimal comminution (MEPS 2A) (Figure 85.3). Key takeaways:

- In the only adequately powered prospective randomized trial of stable displaced olecranon fractures in young active patients (<75 years of age), there were no significant differences in outcomes between nonlocking plate and TBW groups at one year, though there was a trend toward better outcomes in the plating group for patient- and surgeon-reported outcome measures.[20] The authors also demonstrated nonlocking plate fixation had comparable costs and a significantly lower rate of complications as compared to TBW fixation.[20]
- In young active patients, both plate and TBW fixation result in functional elbow ROM; compared to plating, loss of reduction and symptomatic implants are more common with TBW fixation.[20,21]

Summary of answers

- For fractures involving up to 50% (and possibly up to 75%) of the articular surface, fragment excision and triceps advancement can be considered with the expectation of similar postoperative elbow strength compared to fracture fixation.
- Associated injuries to the primary or secondary stabilizers of the elbow may lead to instability with fragment excision; therefore, this technique may be best reserved for isolated, stable, severely comminuted fractures not amenable to fixation.
- For low-demand elderly patients (≥75 years of age) with stable displaced olecranon fractures (MEPS 2A or

2B): an underpowered prospective randomized trial suggests nonsurgical management results in comparable outcomes and fewer complications as compared with surgical fixation (predominantly TBW fixation).[11]

- For young active patients (<75 years of age) with stable displaced olecranon fractures (MEPS 2A): the only adequately powered prospective randomized trial showed no significant difference in outcomes between nonlocking plate and TBW groups at one year, though there was a trend toward better outcomes in the plating group for patient- and surgeon-reported outcome measures. The authors also demonstrated plate fixation had comparable costs and a significantly lower rate of complications as compared with TBW fixation.[20]
- In young active patients, both plate and TBW fixation result in functional elbow ROM; compared to plating, loss of reduction and symptomatic implants are more common with TBW fixation.[20,21]
- Placing Kirschner wire (K-wire) TBW fixation implants deep to triceps tendon and engaging K-wires into the anterior ulnar cortex distal to the coronoid may reduce symptomatic implants, implant removal, and fracture displacement.[24–26]

86
Forearm Fractures

Habeeb Khan CCPA[1] and Rudolf W. Poolman MD PhD[2]
[1]St. Joseph's Healthcare, Hamilton, ON, Canada
[2]Leiden University Medical Center, Amsterdam, The Netherlands

Clinical scenarios

Case 1

- Patient A, a 42-year-old male carpenter, fell from a ladder and landed on his dominant right forearm.
- He was taken to the local Emergency Department, where radiographs showed a displaced fracture of the distal radial shaft.
- Physical examination showed a step deformity in the distal third of the forearm. No neurological or vascular deficits were found.
- He was treated with an open reduction and internal fixation (ORIF).

Case 2

- Patient B, a 38-year-old male construction worker, was struck on the ulnar aspect of his left forearm by a falling metal rod at a construction site.
- He was taken to the local Emergency Department, where radiographs showed an isolated minimally displaced midulnar shaft fracture.
- On examination, he was neurovascularly intact.
- Treatment recommendation was immobilization with a short arm cast for six weeks.

Top four questions

1. In patients with radial shaft fractures/Galeazzi-type fracture-dislocations, does radiological radial shortening more accurately predict distal radioulnar joint (DRUJ) injury compared with radial shaft fracture location?
2. In patients with isolated ulnar fractures, does surgical treatment lead to better functional outcomes compared with nonsurgical treatment?
3. In patients with Galeazzi-type fractures, does surgical reconstruction or temporary transfixion of the DRUJ prevent decrease in range of motion (ROM) of the forearm compared to nonsurgical treatment?
4. In patients with forearm fractures treated with plate fixation, does plate removal after bony union lead to higher refracture/complication rates compared with patients who retain their hardware?

Question 1: In patients with radial shaft fractures/Galeazzi-type fracture-dislocations, does radiological radial shortening more accurately predict distal radioulnar joint (DRUJ) injury compared with radial shaft fracture location?

Rationale

One of the most common causes for residual wrist disability after distal radial fractures is DRUJ instability.[1] As they are not always obvious on radiographs, DRUJ injuries may be missed during the initial assessment and treatment of a radial fracture; potentially delaying a patient's return to full function. Thus, defining radiographic parameters to identify DRUJ involvement in radial shaft fractures would be beneficial to form an optimal treatment plan for the patient.

Clinical comment

In the rehabilitation period, patient A continued to experience pain in his right wrist, as well as weakness during pronosupination. He also complained of decreased grip strength. This was affecting his ability to continue his work as a carpenter. Detailed repeat examination revealed an unstable DRUJ.

Available literature and quality of the evidence

- Level III: 2 retrospective cohort studies.

Findings

Tsismenakis and Tornetta assessed the predictive value of various radiographic parameters of DRUJ injuries (Table 86.1).[2] These included: (i) >5 mm radius shortening on standard PA radiographs, (ii) radial fracture within 7.5 cm from the lunate facet, and (iii) ulnar styloid fracture. Sixty-six patients were assessed. Radiographs of 21 patients showed radial shortening >5 mm; six of these patients had DRUJ instability. Twenty-six of the radial fractures were within 7.5 cm of the lunate facet; five of these had DRUJ instability. Ulnar styloid fractures were seen in 13 patients; DRUJ instability was present in four of these patients. Thus, they concluded that radiographs alone are insufficient to diagnose DRUJ instability preoperatively. However, due to the high negative predictive value (NPV) of the parameters, it is unlikely for DRUJ instability to occur in patients with <5 mm shortening or fractures >7.5 cm from the lunar facet.

Additionally, Ding et al. assessed radial shaft fracture obliquity, in addition to the previously mentioned radiographic parameters (Table 86.1).[3] A total of 102 patients were assessed. Radiographs of 59 patients showed fracture obliquity >30°; 35 of these had DRUJ instability. Forty-four fractures were <7.5 cm from the midarticular surface of the radius; 25 of these were associated with DRUJ instability. Radial shortening of >5 mm was seen in 35 patients; 29 of these had DRUJ instability. Twenty-nine ulnar styloid fractures were seen; 19 were associated with DRUJ instability. They concluded that the most sensitive radiographic parameter to

predict DRUJ instability was radial shaft fracture obliquity >30°, while radial shortening <5 mm was the most specific parameter to exclude DRUJ instability.

Resolution of clinical scenario

- Due to the low sensitivity of radiographic parameters (fracture obliquity >30°, fracture distance >7.5 cm from lunate facet, radial shortening >5 mm, and ulnar styloid fracture) in predicting DRUJ instability, radiographs alone are insufficient to diagnose DRUJ injuries.
- Along with careful physical examination, the above-mentioned parameters may be helpful in ruling out DRUJ injuries.
- Fractures of the middle and proximal thirds of the radial shaft (>7.5 cm from lunate facet) are less likely to be associated with clinically significant DRUJ injuries.
- In both cases, given that the injuries are distal, DRUJ injury should be considered. All radiographic parameters should be considered and assessed, though given their poor diagnostic performance further imaging may be needed .

Question 2: In patients with isolated ulnar fractures, does surgical treatment lead to better functional outcomes compared with nonsurgical treatment?

Rationale

There is currently no consensus as to the best treatment plan for isolated ulnar shaft fractures, which may lead to complications such as nonunion, radioulnar synostosis, and decreased forearm ROM.[4]

Clinical comment

The recommended treatment plan for patient B was immobilization with a short arm cast for six weeks. However, the patient was interested in surgical treatment options as he believed he could return to work sooner, and have better stability and functional outcomes with a surgical fixation.

Table 86.1 Radial shaft fracture obliquity and radiographic parameters.

	Tsismenakis and Tornetta				Ding et al.			
	Sensitivity	**Specificity**	**PPV**	**NPV**	**Sensitivity**	**Specificity**	**PPV**	**NPV**
Fracture distance <7.5 cm	71%	64%	19%	95%	54.3%	66.1%	56.8%	63.8%
Radial shortening >5 mm	86%	69%	29%	97%	63.0%	89.3%	82.9%	74.6%
Ulna styloid fracture	57%	85%	31%	94%	41.3%	82.1%	65.5%	63.0%
Fracture obliquity >30°	—	—	—	—	76.1%	57.1%	59.3%	74.4%

NPV: negative predictive value; PPV: positive predictive value.

Available literature and quality of the evidence

- Level II: 1 randomized controlled trial (RCT).
- Level III: 1 retrospective case control study and 1 retrospective cohort study.

Findings

Hussain et al. randomized 30 patients with isolated ulnar shaft fractures to two groups; one group was treated nonoperatively (n = 16), and the second group surgically (n = 14).[5] The nonoperative group was treated by an above elbow cast for six weeks. Acceptable reduction was defined as <50% of displacement and <10° of angulation on anteroposterior and lateral x-rays. The surgical group was treated with ORIF with a low-contact dynamic compression plate (LC-DCP), with mobilization when pain decreased postoperatively. At the 12-month follow-up, they found no difference between the two groups with regards to VAS (Visual Analog Score) score, grip strength, DASH (Disabilities of Arm, Shoulder, and Hand) score, and elbow/wrist ROM. Mean time to union was 18 weeks in the cast group, and 13 weeks in the ORIF group. There was one nonunion in the cast group and two nonunions in the ORIF group. They thus concluded that ORIF of isolated ulnar shaft fractures can result in anatomical restoration of the ulna; however, this does not translate to improved functional outcomes in short-term follow-up.

Coulibaly et al. retrospectively reviewed 70 patients with isolated ulnar shaft fractures.[6] Thirty-three patients were treated nonoperatively with a long or short arm cast, splint, or brace for 4–6 weeks; 37 patients were treated surgically with various fixation techniques, depending on fracture pattern and surgeon preference. Recorded complications included eight delayed unions in the surgical group versus nine in the nonoperative group; two malunions in the surgical group versus 15 in the nonoperative group; two nonunions in the surgical group versus 12 in the nonoperative group; and one secondary displacement in the surgical group versus 10 in the nonoperative group. Mean time to healing was 116 days in the surgical

group versus 145 days in the nonoperative group. They thus concluded that nonoperative treatment of isolated ulnar shaft fractures is prone to more complications.

Szabo and Skinner retrospectively reviewed 46 patients with isolated ulnar shaft fractures.[7] Eighteen patients were treated with ORIF and 28 were treated nonoperatively. From the ORIF group, one open fracture became infected with subsequent hardware loosening and nonunion. From the nonoperative group, there were seven nonunions after 4–12 months of treatment. All nonunions occurred in high energy fractures (six motor vehicle accidents, one gunshot wound, one fall from 13 m). None of the proximal third fractures that were treated nonoperatively healed. They recommended ORIF for proximal third fractures, as well as high-energy distal two-thirds fractures with 5 mm or more of displacement.

Resolution of clinical scenario

- Based on the literature reviewed, there remains no clear consensus regarding the recommendations for treating isolated ulnar shaft fractures. Treatment choices should be made based on the individual case and patient's preferences.
- A discussion should be had with the patient based on fracture pattern, the patient's lifestyle, and their values in terms of early stability versus tolerance for surgical risk.

Question 3: In patients with Galeazzi-type fractures, does surgical reconstruction or temporary transfixion of the DRUJ prevent decrease in range of motion (ROM) of the forearm compared to nonsurgical treatment?

Rationale

Inadequate treatment of DRUJ injuries can lead to continuing wrist pain, decreased grip strength, and limited pronosupination. There is currently no consensus on the best treatment for DRUJ injuries that leads to improved functional outcomes.

Clinical comment

On follow-up for the ORIF for his distal radius fracture, patient A was noted to have DRUJ instability. He wanted to know if treating the DRUJ injury surgically would allow him to return to full function earlier than conservative treatment.
